Transesophageal endoscopic therapies are a group of minimally invasive antireflux procedures being investigated as alternatives to medical management or fundoplication surgery in the treatment of GERD.

MEDICAL POLICY CRITERIA

Transesophageal endoscopic therapies are considered **investigational** for the treatment of gastroesophageal reflux disease (GERD). These procedures include but are not limited to the following:

I. Transesophageal endoscopic gastroplasty procedure (i.e., MUSE)
II. Transoral incisionless fundoplication (TIF) procedure, (i.e., EsophyX)
III. Transesophageal radiofrequency energy procedure (i.e., Stretta)
IV. Endoscopic submucosal implantation of a prosthesis or injection of a bulking agent (i.e., Durasphere, polymethylmethacrylate [PMMA] beads, the Gatekeeper Reflux Repair system)

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

Gastroesophageal reflux disease (GERD) is a common disorder characterized by heartburn and other symptoms related to reflux of stomach acid into the esophagus. Nearly all individuals experience such symptoms at some point in their lives; a smaller number have chronic symptoms and are at risk for complications of GERD. The prevalence of GERD has been estimated to be 10% to 20% in the Western world, with a lower prevalence in Asia.[1]

The pathophysiology of GERD involves excessive exposure to stomach acid, which occurs for several reasons. There can be an incompetent barrier between the esophagus and stomach, either due to dysfunction of the lower esophageal sphincter (LES) or incompetence of the diaphragm. Another mechanism is abnormally slow clearance of stomach acid by the esophagus. In this situation, delayed clearance leads to an increased reservoir of stomach acid and a greater tendency to reflux.

In addition to troubling symptoms, some patients will have more serious disease, which results in complications such as erosive esophagitis, dysphagia, Barrett esophagus, and esophageal carcinoma. Pulmonary complications may result from aspiration of stomach acid into the lungs and can include asthma, pulmonary fibrosis and bronchitis, or symptoms of chronic hoarseness, cough, and sore throat.

Guidelines on the management of GERD emphasize initial medical management. Weight loss, smoking cessation, head of bed elevation, and elimination of food triggers are all recommended in recent practice guidelines.[1] Proton pump inhibitors (PPIs) have been shown to be the most effective medical treatment. In a Cochrane systematic review, PPIs demonstrated superiority to H_2-receptor agonists and prokinetics in both network meta-analyses and direct comparisons.[2]

The most common surgical procedure used for GERD remains laparoscopic Nissen fundoplication, however, the utilization of this procedure steadily declined between 2009 and 2013 with the advancement of novel nonmedical (endoscopic and surgical) techniques.[3] Fundoplication involves wrapping a portion of the gastric fundus around the distal esophagus to increase LES pressure. If a hiatal hernia is present, the procedure also restores the position of the LES to the correct location. Laparoscopic fundoplication was introduced in 1991 and has been rapidly adopted because it avoids complications associated with an open procedure.

Although fundoplication results in a high proportion of patients reporting symptom relief, complications can occur, and sometimes require conversion to an open procedure. Patients who have relief of symptoms of GERD after fundoplication may have dysphagia or gas-bloat syndrome (excessive gastrointestinal gas).

Due in part to the high prevalence of gastroesophageal reflux disease, there has been interest in creating a minimally invasive transesophageal therapeutic alternative to open or laparoscopic fundoplication or chronic medical therapy. This type of procedure may be

considered natural orifice transluminal surgery. Three types of procedures have been investigated.

1. Transesophageal endoscopic gastroplasty (gastroplication, transoral incisionless fundoplication) can be performed as an outpatient procedure. During this procedure, the fundus of the stomach is folded, and then held in place with staples or fasteners that are deployed by the device. The endoscopic procedure is designed to recreate a valve and barrier to reflux.

2. Radiofrequency (RF) energy has been used to produce submucosal thermal lesions at the gastroesophageal junction. (This technique has also been referred to as the Stretta procedure). Specifically, RF energy is applied through four electrodes inserted into the esophageal wall at multiple sites both above and below the squamocolumnar junction. The mechanism of action of the thermal lesions is not precisely known but may be related to ablation of the nerve pathways responsible for sphincter relaxation or may induce a tissue-tightening effect related to heat-induced collagen contraction and fibrosis.

3. Submucosal injection or implantation of a prosthetic or bulking agent to enhance the volume of the lower esophageal sphincter has also been investigated.

One bulking agent, pyrolytic carbon-coated zirconium oxide spheres (Durasphere®), has been evaluated. The Gatekeeper™ Reflux Repair System (Medtronic) utilizes a soft, pliable, expandable prosthesis made of a polyacrylonitrile-based hydrogel. The prosthesis is implanted into the esophageal submucosa, and with time, the prosthesis absorbs water and expands, creating bulk in the region of implantation. However, the only identified RCT on this system was terminated early due to lack of efficacy (NCT00200044). Endoscopic submucosal implantation of polymethylmethacrylate (PMMA) beads into the lower esophageal folds has also been investigated.

REGULATORY STATUS

In 2007, EsophyX® (EndoGastric Solutions, Redmond, WA) was cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process for full-thickness plication. In 2016, EsophyX® Z Device with SerosaFuse Fasteners was cleared for marketing (K160960) by FDA through the 510(k) process for use in transoral tissue approximation, full thickness plication, ligation in the gastrointestinal tract, narrowing the gastroesophageal junction, and reduction of hiatal hernia of 2 cm or less in patients with symptomatic chronic gastroesophageal reflux disease (GERD).[4] In June 2017, EsophyX2 HD and the third-generation EsophyX Z Devices with SerosaFuse fasteners and accessories were cleared for marketing by FDA through the 510(k) process (K171307) for expanded indications, including patients who require and respond to pharmacologic therapy and in patients with hiatal hernias larger than 2 cm when a laparoscopic hiatal hernia repair reduces the hernia to 2 cm or less.[5] FDA product code: ODE.

The Medigus SRS Endoscopic Stapling System (MUSE, Medigus) was cleared for marketing by FDA through the 510(k) process in 2012 (K120299) and 2014 (K132151). MUSE is intended for endoscopic placement of surgical staples in the soft tissue of the esophagus and stomach to create anterior partial fundoplication for treatment of symptomatic chronic GERD in patients who require and respond to pharmacologic therapy. FDA product code: ODE.

In 2000, the CSM Stretta® System was cleared for marketing by FDA through the 510(k) process for general use in the electrosurgical coagulation of tissue and is specifically intended for use in the treatment of GERD. Stretta® is currently manufactured by Mederi Therapeutics (Greenwich, CT). FDA product code: GEI.

Durasphere® is a bulking agent approved for treatment of urinary and fecal incontinence. Use of this product for esophageal reflux would be considered off-label use. The website of Carbon Medical Technologies states that Durasphere GR is an investigational device in the United States "intended to treat problems associated with GERD."

EVIDENCE SUMMARY

MULTIPLE ENDOSCOPIC PROCEDURES

Systematic Reviews

A 2005 report of the Agency for Healthcare Research and Quality (AHRQ), on "Comparative Effectiveness of Management Strategies for Gastroesophageal Reflux Disease," indicated additional efficacy and safety data on new endoscopic approaches were needed.[6] A 2011 update of the AHRQ report excluded Enteryx and the NDO Plicator, since they were no longer available in the U.S., and added the EsophyX procedure (endoscopic fundoplication), which was commercialized after the 2005 review.[7] The 2011 update reported the following:

> The AHRQ report concluded that for the 3 available endoscopic procedures (EndoCinch, Stretta, EsophyX), effectiveness remains substantially uncertain for the long-term management of GERD. While some clinical benefits were observed in patients who had these procedures, the studies were generally small, of variable quality, and of short duration. In addition, all of these procedures have been associated with complications, including dysphagia, infection/fever, and bloating; complications which are also side effects associated with laparoscopic fundoplication[8] Higher quality studies are needed to determine the role and value of endoscopic procedures in the treatment of patients with GERD. A 2015 review of endoscopic treatment of GERD noted that EndoCinch is no longer manufactured.[9]

A systematic review was conducted in 2009 to examine 7 endoscopic treatments for GERD that included 33 studies, only 2 of which were RCTs.[10] The remainder were case series. The authors concluded, "…despite the potential benefits of these procedures, there is insufficient evidence at present to establish their safety and efficacy, particularly in the long term."

TRANSESOPHAGEAL ENDOSCOPIC GASTROPLASTY AND TRANSORAL INCISIONLESS FUNDOPLICATION (TIF)

Systematic Reviews

Haseeb (2023) conducted a systematic review and meta-analysis that assessed the efficacy of TIF, using the EsophyX device, which uses a minimally invasive endoscopic fundoplication method, for atypical GERD symptoms in patients with chronic or refractory GERD.[11] All study types were included that assessed atypical GERD using the reflux symptom index questionnaire. Data on TIF with concomitant hiatal hernia repair were also included. 10 studies (n=564 patients) were analyzed. At 6- and 12- month follow-up, there was a mean reduction of 15.72 (95% confidence interval, 12.15 to 19.29) and 14.73 (95% confidence interval, 11.74 to 17.72) points, respectively, in the reflux symptom index score post-TIF. At both follow-ups,

more than two-thirds of patients were satisfied with their health condition and approximately three-fourths of patients were no longer taking daily proton pump inhibitors. Limitations of this meta-analysis include heterogeneity across studies for self-reported patient satisfaction and methodological quality of included studies.

Testoni (2021) published a systematic review with meta-analysis focusing on long-term (≥3 years) outcomes of patients with GERD undergoing TIF (using either EsophyX or MUSE).[12] Outcomes of interest included patient satisfaction, QOL, and PPI use. The mean follow-up time across studies was 5.3 years (range: 3 to 10 years). Daily PPI use was 100% in five studies, 97% in one study, and was not provided in the other two studies. Overall, the pooled proportion of patient-reported satisfaction before and after TIF was 12.3% and 70.6%, respectively. Additionally, the pooled rates of patients completely off, or on occasional, PPIs post-TIF was 53.8% and 75.8%. The analysis was limited by various factors including the nature of included studies, which involved only one open-label RCT among the eight studies included, and the high heterogeneity across studies for patient reported overall satisfaction after the TIF procedure.

McCarty (2018) published a systematic review of RCTs and nonrandomized studies that showed significant improvement in a number of clinical outcomes for patients treated with TIF.[13] For example, 89% of TIF patients discontinued PPI therapy after the procedure, and the Gastroesophageal Reflux Disease Health-Related Quality of Life (GERD-HRQL) questionnaire, Gastroesophageal Reflux Symptom Score, and Reflux Symptom Index (RSI) measures showed significant improvement. The review had several limitations, including the risk of heterogeneity bias, due to the inclusion of studies of first- and second-generation TIF devices and protocols.

Richter (2018) published a network meta-analysis of RCTs comparing TIF or laparoscopic Nissen fundoplication (LNF) with sham or PPIs.[14] The meta-analysis was limited by low-quality studies (one did not report randomization method, others lacked data on allocation concealment, blinding of outcome assessors, or other aspects of study protocol). It should be noted that a reason behind for scarcity of direct comparisons between TIF and LNF is the discrepancy in populations requiring the respective treatments: consequently, TIF studies included patients with mild esophagitis and small hiatal hernias (<2 cm), while LNF studies included patients with Los Angeles grade A, B, C, or D esophagitis and all sizes of hiatal hernias.

Randomized Controlled Trials

In 2018, Trad reported five-year outcomes on the manufacturer-sponsored TEMPO randomized controlled trial (RCT).[15] Three-year results were reported in 2016[16], other interim results were previously reported as well.[17, 18] Below are highlights from each publication:

- Participants with small or absent hiatal hernias (<2cm) and GERD symptoms while on PPI therapy for at least six months who also had abnormal esophageal acid exposure (EAE) were randomized to either EsophyX® (n=40) treatment or PPI therapy (n=23). After six months of evaluation, 21 remaining PPI therapy participants elected to crossover to EsophyX.
- At three years follow-up, 52 participants were assessed for (1) GERD symptom resolution, (2) healing of esophagitis using endoscopy, (3) EAE, and (4) discontinuation of PPI use. Two participants required revision surgery. As assessed by questionnaire

(the Reflux Disease Questionnaire [RDQ], and the Reflux Symptom Index [RSI]), primary outcomes of GERD resolution and elimination of all troublesome atypical symptoms was observed in 37/40 participants, and 42/48 participants, respectively.

- At five years follow-up, data were available for 44 patients, of whom 37 (86%) showed elimination of troublesome regurgitation at 5 years. Twenty (43%) patients were completely off PPIs at the 5-year follow-up, and 31 (70%) patients expressed satisfaction with the procedure, as assessed by the GERD-HRQL scores. While data on pH normalization were available for 24 patients at the 3-year follow-up, at 5 years, 22% (n=5) of these patients could not be assessed for pH normalization.
- Although mean symptom scores were reportedly improved, standard deviations for primary (and secondary) outcomes suggest a wide range of responses and further well-designed studies may be warranted.

In 2015, four RCTs that compared the EsophyX® device to proton pump inhibitor (PPI) treatment or to a sham control were identified, two of which were industry sponsored. The studies differed in whether patients' symptoms were or were not controlled on PPI therapy, in the control used (i.e., sham, sham plus PPI, PPI alone), whether patients were blinded to treatment, and in outcome measures. Included in the studies were patients on daily PPI therapy for moderate-to-severe GERD symptoms. Exclusion criteria common to the RCTs are body mass index (BMI) over 35 kg/m^2, hiatal hernia greater than 2 cm; esophagitis grade C or D; Barrett esophagus greater than 2 cm, and esophageal ulcer. Most studies allowed crossover to the other intervention with continued follow-up after the randomized portion of the study.

The largest RCT with the lowest risk of bias was an industry-sponsored, double-blind, sham-controlled multicenter study (RESPECT) that evaluated TIF in patients whose symptoms were not well controlled on PPIs.[19] Of 696 patients screened, 129 met inclusion and exclusion criteria and were randomized in a 2:1 ratio; 87 patients received TIF with EsophyX®-2 combined with 6 months of placebo (TIF/placebo) and 42 patients received sham surgery with 6 months of daily PPI therapy (sham/PPI). The primary outcome measure was elimination of troublesome regurgitation, defined as mild symptoms for 2 or more days per week or moderate-to-severe symptoms for more than 1 day per week. Crossover was allowed at 3 months in the case of treatment failure or at 6 months when the blind was broken. Lack of response at 3 months was observed in 36% of patients in the sham/PPI group compared with 11% in the TIF/placebo group (p=0.002). Self-reported regurgitation was eliminated in 22% more patients following TIF compared to continued PPI therapy patients (67% vs 45%, p=0.023), while reductions in GERD symptoms scores were similar in the 2 groups. The objective measure of control of esophageal pH was significantly reduced after TIF (mean percent time esophageal pH <4 decreased from 9.3% to 6.3%, p<0.001), but not after sham surgery (from 8.6% to 8.9%). By the 18-month follow-up, 71% of patients in the sham/PPI group had crossed over to TIF, compared with 28% of patients in the TIF/placebo group who resumed PPI therapy (p<0.001). There were 5 moderate-to-severe complications in the TIF group compared to one in the sham group. Strengths of this study include the use of both sham surgery and placebo control to maintain double-blinding, adequate power, objective as well as subjective outcome measures, and use of intention-to-treat analysis. A limitation is the relatively short duration of follow-up for most outcome measures.

Several other RCTs from 2015 have evaluated TIF in patients whose symptoms are at least partially controlled by PPI therapy.

Hakonsson reported a double-blind, sham-controlled randomized trial with 44 patients who had moderate-to-severe GERD symptoms without PPI therapy.[20] Controls received a sham procedure, and the primary outcome was the time in remission, which was longer following TIF than sham (197 days vs 107 days, p<0.0001). Secondary outcomes measuring GERD symptoms showed results consistent with more favorable outcomes in the TIF group, however, no statistical between-group analysis was reported for these outcomes. Dysphagia, bloating, and flatulence were reported in twice as many patients undergoing TIF (4, 4, and 2 respectively) compared with sham (2, 2, and 1, respectively). These were reported as not statistically different, however, it is unlikely that the study was powered to detect differences in these outcomes.

Witteman reported an unplanned interim analysis of an RCT of 60 patients randomized to TIF using EsophyX®-2 or continued PPI therapy.[21] Sixty of the planned 120 patients had been recruited at the time of analysis. The patients' symptoms were adequately controlled by PPIs but they wanted to avoid lifelong PPI therapy. At 6 months, subjective GERD symptoms improved to a greater extent in the TIF group (p<0.001), and satisfaction scores were higher (50% satisfied vs 0%), but there was no significant difference in esophageal acid exposure (p=0.228) or pH normalization (50% vs 63%) between the TIF and PPI groups, respectively. At 12 months after TIF, normalization of pH was achieved in only 29% of patients and there was deteriorated valve appearance at endoscopy; 61% of TIF patients had resumed use of PPIs.

Trad reported 6- and 12-month results of an industry-funded, multicenter RCT (TEMPO) that compared TIF using EsophyX®-2 (n=40) versus maximal dose PPI therapy (n=23) in partial responders to PPI therapy.[17, 18] At the 6-month follow-up, the subjective measure of troublesome regurgitation was eliminated in 97% of TIF patients versus 50% of PPI patients (relative risk, 1.9; p=0.006). At 6 months, 90% of patients in the TIF group had completely stopped PPI therapy. However, the objective measure of normalized esophageal acid exposure did not differ significantly between groups (TIF=54% vs PPI=52%, p=0.914). At 12 months after TIF, 77% of patients had symptom control, 82% had stopped PPI therapy, 100% had healed esophagitis, and 45% had normalized esophageal acid exposure.

Additional controlled trials (RCTs) comparing transesophageal endoscopic gastroplasty or plication procedures to sham or other endoscopic procedures have been identified.[18, 22-27] Though these studies showed a promising decrease in PPI use and symptom control at 3 to 12 months, they do not allow conclusions regarding long-term health outcomes, safety or durability of the procedure in patients with GERD for one or more of the following reasons:

Insufficient study durations – Only short-term follow-up of 3 to 12 months is available, which does not address the long-term safety and durability of the procedures.[18, 23-28] For example, there may be suture loss over time. One study reported up to 29 % of study subjects required a second procedure at 12-month follow-up.[23] Of these patients, 72% of sutures were still present but only 19% were judged functional. A second study noted marked loss of sutures with 67% remaining at 12 months.[25]

Small sample size – Given the prevalence of GERD in the general population, available randomized trials include very small sample sizes. The largest study of 159 patients had an almost 10% loss in reported data with an intention to treat analysis that did not include these patients. All other studies include sample sizes of 60 or fewer patients. It is unclear if these studies are adequately powered.[18, 23, 25-29]

Unreliable endpoints – The use of subjective, point in time GERD questionnaires as a primary endpoint may give variable results depending upon symptoms present at the time the subject completes the questionnaire.[18, 23, 24]

Improvement over the gold standard procedures was not demonstrated. In order to establish the efficacy of transoral procedures, an improvement in symptoms of gastric reflux over the current open or laparoscopic anti-reflux procedures, must be shown.[18, 27, 29]

There is a single randomized trial of the TIF procedure, which compares TIF to Nissen laparoscopic fundoplication.[28] Although the authors reported comparable results at 12 months, conclusions based upon this trial are limited by the small sample size (n=52) and the different methods used for TIF (both the Plicator® and the EsophyX).

Nonrandomized Studies

Observational studies[30-63], registry data[64, 65] nonrandomized comparative studies[66] of gastroplication and fundoplication (specifically, transoral incisionless fundoplication) procedures do not allow conclusions about their long-term effectiveness and durability.

Case Series

Bell (2021) evaluated the durability of TIF with the EsophyX2 in 151 patients via a single institution prospective registry between November 2008 and July 2015.[62] Of these patients, the average duration of GERD symptoms was 11.3 years and 78% reported moderate to severe ongoing symptoms preoperatively despite PPI therapy. Eighty-six percent (n=131) were available for follow-up at a median of 4.92 years (0.7 to 9.7 years). Results revealed a reduction in the median GERD-HRQL scores from 21 (off PPI) and 14 (on PPI) at baseline to 4 (at 4.92 years) and 5 (at 5 to 9 years post-TIF). A successful (>50%) reduction in GERD-HRQL score at 4.92 years was seen in 64% of evaluable patients and 68% of patients followed for ≥5 years. Thirty-three (22%) of TIP patients underwent laparoscopic revisional surgery at a median of 14.7 months after surgery. Approximately 70% of patients remained free of daily PPI use throughout follow-up. The authors concluded that TIF provides durable relief of GERD symptoms for up to 9 years with a significant portion of patients having a successful outcome by symptom response and PPI use.

Harms

Although harms are not systematically reported across observational studies, there have been several publications on potential harms of TIF procedures.

Ramai (2021) published a report of complications associated with TIF from post-marketing surveillance data from the FDA Manufacturer and User Facility Device Experience (MAUDE) database from Jan 2011 through Jan 2021.[67] During the period studied, approximately 95 event cases were reported to the FDA and approximately 131 patient complications were identified. The most common adverse events were perforation (19.8%), laceration 17.6%, bleeding (9.2%), and pleural effusion (9.2%). Patient complications were treated using endoscopic clips (12.3%), chest tube or drain insertion (12.3%), use of endoscopic retriever device (11.1%), esophageal stent (8.6%), and emergent or open surgery (11.1%).

Furnee reported an increased risk of gastric injury with laparoscopic Nissen fundoplication after failed EsophyX fundoplication.[68] Of 88 patients in their database who underwent EsophyX fundoplication, 11 (12.5%) subsequently underwent Nissen fundoplication for

persistent or recurrent symptoms at a mean 8.1 months after the primary procedure. Endoscopy showed partial or total disruption of fasteners in 8 of the 11 patients (72.7%). Nissen fundoplication after EsophyX resulted in gastric perforation (n=2), conversion to laparotomy (n=1), subphrenic abscess requiring surgical exploration (n=1) and symptom-worsening in four patients.

In 2017, Huang conducted a systematic review with meta-analysis of TIF for the treatment of GERD.[69] Authors included 5 RCTs and 13 prospective observational studies, of which 14 were performed with the TIF 2 procedure. Efficacy results from the RCTs were combined for patients whose symptoms were controlled by PPIs and for those whose symptoms were not controlled by PPIs and are not further discussed here. Follow-up out to six years in prospective observational studies indicated a decrease in efficacy over time. The reported incidence of severe adverse events, consisting of gastrointestinal perforation and bleeding, was 19 (2.4%) out of 781 patients. This included seven perforations, five cases of post-TIF bleeding, four cases of pneumothorax, one case requiring intravenous antibiotics, and one case of severe epigastric pain.

TRANSESOPHAGEAL RADIOFREQUENCY ENERGY (I.E., THE STRETTA PROCEDURE)

Systematic Reviews

Xie (2021) published a systematic review and network meta-analysis of 10 RCTs that evaluated the comparative effects of Stretta, TIF, and PPIs in patients with GERD.[70] Of the included RCTs, five compared Stretta to control (PPI or sham + PPI) and five compared TIF to control (PPI or sham + PPI). Results of the network meta-analysis revealed that improvements in the HRQoL score in patients treated by Stretta were not significantly different than the improvements seen with TIF (mean difference [MD], 2.45; 95% CI, -2.37 to 7.26); however, both Stretta and TIF were significantly superior to PPIs in this outcome. Additionally, both Stretta and TIF were significantly better than PPIs at improving heartburn scores. Regarding reduction in PPI use and esophagitis incidence, no significant difference between TIF and Stretta was observed. This network meta-analysis had several limitations including a lack of assessment of long-term efficacy, the inclusion of only 10 studies with even fewer studies evaluated for each individual outcome, and lack of RCTs directly comparing Stretta and TIF. Additionally, some of the comparisons were significantly affected by heterogeneity and the evidence quality of each outcome (as assessed by GRADE) ranged from moderate to very low.

Fass (2017) published a meta-analysis of cohort studies and RCTs evaluating the Stretta procedure for patients with GERD (N=2468 total, 9-558 per study).[71] The meta-analysis included 4 RCTs, 23 cohort studies, and one registry. Follow-up time varied from 3 to 120 months. When RCT and cohort results were pooled, there were clinically significant treatment effects for several of end points; however, the analysis was limited by the lack of control groups in many studies. Also, only 1 end point was shared between the four included RCTs.

A meta-analysis of four RCTs (total N=165 patients) was published by Lipka in 2015.[72] Three trials compared Stretta with sham, and one trial compared Stretta with PPI therapy. Results of the individual sham-controlled trials were inconsistent, generally supporting some improvement in symptoms, but not in objective measures of esophageal acid exposure. For example, Corley (2008) reported improvement in heartburn symptoms, quality of life, and general physical quality of life in the active treatment group compared with the sham group, but there were no significant differences in medication use and esophageal acid exposure.[73] Aziz (2010) found

statistically significant improvements in GERD-HRQL in all treatment groups.[74] Arts (2012) reported that the symptom score and quality-of-life score for bodily pain improved, but no changes were observed in PPI use, esophageal acid exposure, or lower esophageal sphincter pressure after RF.[75] Pooled results of the meta-analysis showed no significant difference between Stretta and either sham treatment or PPI management for the measured outcomes, including the ability to stop PPI therapy. The overall quality of evidence was considered to be very low with a high risk of bias, and the meta-analysis was limited by heterogeneity in the included studies, which may be due to small sample sizes, differences in measures, and differences in follow-up time.

A 2014 systematic review and meta-analysis of four randomized trials; three reviewed previously[73-75] and one trial which compared Stretta with PPI therapy,[76] included a total of 165 patients. The overall quality of the evidence was considered to be very low with a high risk of bias. The pooled results showed no significant difference between Stretta and sham or PPI management for the measured outcomes. The meta-analysis was limited by heterogeneity in the included studies, which may be due to small sample sizes, differences in measures, and differences in follow-up time. The author also identified significant risks associated with Stretta, including pneumonia, gastroparesis, esophageal perforation, cardiac arrest, and at least 4 deaths from review of the Manufacturer and User Facility Device Experience database.

A meta-analysis completed by Perry, included 20 studies, only 2 of which were RCTs. This meta-analysis was limited by the inclusion of lower quality studies and by the analysis, which only examined within-subject differences and did not include between-subject differences, as reported in the RCTs.[77]

Randomized Controlled Trials

Zerbib (2020) published a double-blind RCT that compared Stretta plus PPI therapy (n=29) to sham plus PPI therapy (n=33) in individuals with PPI-refractory heartburn.[78] The primary endpoint was clinical success at week 24, defined as an intake of fewer than seven PPI doses over the previous two weeks and adequate subjective patient-reported symptom control. Fewer patients achieved the primary endpoint in the Stretta group, but the difference was not statistically significant (3.4% vs 15.1%; odds ratio [OR]=0.20; 95% CI, 0.02 to 1.88). Severe adverse events were more frequent in the Stretta group (7 vs 2) and included epigastric pain (n = 3), delayed gastric emptying, vomiting, headache, and 1 leiomyoma. Limitations of this RCT include that pH-impedance monitoring was not performed either at enrollment or during follow-up. Thus, baseline status of GERD diagnosis is unclear and the physiologic effects of Stretta are unknown.

There are several randomized trials comparing transesophageal radiofrequency (RF) energy with a sham procedure that involved balloon inflation but no needle deployment or RF energy delivery.[73-75]

Results of the first study failed to include 20% of the randomized patients in analysis of primary endpoints, and no intention to treat analysis was provided. Therefore, reported results of improved heartburn symptoms and GERD quality of life scores are not reliable.

Results of the second, third and fourth studies were flawed due to a small patient population and inadequate timeframe for follow up.

Other small RCT's have been published. Two compared RF to PPI therapy. One trial showed promising short-term (6 months) results but does not permit conclusions about mid- to long-term effectiveness and durability.[76] Another compared RF with PPI therapy to PPI therapy alone.[79] Results at 3 months appeared favorable to the Stretta group, however, the study sample was small (N=20) and power calculations were not conducted.

Nonrandomized Studies

Other clinical studies concerning transesophageal radiofrequency are limited to observational case series that do not allow conclusions about long-term effectiveness and durability.[22, 80-92] Though several case series report up to 4-10 year outcomes, there was a significant loss to follow-up in these studies such that conclusions on durability and health outcomes cannot be made.[93]

INJECTION OR IMPLANTATION OF BIOCOMPATIBLE POLYMERS

Randomized Controlled Trials

The available evidence for the Gatekeeper Reflux Repair System consists of one RCT.[94] This industry-funded sham-controlled single-blind multicenter study randomized 118 patients into Gatekeeper (n=75) or sham (n=43) treatment. An additional 25 patients were treated as lead-ins during the initial training of investigators and included only in the safety analysis. The patients were implanted initially with 4 Gatekeeper prostheses. At three months, 44% of implanted patients received retreatment with up to four additional prostheses due to unsatisfactory symptom control. The primary safety end point was reduction in serious device- and procedure-related adverse device effects, compared with a surgical procedure composite complication rate of 15%. Four serious adverse events were reported (2 perforations, 1 pulmonary infiltrate related to a perforation, 1 severe chest pain). The primary efficacy end point was reduction in heartburn symptoms using the GERD-HRQL questionnaire. Planned interim analysis after 143 patients were enrolled found that heartburn symptoms and esophageal acid exposure had improved significantly in both the Gatekeeper and sham groups at six months, but there was no significant difference between the two groups. The study was terminated early due to a lack of efficacy.

There is one randomized sham-controlled trial which reports results of patients randomized to receive either injection of Enteryx biopolymer or a sham procedure.[95] At 3- and 6-months follow-up, patients in the Enteryx group had greater reductions in PPI use and more improvement in GERD health-related quality of life heartburn scores. However, the small size and short duration of the study limit interpretation of findings.

Nonrandomized Studies

Other data on injectable or implantable polymers consists of very small case series.[22, 96] The small number of patients and lack of long-term follow-up precludes scientific analysis.

PRACTICE GUIDELINE SUMMARY

Several clinical practice guidelines consider the use of transoral fundoplication or other endoscopic procedures, although none were able to recommend this treatment based upon high level evidence.

AMERICAN SOCIETY OF GENERAL SURGEONS

The American Society of General Surgeons (ASGS) consensus-based position statement on transoral fundoplication states, “the ASGS supports the use of transoral fundoplication by trained General Surgeons for the treatment of symptomatic chronic gastroesophageal reflux disease (GERD) in patients who fail to achieve satisfactory response to a standard dose of Proton Pump Inhibitor (PPI) therapy or for those who wish to avoid the need for a lifetime of medication dependence.”[97]

AMERICAN GASTROENTEROLOGICAL ASSOCIATION

The 2008 Medical Position Statement of the American Gastroenterological Association (AGA), makes no recommendation for or against “the use of currently commercially available endoluminal antireflux procedures in the management of patients with an esophageal syndrome” based on insufficient evidence (Grade Insufficient).[98]

AMERICAN COLLEGE OF GASTROENTEROLOGY

In 2022, the American College of Gastroenterology (ACG) released updated guidelines for the diagnosis and management of gastroesophageal reflux disease.[99] The guidelines state the following:

- Because data on the efficacy of radiofrequency energy (Stretta) as an antireflux procedure is inconsistent and highly variable, we cannot recommend its use as an alternative to medical or surgical antireflux therapies (conditional recommendation, low level of evidence).
- We suggest consideration of TIF for patients with troublesome regurgitation or heartburn who do not wish to undergo antireflux surgery and who do not have severe reflux esophagitis (LA grade C or D) or hiatal hernias >2 cm (conditional recommendation, low level of evidence).
- For patients who have regurgitation as their primary PPI-refractory symptom and who have had abnormal gastroesophageal reflux documented by objective testing, we suggest consideration of antireflux surgery or TIF (conditional recommendation, low level of evidence).

SOCIETY OF AMERICAN GASTROINTESTINAL ENDOSCOPIC SURGEONS

In 2021, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) published guidelines for the surgical treatment of gastroesophageal reflux (GERD).[100] Although several recommendations regarding fundoplication were provided, the guideline does not mention transesophageal endoscopic approaches.

In 2017, SAGES updated its evidence-based guidelines on endoluminal treatments for GERD.[101] SAGES gave a strong recommendation based on moderate quality evidence that TIF with EsophyX can be performed with an acceptable safety risk in selected patients. SAGES concluded that EsophyX results in better control of GERD symptoms compared with proton pump inhibitor (PPI) treatment in the short term (six months) but leads to similar improvement in objective GERD measures compared with PPIs. TIF appears to lose effectiveness during longer term follow-up and is associated with moderate patient satisfaction scores. SAGES found no comparative, controlled trials between TIF and surgical fundoplication, but preliminary evidence suggested that the surgical fundoplication can be used safely after TIF failure. SAGES gave a strong recommendation based on moderate quality evidence that Stretta is safe for adults and significantly improves health-related quality of life

score, heartburn scores, the incidence of esophagitis, and esophageal acid exposure in patients with GERD. Stretta is more effective than PPI, but less so than fundoplication.

SUMMARY

There is not enough research to show that transesophageal endoscopic therapies for the treatment of gastroesophageal reflux disease (GERD) improves health outcomes. Although clinical guidelines based on research may recommend treating GERD with one or more of the therapies mentioned, there is not enough research to know if or how well these procedures work to treat people with GERD. This does not mean that it does not work, but more research is needed to know. Therefore, the use of any of these procedures is considered investigational for the treatment of GERD.

Gastric Electrical Stimulation

Effective: January 1, 2024

Next Review: April 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Gastric electrical stimulation (GES) is performed using an implantable device designed to treat chronic drug-refractory nausea and vomiting secondary to gastroparesis of diabetic or idiopathic etiology. Gastric electrical stimulation is also proposed as a treatment of obesity. The device may also be referred to as a gastric pacemaker or gastric pacing.

MEDICAL POLICY CRITERIA

I. Gastric electrical stimulation may be considered **medically necessary** in the treatment of chronic intractable nausea and vomiting secondary to gastroparesis of diabetic, idiopathic or post-surgical etiology when all of the following (A – C) Criteria are met:

   A. Significantly delayed gastric emptying as documented by standard scintigraphic imaging of solid food; and

   B. Patient is refractory or intolerant of 2 out of 3 classes of prokinetic medications and 2 out of 3 antiemetic medications. (see Appendices for classes); and

   C. Patient's nutritional status is sufficiently low that weight has decreased to 90 percent or less of normal body weight for a patient’s height and age in comparison with pre-illness weight.

II. The replacement of an existing gastric electrical stimulator and/or generator is considered **medically necessary** when the existing gastric electrical stimulator and/or generator is malfunctioning, cannot be repaired, and is no longer under warranty.

III. Replacement of a gastric electrical stimulator and/or generator is considered **not medically necessary** when Criterion II. is not met.

IV. Gastric electrical stimulation for the treatment of chronic intractable nausea and vomiting secondary to gastroparesis of diabetic, idiopathic or post-surgical etiology is considered **not medically necessary** when Criterion I. is not met.

V. Gastric electrical stimulation is **investigational** for all other indications including but not limited to the treatment of obesity.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Current Symptomology
- Prokinetic and Antiemetic Medications given and response
- Replacement and Revisions
    - Name and type of device requested
    - Documentation of specifically why the stimulator is no longer able to perform its basic function
    - Documentation that the current device cannot be repaired or adapted adequately to meet the patient's needs

BACKGROUND

A subcutaneously implanted pulse generator delivers electrical stimulation to the stomach via intramuscular leads that are implanted on the outer surface of the greater curvature of the stomach either laparoscopically or during a laparotomy. Stimulation parameters are typically programmed at an "on time" (ON) (e.g., 0.1 second) alternating with an "off time" (OFF) (e.g., 5.0 seconds).

GASTRIC STIMULATION FOR THE TREATMENT OF INTRACTABLE NAUSEA AND VOMITING DUE TO GASTROPARESIS

Gastroparesis is a chronic disorder of gastric motility characterized by delayed emptying of a solid meal. Symptoms include bloating, distension, nausea, and vomiting. When severe and chronic, gastroparesis can be associated with dehydration, poor nutritional status, and poor glycemic control in diabetics. While most commonly associated with diabetes, gastroparesis is

also found in chronic pseudo-obstruction, connective tissue disorders, Parkinson disease, and psychological pathology. Idiopathic gastroparesis refers to symptoms of gastroparesis which are not associated with an identifiable cause. Treatment of gastroparesis includes prokinetic agents such as metoclopramide, and antiemetic agents such as metoclopramide, granisetron, or ondansetron. Severe cases may require enteral or total parenteral nutrition.

GASTRIC STIMULATION FOR THE TREATMENT OF OBESITY

GES has also been investigated as a treatment of obesity as a technique to increase a feeling of satiety with subsequent reduced food intake and weight loss. The exact mechanisms resulting in changes in eating behavior are uncertain but may be related to neurohormonal modulation and/or stomach muscle stimulation.

REGULATORY STATUS

The Enterra™ Therapy System (formerly named Gastric Electrical Stimulation [GES] System; manufactured by Medtronic) is the only device approved for treatment of chronic refractory gastroparesis. It received approval for marketing from the U.S. Food and Drug Administration (FDA) in 2000 through the humanitarian device exemption (HDE) process.[1] This process requires the manufacturer to provide adequate information for the FDA to determine that the device has “probable” benefit but does not pose an unreasonable or significant risk; it does not require data confirming the efficacy of the device. The HDE process is available for devices treating conditions that affect fewer than 4,000 Americans per year.

EVIDENCE SUMMARY

GASTRIC STIMULATION FOR THE TREATMENT OF INTRACTABLE NAUSEA AND VOMITING DUE TO GASTROPARESIS

Systematic Reviews

Several systematic reviews of studies of gastric electrical stimulation (GES) for gastroparesis have been published, the most recent and comprehensive of which is by Saleem (2022).[2-5]

Saleem identified 9 studies (7 RCTs; N=730) including a recent large (N=172) crossover study by Durcotte (2020). The primary outcome evaluated in this analysis was total symptom score (TSS). The included studies were deemed of moderate quality and low risk of bias. Analysis of the 7 blind RCTs found the TSS was significantly improved at the 4-day, 2-month, 4-month, and 12-month follow-up (mean difference [MD], -6.07; 95% confidence interval [CI], -4.5 to -7.65; p<0.00001) but not at all follow-up time points (not further defined). These studies had high heterogeneity (I2=70%) due to variable follow-up duration. The weekly vomiting frequency was not different between groups (MD, -1.76; 95% CI -6.15 to 2.63; p=0.43) when the blind RCTs were pooled; however, in the open trials, vomiting episodes were lower after GES (MD, 15.59; 95% CI 10.29 to 20.9; p<0.00001). The analysis is limited by the variety of scoring systems, variable time points of follow up, and relatively small sample sizes of the individual trials.

An older, but more inclusive meta-analysis, was published by Levinthal (2017).[2] To be included in the Levinthal review, studies had to include adults with established gastroparesis, report patient symptom scores and administer treatment for at least one week. Five randomized controlled trials (RCTs) and 13 non-RCTs meeting criteria were identified. Pooled analysis of data from the five RCTs (n=185 patients) did not find a statistically significant

difference in symptom severity when the GES was turned on versus off (standardized mean difference [SMD], 0.17; 95% confidence interval [CI], -0.06 to 0.40; p=0.15). Another pooled analysis did not find a statistically significant difference in nausea severity scores when the GES was on or off (SMD = -0.143; 95% CI, -0.50 to 0.22; p=0.45). In a pooled analysis of 13 open-label single-arm studies and data from open-label extensions of three RCTs, mean total symptom severity score decreased 2.68 (95% CI, 2.04 to 3.32) at follow-up from a mean of 6.85 (95% CI, 6.28 to 7.42) at baseline. The rate of adverse events in the immediate postoperative period (reported in seven studies) was 8.7% (95% CI, 4.3% to 17.1%). The in-hospital mortality rate within 30 days of surgery was 1.4% (95% CI, 0.8% to 2.5%), the rate of reoperations (up to 10 years of follow-up) was 11.1% (95% CI, 8.7% to 14.1%), and the rate of device removal was 8.4% (95% CI, 5.7% to 12.2%).

Randomized Controlled Trials

The data presented to the FDA documenting the “probable benefit” of the GES (Enterra™) system was based on a multicenter double-blind cross-over study referred to as the Worldwide Anti-Vomiting Electrical Stimulation Study (WAVESS).[1] The study included 33 patients with intractable idiopathic or diabetic gastroparesis. The primary endpoint of the study was a reduction in vomiting frequency, as measured by patient diaries. In the initial phase of the study, all patients underwent implantation of the stimulator and were randomly and blindly assigned to stimulation ON or stimulation OFF for the first month, with crossover to OFF and ON during the second month. The baseline vomiting frequency was 47 episodes per month, which significantly declined in both ON and OFF groups to 23 and 29 episodes, respectively. However, there were no significant differences in the number of vomiting episodes between the two groups, suggesting a placebo effect.

After the first two months of therapy, patients were asked which month of the cross-over stimulation they preferred. Twenty-one of the 33 patients selected the ON mode as their preferred month, compared to 7 who preferred the OFF mode, and 5 who had no preference. The greater preference for ON stimulation suggested some short-term effect that was not placebo.

In a continuing open phase of the trial, the patients then received the stimulation consistent with their preference. However, by four months all patients had the device turned ON (it was not clear whether this phase was by preference or design). At 6 and 12 months follow-up, the mean number of vomiting episodes continued to decline, although only 15 patients were followed for a period of 12 months. Data regarding quality of life were also obtained at 6 and 12 months and showed improvement. At 6 months, there was a significant improvement in 2-hour gastric retention (from 80% retention to 60% retention), but not in 4-hour gastric retention. (Fifty percent gastric retention at two hours was considered the upper limits of normal.)

The results of the randomized portion of the study suggest a placebo effect. Therefore, long-term results of GES must be validated in a longer-term randomized trial. It is interesting to note that GES did not return gastric emptying to normal in the majority of the patients tested. In as much as the device is intended to improve gastric emptying, as a proof of principle, it would be interesting to investigate the correlation between the degree of gastric emptying and symptom improvement.

Ducrotte (2020) evaluated permanent GES (Enterra) in a cross-over trial. Patients (N=172) had refractory and chronic vomiting. After GES implantation, patients were randomized to receive stimulation or no stimulation then crossed over to the other treatment after 4 months. The

primary endpoints were vomiting score (range 0 to 4 where 0 is daily vomiting and 4 is no vomiting) and the Gastrointestinal Quality of Life Index. The median vomiting score with device on was 2 versus 1 with the device off (p<0.002); however, over 50% of patients reported similar vomiting scores during the on and off period. There was no difference between groups in the quality of life measure (73.3 on the on phase and 71.1 in the off; p=0.06). Delayed gastric emptying was not different in the on versus off period. Limitations of this trial include use of an unvalidated scale for the primary endpoint, inclusion of only refractory patients, and 4-month duration of treatment. Importantly, this trial was not limited to patients with gastroparesis.

In a 2003 update to WAVESS, Abell reported 12-month outcomes for all of the patients.[6] Statistically significant improvements were found for weekly vomiting frequency, total abdominal symptom score, and scintigraphic solid food emptying. At baseline the median vomiting frequency was 17.3 episodes per week with gastroparetic symptoms over a mean of 6.2 years. All patients had scintigraphic evidence of delayed gastric emptying at 2 and 4 hours, all patients were refractory to prokinetic and antiemetic medications, and 14 required some form of parenteral or enteral feedings. Results at the end of phase 1 (the blinded phase) showed a 50% decreased vomiting frequency for patients whose devices were ON compared to patients whose devices were OFF (p=0.05).

Symptom severity trended toward improvement in the ON versus OFF period, although these changes did not reach statistical significance in phase 1. In a second phase of the study all patients were switched to the ON position with 6- and 12- months follow-up. Vomiting at 12 months was compared to baseline; 72% for the combined group, 63% for diabetics with gastroparesis, and 83% for patients with idiopathic gastroparesis. Total symptom score improved significantly (p<0.05) at 6 and 12 months. Physical and mental quality of life scores improved significantly compared to baseline (p= less than 0.025). Baseline gastric retention was 78% at 2 hours. This decreased significantly with electrical stimulation to 65% at 6 months and 56% at 12 months for the combined group. The changes in 2-hour gastric emptying were not significant for the diabetic and idiopathic groups separately. Four-hour gastric emptying improved from 34% retention at baseline to 22% retention at 12 months. The difference was statistically significant for the combined group as well as the diabetic and idiopathic groups separately.

McCallum (2010) performed a multicenter prospective study to evaluate Enterra™ therapy in patients with chronic intractable nausea and vomiting from diabetic gastroparesis (DGP).[7] In this study, 55 patients with refractory DGP (5.9 years of DGP) were implanted with the Enterra™ system. After surgery, all patients had the stimulator turned ON for 6 weeks and then were randomly assigned to groups that had consecutive 3-month cross-over periods with the device ON or OFF. After this period, the device was turned ON in all patients and they were followed up unblinded for 4.5 months. During the initial 6-week phase with the stimulator turned ON, the median reduction in weekly vomiting frequency (WVF) compared with baseline was 57%. There was no difference in WVF between patients who had the device turned ON or OFF during the 3-month cross-over period. At 1 year, the WVF of all patients was significantly lower than baseline values (median reduction, 68%; P < 0.001). One of the patients had the device removed due to infection; 2 patients required surgical intervention due to lead-related problems.

In a later study, McCallum (2013) evaluated GES (Enterra™ system) in patients with chronic vomiting due to idiopathic gastroparesis in a randomized, double-blind crossover trial.[8] In this

study, 32 patients with nausea and vomiting associated with idiopathic gastroparesis, which was unresponsive or intolerant to prokinetic and antiemetic drugs, received Enterra™ implants and had the device turned on for 6 weeks. Subsequently, 27 of these patients were randomized to have the device turned on or off for 2 consecutive 3 month periods. Twenty five of these subjects completed the randomized phase; of note, 2 subjects had the device turned on early, 2 subjects had randomization assignment errors, and 1 subject had missing diaries. During the initial 6-week on period, all subjects demonstrated improvements in their WVF, demonstrating a median reduction of 61.2% compared with baseline (17.3 episodes/week at baseline vs 5.5 episodes/week at 6 week postimplant, p<0.001). During the on-off crossover phase, subjects demonstrated no significant differences between the on and off phase in the study's primary end point, median WVF (median 6.4 in the on phase vs 9.8 in the off phase; p=1.0). Among the 19 subjects who completed 12 months of follow up, there was an 87.1% reduction in median WVF compared with baseline (17.3 episodes/week at baseline vs 2 episodes/week at 12-month follow-up, p<0.001). Two subjects required surgical intervention for lead migration/dislodgement or neurostimulator migration.

Nonrandomized Studies

Samaan (2022) compared GES to laparoscopic gastrectomy in a retrospective, single-center analysis.[9] Overall, 130 refractory patients underwent GES while 51 received laparoscopic gastrectomy. Patients receiving GES were less likely to report symptom improvement compared with gastrectomy (odds ratio [OR], 0.16; 95% CI 0.048 to 0.532) over a mean follow-up period of 35 months. However, patients receiving gastrectomy had greater in-hospital morbidity (18% vs. 5%; p=0.017) and longer hospital stays (9 days vs. 3 days (p<0.001). The authors concluded that further study was needed to determine which patients might benefit from operative treatment of refractory gastroparesis.

Laine (2018) published a retrospective, multicenter analysis of patients with severe, medically refractory gastroparesis who received GES.[10] Fourteen patients (11 diabetic, 1 idiopathic, and 2 postoperative) treated in Finland between 2007 and 2015 were included; median follow-up was 3 years. Eight (57.1%) patients experience marked relief of gastroparesis symptoms, while 3 (21.4%) patients experience partial relief. There was a median weight gain of 5.1 kg in 11 (78.6%) patients after GES implantation, and, at last possible follow-up, 5 out of 10 (50%) patients were without medication for gastroparesis. The study was limited by its retrospective nature, small population size, and relatively short follow-up time.

Shada (2018) published a prospective study of patients with medically refractory gastroparesis who underwent implantation of GES between 2005 and 2016.[10] One hundred nineteen patients (64 diabetic, 55 idiopathic), with mean follow-up of 39.0 ± 32.0 months, were included in the analysis. Before GES placement, operatively placed feeding tubes were present in 22% of diabetic and 17% of idiopathic patients, however, after GES placement, 67% of feeding tubes were removed. Due to a perceived lack of benefit, 8 patients decided to have their GES device removed after a mean time of 36 ± 29 months. Also, there was significant improvement in GCSI scores for both diabetic (p=0.01) and idiopathic (p=0.003) subgroups at ≥2 years after implantation. The study was limited by its not all patients being administered the GCSI before GES, and a number of patients being lost to follow-up.

In 2016, Heckert reported on GES as a treatment for refractory symptoms of gastroparesis in 138 patients (65 diabetic, 68 idiopathic, and 5 other) with delayed gastric emptying at one-year follow-up (1.4 ± 1.0 years).[11] Patients reported their response to GES using the Clinical

Patient Grading Assessment Scale (CPGAS), of which, 75% of patients felt their symptoms had improved, and 25% felt their symptoms were the same or worsened (diabetics had a greater response than idiopathic patients). Symptom severity was assessed by analyzing Patient Assessment of GI Symptoms (PAGI-SYM) questionnaires, before insertion of GES and at the last follow-up visit. PAGI-SYM scores were improved for all symptoms, though the authors report nausea, early satiety and loss of appetite to have been most improved; and constipation, diarrhea, and abdominal distension to have been least improved. In this selected group of patients, the authors concluded GES to be beneficial in the majority of patients.

In 2013, Keller reported complication rates and need for a second surgery in 233 patients who had GES implantation surgery over a ten year period at a single institution.[12] Additional surgery was required in 58% of patients. The majority of reoperations were due to the following complications: nutritional access (45 patients, requiring 77 procedures), subcutaneous pocket issues (n = 21), gastroparetic symptoms (n = 11), mechanical issues (n = 9) and infection (n = 4). The study reported that patient BMI was predictive of additional surgeries, with 4.45 overall increased risk of pocket revision surgery. Although 70% of patients reported improved symptoms of pain, bloating and nausea, GES had a significantly high reoperation rate due to complications associated with the initial procedure.

In 2007, Anand reported on a study of 214 consecutive drug-refractory patients with the symptoms of gastroparesis (146 idiopathic, 45 diabetic, 23 after surgery).[13] A GES device was implanted in 156 patients. The remaining 58 patients, designated as the control group, were either on the waiting list for permanent implantation or consented to not receive a permanent implant. At last follow-up (median 4 years), most patients who received implants (135 of 156) were alive with intact devices, significantly reduced gastrointestinal symptoms, and improved health-related quality of life, with evidence of improved gastric emptying. Also, 90% of the patients had a response in at least 1 of 3 main symptoms. Most patients that explanted, usually for pocket infections, were later successfully reimplanted.

GES placement using minimally invasive surgical approaches has also been evaluated in several publications. Laparoscopy has been reported in at least two studies as a feasible approach in placement of GES for patients with medically refractory diabetic or idiopathic gastroparesis.[14, 15]

Several small case series and retrospective reviews have been reported, some with long-term outcomes up to 5 years.[14, 16-32] The data indicate that GES may be associated with improvements in gastrointestinal symptom scores, nutrition and quality-of-life for patients; these improvements were sustained over time. However, gastric emptying rates were mixed.

Adverse Events

In 2017, Bielefeldt analyzed the number, severity and type of voluntarily reported adverse events related to Enterra™ in the Manufacturer and User Device Experience (MAUDE) databank of the FDA.[33] Data were retrieved for 2001 through October 31, 2015, of which 1472 reports were abstracted. Thirty-six perioperative complication reports were reviewed; six were serious events, including three deaths (one due to cardiac arrest, two due to septic complications with resulting multi organ failure), one stroke, and one myocardial infarction complicated further by a pulmonary embolism. Overall, most of the reports were regarding patient concerns, local complications, or system failure. Limitations of these findings include reporting bias (the MAUDE data are voluntarily submitted), and report misclassification bias (MAUDE data sources vary from patient reports to published articles and inconsistencies in reporting have been found). Risk-

benefit could not directly be assessed given the nature of the MAUDE database, though the author cites other studies for outcomes measurement, most of which are included in the other sections of this evidence review. Overall, 35% of the reported adverse events prompted an additional surgery.

Section Summary

The evidence regarding the clinical utility of GES for gastroparesis due to intractable nausea and vomiting is limited to three small crossover RCTs. However, longer-term data suggest improvements in gastrointestinal symptom scores, nutrition, and quality-of-life scores, suggesting some benefit with GES treatment. Given the lack of alternative treatment options in this specific patient population, GES may be considered reasonable treatment of symptoms of gastroparesis.

GASTRIC STIMULATION FOR THE TREATMENT OF OBESITY

Systematic Review

In 2014, Cha published a review of 33 studies evaluating various methods of gastric stimulation as a treatment of obesity, including implantable GES.[34] The majority of included studies were small in nature with 24 studies evaluating 30 or fewer patients. In addition, many of the studies reported high dropout rates of more than 50% of patients at the end of the study follow-up period. A major limitation of the review was the inclusion of studies which did not include the treatment of obesity (i.e., BMI or weight loss) as a primary outcome measure. Furthermore, there were methodological difference in the patient inclusion criteria and most of the studies included in the review were limited by short-term follow-up of less than one year. The authors concluded that the level of evidence regarding GES as a treatment of obesity was low. Long-term RCTs which compare GES to other treatments of obesity and sham are needed in order to assess the safety and efficacy of GES in this population.

Randomized Controlled Trials

There is one published RCT on GES for the treatment of obesity. In 2009, Shikora reported on a randomized controlled, double-blind study (SHAPE trial) to evaluate GES for the treatment of obesity.[35] All 190 patients participating in the study received an implantable gastric stimulator and were randomized to have the stimulator turned on or off. All patients were evaluated monthly, participated in support groups and reduced their diet by 500-kcal/day. At 12-month follow-up, there was no difference in excess weight loss between the treatment group (weight loss of 11.8% +/- 17.6%) and the control group (weight loss of 11.7% +/- 16.9%) using intention-to-treat analysis (p=0.717).

Nonrandomized Studies

Additional, small studies – including one patient population with comorbidities of gastroparesis and morbid obesity – have reported positive outcomes in weight loss and maintenance of weight loss along with minimal complications.[36-41] However, due to lack of long-term outcomes from well-designed randomized clinical trials, conclusions cannot be made concerning the safety and efficacy of chronic gastric stimulation as a treatment for morbid obesity.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF GASTROENTEROLOGY[42]

In 2022, the American College of Gastroenterology updated practice guidelines on the management of gastroparesis.[43] and recommended that "Gastric electric stimulation (GES) may be considered for control of GP [gastroparesis] symptoms as a humanitarian use device (HUD) (conditional recommendation, low quality of evidence)."

The American College of Gastroenterology (ACG) published a clinical practice guideline on management of gastroparesis in 2013. The recommendations for this guideline were based on review of the evidence-base through 2011. The ACG concluded that GES treatment does not adequately address the clinical needs of these patients, but that, “GES may be considered for compassionate treatment in patients with refractory symptoms, particularly nausea and vomiting. Symptom severity and gastric emptying have been shown to improve in patients with diabetic gastroparesis (DG), but not in patients with idiopathic gastroparesis (IG) or postsurgical gastroparesis (PSG). (Conditional recommendation, moderate level of evidence.).”

SUMMARY

It appears that gastric electrical stimulation (GES) may improve intractable nausea and vomiting for patients with gastroparesis. Clinical guidelines based on research state GES may be considered for compassionate treatment in patients with refractory symptoms, particularly nausea and vomiting. Therefore, given the lack of treatment options in this very specific patient population, GES may be medically necessary in carefully selected patients with gastroparesis when policy Criteria are met. GES for the treatment of chronic intractable nausea and vomiting secondary to gastroparesis of diabetic, idiopathic or post-surgical etiology is considered not medically necessary when policy Criteria are not met.

There is limited evidence on the efficacy and safety gastric electrical stimulation for any other indication including but not limited to the treatment of obesity. There are no clinical practice guidelines that recommend the use of gastric electrical stimulation for any other indication. Therefore, the use of electrical gastric stimulation for all other indications including treatment for obesity are considered investigational.

In certain situations, a stimulator may require revision after it has been placed. In these cases, revision may be medically appropriate to allow for the proper functioning of the device. Therefore, revision(s) to an existing gastric electrical stimulator may be considered medically necessary after the device has been placed.

In certain situations, a gastric electrical stimulator may no longer be able to perform its basic function due to damage or wear. When a gastric electrical stimulator is out of its warranty period and cannot be repaired adequately to meet the patient’s medical needs, replacement of the device may be medically appropriate. Therefore, replacement of all or part of a gastric electrical stimulator may be considered medically necessary when device replacement Criteria are met.

When a gastric electrical stimulator is in its warranty period or can be repaired or adapted adequately to meet the patient’s medical needs, replacement of the device is not medically appropriate. Therefore, replacement of all or part of a gastric electrical stimulator is considered not medically necessary when device replacement Criteria are not met.

CODES

NOTES:

- The CPT coding manual indicates that procedures related to laparoscopic gastric stimulation electrodes for morbid obesity should be reported using code 43659 - Unlisted laparoscopy procedure, stomach
- HCPCS code C1823 is NOT the correct code to use for reporting these services. Please refer to the codes listed below for guidance.

Codes	Number	Description
CPT	43647	Laparoscopy, surgical; implantation or replacement of gastric neurostimulator electrodes, antrum
	43648	Laparoscopy, surgical; revision or removal of gastric neurostimulator electrodes, antrum
	43659	Unlisted laparoscopy procedure, stomach
	43881	Implantation or replacement of gastric neurostimulator electrodes, antrum, open
	43882	Revision or removal of gastric neurostimulator electrodes, antrum, open
	43999	Unlisted procedure, stomach
	64590	Insertion or replacement of peripheral, sacral, or gastric neurostimulator pulse generator or receiver, requiring pocket creation and connection between electrode array and pulse generator or receiver

Codes	Number	Description
	64595	Revision or removal of peripheral, sacral, or gastric neurostimulator pulse generator or receiver, with detachable connection to electrode array
		Electronic analysis of implanted neurostimulator pulse generator system (eg, rate, pulse amplitude and duration, configuration of wave form, battery status, electrode selectability, output modulation, cycling, impedance and patient measurements) gastric neurostimulator pulse generator/transmitter; intraoperative, with programming
	95981	;subsequent, without programming
		;subsequent, with reprogramming
HCPCS	C1767	Generator, neurostimulator (implantable), nonrechargeable
	C1883	Adaptor/Extension, pacing lead or neurostimular lead (implantable)
		Lead neurostimulator test kit (implantable)
	E0765	FDA approved nerve stimulator, with replaceable batteries, for treatment of nausea and vomiting
		Electrical stimulator supplies (external) for use with implantable neurostimulator, per month
	L8679	Implantable neurostimulator, pulse generator, any type
	L8680	Implantable neurostimulator electrode, each
	L8685	Implantable neurostimulator pulse generator, single array, rechargeable, includes extension
	L8686	;non-rechargeable, includes extension
	L8687	Implantable neurostimulator pulse generator, dual array, rechargeable, includes extension
	L8688	;non-rechargeable, includes extension

Appendix 1: Prokinetic Medications	
Class	**Common Examples**
Cholinergic Agonists	dexpanthenol (Ilopan®), bethanechol (Urecholine®)
Motolin receptor agonists	erythromycin
	metoclopramide (Reglan®)

Appendix 2: Antiemetic Medications	
Class	**Common Examples**
Antihistamines	diphenhydramine (Benadryl®), dimenhydrinate (Dramamine®), meclizine (Antivert®), hydroxyzine (Vistaril®), trimethobenzamide (Tigan®)
Serotonin ($5HT_3$) receptor antagonists	ondansetron (Zofran®), granisetron (Kytril®), dolasetron (Anzemet®)
Dopamine receptor antagonists	Metoclopramide (Reglan®), perphenazine (Trilafon®), prochlorperazine (Compazine®), promethazine (Phenergan®), thiethylperazine (Torecan®), cyclizine (Marezine®)

Date of Origin: *February 2001*

Medical Policy Manual Surgery, Policy No. 121

Transcutaneous Bone-Conduction and Bone-Anchored Hearing Aids

Effective: May 1, 2024

Next Review: March 2025
Last Review: March 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

External bone-conduction hearing aids function by transmitting sound waves through the bone of the skull to the inner ear.

MEDICAL POLICY CRITERIA

Notes:

- This policy applies *only* to bone-conduction hearing aid systems that are bone anchored (also called bone-anchored hearing aids (BAHAs) or osseointegrated implants) or transcutaneous (non-surgical, secured by a Softband or other method). It does *not* apply to cochlear implants, which are addressed in a separate medical policy (see Cross References), or to intraoral bone-conduction hearing aids.
- Both bone-anchored and transcutaneous bone-conduction systems are hearing aids. There may be specific member benefit language addressing coverage of hearing aids. Any specific contract language supersedes medical policy. Unless otherwise specified, the contract language addressing coverage of hearing aids applies to both bone-conduction hearing aids and externally worn air-conduction hearing aids.

- Oregon HB 4104 Coverage of Hearing Loss Treatments (Oregon Hearing Mandate), effective January 1, 2019, requires coverage of medically necessary hearing aids, including specified replacement supplies, for Oregon members meeting age and educational enrollment requirements. This coverage is detailed in applicable contracts. Note that contract language rather than Criterion IV. may apply for Oregon members meeting the parameters of the Oregon Hearing Mandate.

I. **Unilateral or bilateral transcutaneous bone-conduction or bone-anchored hearing aid(s)** may be considered **medically necessary** as an alternative to air-conduction hearing aid(s) for conductive or mixed hearing loss when all of the following criteria (A.-D.) are met:

A. Patients who meet any of the following criteria:

1. Congenital or surgically induced malformations (e.g., atresia) of the external ear canal or middle ear; or
2. Chronic external otitis or otitis media; or
3. Tumors of the external canal and/or tympanic cavity; or
4. Dermatitis of the external canal.

B. A bone-conduction pure tone average threshold at 0.5, 1, 2, and 3 kHz no poorer than (i.e. threshold average of 0.5, 1, 2, and 3 kHz no higher than) one of the following (see Policy Guidelines):

1. 25 dB for ADHEAR; or
2. 45 dB for OBC, Ponto 3, Ponto 4, BONEBRIDGE, Baha4 and Baha5 devices; or
3. 55 dB for Ponto 3 Power, BAHA 5 Power, BAHA 6 Max, Osia, and Osia 2 devices; or
4. 65 dB for Ponto 3 SuperPower and BAHA 5 SuperPower devices; or
5. For a device not listed above, average threshold consistent with the device-specific FDA indication.

C. Meet one of the following age requirements:

1. 12 years or older for BONEBRIDGE, Osia, or Osia 2; or
2. 5 years or older for all other surgically implanted devices; or
3. Any age for non-surgically implanted devices; or
4. For a device not listed above, age consistent with the device-specific FDA indication (See Policy Guidelines).

D. Patients are to receive either:

1. A unilateral bone-conduction hearing aid; or
2. Bilateral bone-conduction hearing aids and have symmetrically conductive or mixed hearing loss (measured without augmentation) as defined by a difference between left- and right-side bone-conduction threshold of less than 10 dB on average measured at 0.5, 1, 2 and 3 kHz (and also 4 kHz for OBC,

Ponto Pro 3, and Otomag Alpha 1 [M]), or less than 15 dB at individual frequencies.

II. **A transcutaneous bone-conduction or bone-anchored hearing aid** may be considered **medically necessary** as an alternative to an air-conduction contralateral routing of signals (CROS) hearing aid in patients five years of age and older with single-sided sensorineural deafness and normal hearing in the other ear.

III. Other uses of transcutaneous bone-conduction or bone-anchored hearing aids, including but not limited to when Criterion I or II is not met and use in patients with bilateral sensorineural hearing loss, are considered **investigational**.

IV. **Implant replacement**, including **replacement parts or upgrades** to existing bone-anchored hearing aids and/or components, may be considered **medically necessary** when components are no longer functional, or for functional devices only in the small subset of patients whose response to existing components is inadequate to the point of interfering with activities of daily living, which would include school and work.

V. **Implant replacement,** including **replacement parts or upgrades** to existing bone-anchored hearing aids and/or components are considered **not medically necessary** when Criterion IV. is not met, including but not limited to when requested for convenience or technology upgrade. Replacement parts or upgrades include, but are not limited to batteries, processors, headbands or Softbands. This criterion may not apply to Oregon members who meet the parameters of the Oregon Hearing Mandate (see applicable contracts for details).

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

HEARING TESTS

Pure tone hearing tests measure the faintest level (hearing threshold) at which a tone can be heard at selected frequencies approximately 50% of the time. Lower thresholds represent better hearing.

Each ear is tested separately. The pure tone average threshold hearing level is calculated separately for each ear by averaging the hearing levels at each frequency. For example, if a patient's bone-conduction hearing threshold in the right ear at frequencies 0.5, 1, 2, and 3 kHz is 20, 20, 30, and 40 dB, respectively, the pure tone average for that ear is (20 + 20 + 30 + 40) divided by 4 = 27.5 dB.

Bone-conduction hearing is necessary for bone conduction hearing aids to provide value. The threshold required depends on the specific device, as listed in the policy criteria and in the FDA approval documentation. For example, given that lower thresholds represent better hearing, a bone-conduction pure tone average threshold of 40 dB would meet the criteria of no poorer than (*no higher than*) 45 dB (e.g. for the Ponto 3 device), while a bone-conduction pure tone average threshold of 50 dB would *not* meet the criteria of no poorer than (*no higher than*) 45 dB, but it would meet the criteria of no poorer than (*no higher than*) 55 dB (e.g. for the Ponto 3 Power device).

FDA APPROVAL

FDA-approved indications can be found by searching by device name in the FDA 510(k) Premarket Notification Database or the De Novo Database and viewing the Summary. Product codes for these devices include LXB, MAH, and PFO.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF DOCUMENTATION

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Audiology test results

1. Cochlear Implant, Surgery Policy No. 8

BACKGROUND

Conventional external hearing aids can be generally subdivided into air-conduction hearing aids and bone-conduction hearing aids. Air-conduction hearing aids require the use of ear molds, which may be problematic in patients with chronic middle ear and ear canal infections, atresia of the external canal, or an ear canal that cannot accommodate an ear mold. In these patients, bone-conduction hearing aids may be an alternative.

External bone-conduction hearing aids historically were closely applied to the temporal bone with either a steel spring over the top of the head or with the use of a spring-loaded arm on a pair of spectacles. These devices may be associated with either pressure headaches or soreness. Partially implantable bone-conduction hearing aids have been investigated as an alternative, and external bone-conduction hearing aids applied with less or no pressure have also become available.

The bone-anchored hearing aid (BAHA) implant systems, also called osseointegrated devices, work by combining a vibrational transducer coupled directly to the skull via a percutaneous abutment that permanently protrudes through the skin from a small titanium implant anchored in the temporal bone. The system is based on the process of “osseointegration” through which living tissue integrates with titanium in the implant over a period of three to six months, allowing amplified and processed sound to be conducted via the skull bone directly to the cochlea. The lack of intervening skin permits the transmission of vibrations at a lower energy level than required for external bone-conduction hearing aids.

The BAHA device has been used successfully in children younger than five years in Europe and the United Kingdom. (The most recent [1999] update of the U.S. Food and Drug Administration [FDA] notification lists age less than five years as a contraindication.) A number of reports describe experience with preschool children or children with developmental issues that might interfere with maintenance of the device and skin integrity. A two-stage procedure is used in young children with the fixture placed into the bone at the first stage and, after three to six months to allow for osseointegration, a second procedure to connect the abutment through the skin to the fixture.

Baha sound processors can also be used with the Baha® Softband™. With this application there is no implantation surgery. The sound processor is attached to the head using either a hard or soft headband. The band can be adjusted to the individual's head size. The amplified sound is transmitted transcutaneously to the bones of the skull for transmission to the cochlea. These devices have been suggested as a bridge to bone anchor implantation in young children who are not eligible for the implant due to young age and/or bone strength/thickness not yet adequate. The recently approved ADHEAR device attaches with an adhesive and no headband is required.

Partially implantable magnetic bone conduction hearing systems, also referred to as transcutaneous bone-anchored systems, are an alternative to bone conduction hearing systems connected percutaneously via an abutment. With this technique, acoustic transmission occurs transcutaneously via magnetic coupling of the external sound processor and the internally implanted device components. The bone conduction hearing processor contains a magnet that adheres externally to magnets implanted in shallow bone beds with the bone conduction hearing implant. Since the processor adheres magnetically to the implant, there is no need for a percutaneous abutment. To facilitate greater transmission of acoustics between magnets, skin thickness may be reduced to 4-5 mm over the implant when it is surgically placed.

REGULATORY STATUS

The following *Baha® sound processors, currently marketed by Cochlear™ (formerly called Cochlear™ Americas), have received 510(k) clearance from the U.S. Food and Drug Administration (FDA) for use with the Baha auditory osseointegrated implant (hearing aid) systems (such as the Baha® Connect and Attract systems):

- Baha® 5 Sound Processor
- Baha® 5 SuperPower Sound Processor
- Baha® 5 Power Sound Processor
- Baha® 6 Max Sound Processor

The above devices are currently available from Cochlear™. However, predicate devices include the Baha®4, Cordelle II, Divino®, Intenso™ and BP100™.

*Note: These devices may be referred to as Cochlear™ Baha® systems or Cochlear osseointegrated implants, reflecting the manufacturer’s name. These devices are bone conduction hearing aids and *should not* be confused with cochlear implants which are prostheses that replace a damaged or absent cochlea in the inner ear. Cochlear implants are addressed in a separate medical policy (see Cross References).

The FDA approved the Cochlear™ Baha® system (initially approved under the trade name Branemark Bone-Anchored Hearing Aid [BAHA™] by Entific Medical Systems, Inc.) for use in children aged five years and older, and in adults, for the following indications:

- Patients who have conductive or mixed hearing loss and can still benefit from sound amplification;
- Patients with bilaterally symmetric conductive or mixed hearing loss, may be implanted bilaterally;
- Patients with sensorineural deafness in one ear and normal hearing in the other (i.e., single-sided deafness, SSD);
- Patients who are candidates for an air-conduction contralateral routing of signals (AC

CROS) hearing aid but who cannot or will not wear an AC CROS device.

Baha sound processors can also be used with the Baha® Softband and Baha® SoundArc. The Baha® Softband received FDA clearance in 2002 for use in children under the age of five years. The Baha® SoundArc received FDA clearance in 2017 for use in people of any age.

Subsequent bone conduction hearing systems (listed below) share similar indications as the Cochlear™ Baha® devices:

- OBC Bone Anchored Hearing Aid System (Oticon Medical)
- Sophono® (S) (Cochlear) (predicate device was Otomag [Sophono])
- Ponto Pro, Ponto Plus, Ponto Plus Power, Ponto 3, Ponto 3 Power, Ponto 3 SuperPower,Ponto 4 and Ponto 5 SuperPower processors (Oticon Medical), to be used with the Oticon or BAHA osseointegrated implant.

The MedEl ADHEAR device, which has no implantable components, received FDA 510(k) clearance with the Contact Mini (audiofon) and BAHA 5 (Cochlear) as predicate devices.

The following partially implantable magnetic bone conduction devices have received FDA 510(k) clearance:

- Sophono® (M) (Cochlear) (predicate device was Otomag Alpha [Sophono])
- Sophono™ Alpha 2 MPO™ (Medtronic)
- Baha® Attract (Cochlear®)

The BoneBridge™ (MedEl) partially implantable bone-conduction hearing aid received FDA approval via the de novo pathway in 2018.

The Osia™ (Cochlear) bone-conduction hearing aid received FDA 510(k) approval with BoneBridge™ as the predicate device in July 2019. The Osia™ 2 received FDA 510(k) approval with Osia™ as the predicate device in November 2019.

EVIDENCE SUMMARY

Hearing results of semi-implantable bone-conduction hearing aids may be compared either to 1) external bone-conduction hearing aids in patients with atresias who are unable to use external air-conduction hearing aids, or 2) external air-conduction hearing aids in patients who are unable to tolerate air-conduction hearing aids due to chronic infection. Reported studies have suggested that the bone-anchored hearing aid (BAHA) is associated with improved hearing outcomes compared to external bone-conduction hearing aids and equivalent outcomes compared to conventional air-conduction hearing aids.[1-4] However, given the objectively measured outcomes and the largely invariable natural history of hearing loss in individuals who would be eligible for an implantable bone-conduction device, a within-subjects comparison of hearing before and after device placement may be a reasonable study design.

UNILATERAL DEVICES

Systematic Review

In 2017 Kim conducted a systematic review on the efficacy of BAHAs in single-sided deafness, including 14 studies (n=296 patients). The reviewers reported that in the six studies that dealt with sound localization, no significant difference was found after the implantation. However,

twelve studies showed the benefits of BAHAs for speech discrimination in noise. Regarding subjective outcomes of using the prosthesis in patients with SSD (abbreviated profile of hearing aid benefit [APHAB] and the Glasgow hearing aid benefit profile [GHABP], etc.), improvements in quality of life were reported in the majority of studies.

This systematic review has indicated that BAHAs may successfully rehabilitate patients with SSD by alleviating the hearing handicap to a certain degree, which could improve patients' quality of life. This report has presented additional evidence of effective auditory rehabilitation for SSD and will be helpful to clinicians counseling patients regarding treatment options for SSD

In a 2015 Peters published a systematic review of the literature through April 7, 2014 on the use of BAHA devices with contralateral routing of sound systems for single-sided deafness (SSD).[5] Five[6-10] of the six studies that met inclusion criteria were rated as moderate to high directness of evidence and low to moderate risk of bias and, thus, were included in the review. Significant heterogeneity was found in the 91 total patients included. For speech perception in noise there was not consistent improvement with aided hearing over unaided hearing in all environments. All studies reported equal sound localization in the aided and unaided conditions, and quality of life measures were similar for the aided and unaided conditions. Interpretation of these outcomes was limited by the methodological limitations of the included studies, including the lack of RCTs, unclear inclusion criteria, small sample sizes, use in some studies of headband devices which have different bone conduction thresholds in the higher frequencies than implanted devices, clinical heterogeneity of included populations (e.g., duration of deafness, grade of hearing loss), unexplained missing data, and lack of long-term audiometric follow-up. The authors also noted that the lack of recent studies was surprising considering the recent advances in these devices and recommended high-quality studies on the clinical outcome of current devices.

Randomized Controlled Trials

No RCTs of unilateral BAHAs have been published.

Nonrandomized Studies

One retrospective study (Wazen 2021) compared results of BAHA implantation for SSD based on bone-conduction pure tone average (PTA) of the better-hearing ear.[11] Subjects were divided into three groups by bone conduction PTA of the better hearing ear, with the ranges of 0 to 20 dB, 21 to 40 dB, and 41 to 55 dB. All three groups showed statistically significant improvement in bone conduction PTA and quality of life.

Additionally, since publication of the Peters systematic review, the following prospective, interventional studies compared patient satisfaction with transcutaneous BAHA devices to CROS hearing aids for SSD.

Jakob (2021) compared long-term (one-year) results in patients with SSD who chose between a CROS, a BAHA, and a cochlear implant (CI) following a three-week test phase with CROS and a bone-anchored hearing system.[12] At the one-year follow up, study results showed an improvement in speech comprehension when speech was delivered to the deaf ear and noise to the hearing ear for the BAHA (p=0.008; median unaided=0%, median 12 m=40.59) and CI (p<0.001), but the CROS group had poorer speech comprehension compared to the unaided situation (median unaided=98.58%; median 12 m=64.62%, p=0.603). Localization error was

significantly reduced in the CI group after 12 months (median unaided 26.36°, median CI 12 m=15.43°; p<0.001) compared to the unaided conditions. No differences in localization error were found for the BAHA or CROS groups.

den Besten (2019) assessed 54 adults with SSD, each of whom underwent a trial with the Baha Softband before a trial of the percutaneous, partially implantable Baha Attract device.[13] No statistically significant difference in audiological outcomes was seen between the two devices (p>0.05). At a six-month follow-up after implantation, patients reported numbness (20%) and slight pain/discomfort (38%) associated with the device.

Choi (2019) compared the performance of contralateral routing of signal (CROS)/bilateral routing of signal (BiCROS) and soft-band bone-anchored hearing aid (BAHA) devices in 21 patients with unilateral sensorineural hearing loss.[14] All participants were naïve to hearing devices. Sound localization, speech perception, psychoacoustic performance, and subjective assessments were analyzed. The subjects were assessed with each device and in the unaided condition. Sound localization was not improved in the soft-band BAHA condition and was significantly impaired with the CROS/BiCROS. Both devices significantly improved speech-in-noise perception when targeted to the impaired ear side. With regard to psychoacoustic performance, temporal resolution was significantly decreased with the BAHA compared to the unaided condition and CROS/BiCROS. There were no significant differences reported for preference between devices or subjective assessments of background noise or sound quality.

In 2017, Snapp reported a prospective single-center study of 27 patients with unilateral severe-profound sensorineural hearing loss who had either a CROS (n=13) or transcutaneous BAHA (n=14) device.[15] Mean device use was 66 months for the BAHAs and 34 months for CROS devices. Both BAHA and CROS groups had significant improvement in speech-in-noise performance, but neither showed improvement in localization ability. There were no differences between the devices for subjective measures of posttreatment residual disability or satisfaction as measured by the Glasgow Hearing Aid Benefit Profile (GHABP).

Leterme (2015) assessed 24 adults with SSD, 18 of whom were evaluated with trials of both hearing aids with CROS and bone conduction–assisted hearing using the Baha Softband.[16] Most patients (72%), after completing trials of both devices, preferred the BAHA device to hearing aid with CROS. Glasgow Benefit Index and Abbreviated Profile of Hearing Aid Benefit (APHAB) scores did not differ significantly between devices. Sixteen of the 18 subjects elected to undergo implantation of a percutaneous BAHA device. In general, hearing improvement with the Baha Softband trial correlated with hearing improvements following device implantation.

BILATERAL DEVICES

Use of bilateral devices has been evaluated in nonrandomized studies of patients with conductive or mixed hearing losses. In general, bilateral BAHAs seem to provide additional objective and subjective benefit compared with unilateral BAHAs.

Systematic Reviews

Heath (2022) conducted a systematic review (SR) of studies that compared outcomes between bilateral and unilateral BAHA for patients with no benefit from conventional hearing aids.[17] A total of 14 articles were included; all studies were retrospective with the exception of one case report, and all studies had a substantial risk of bias. A meta-analysis was not performed, but descriptive comparison found that bilateral BAHA were associated with greater improvement in

hearing thresholds, understanding speech, and localization. Unilateral BAHA were more effective when noise was one-sided. All studies reported improvement in quality of life.

A systematic review by the Health Technology Assessment Program was published in 2011 on the use of bone-anchored hearing aids (BAHAs) for bilateral hearing impairment.[18, 19]The authors noted that the quality of available studies on the use of BAHAs is weak. No studies with control groups were identified for the review. Cohort pre-post studies and cross-sectional comparative studies demonstrated improvements in hearing with use of BAHAs over conventional bone-conduction hearing aids or unaided hearing. However, whether improvements in hearing with BAHAs are greater than air-conduction hearing aids is uncertain. Additionally, bilateral use of BAHAs improved hearing outcomes in some patients over unilateral use, but the evidence was uncertain. Implant loss was noted to be between 6.1% and 19.4%. The authors noted hearing-specific quality of life improved, but overall quality of life did not differ.

In 2012 Janssen reported similar findings in a systematic review that assessed the outcomes of bilateral versus unilateral BAHA for individuals with bilateral permanent conductive hearing loss (CHL).[20] Their search strategy included studies of all languages published between 1977 and July 2011. Studies were included if subjects of any age had permanent bilateral CHL and bilateral implanted BAHAs. Outcome measures of interest were any subjective or objective audiologic measures, quality of life indicators, or reports of adverse events. Eleven studies met their inclusion criteria. All 11 studies were observational. There were a total of 168 patients in the 11 studies, 155 of whom had BAHAs and 146 of whom had bilateral BAHAs. In most studies, comparisons between unilateral and bilateral BAHA were intra-subject. Patients ranged from 5 to 83 years of age; 46% were male, and 54% were female. Heterogeneity of the methodologies between studies precluded meta-analysis, therefore a qualitative review was performed. Results from three studies were excluded from synthesis because their patients had been included in multiple publications. Adverse events were not an outcome measure of any of the included studies. In general, bilateral BAHA was observed to provide additional objective and subjective benefit compared to unilateral BAHA. For example, the improvement in tone thresholds associated with bilateral BAHA ranged from 2 to 15dB, the improvement in speech recognition patterns ranged from 4 to 5.4dB, and the improvement in the Word Recognition Score ranged from 1 to 8%. However, these results were based on a limited number of small observational studies consisting of heterogeneous patient groups that varied in age, severity of hearing loss, etiology of hearing loss, and previous amplification experience.

Randomized Controlled Trials

No RCTs of bilateral BAHAs have been published.

Nonrandomized Studies

No new studies have been published since the most recent systematic review.

BAHA IN CHILDREN UNDER AGE FIVE YEARS

Nonrandomized Studies

The literature on the use of these devices in children consists of a review article and several nonrandomized studies.

The largest series in children under five years identified for this review, described by Amonoo-

Kuofi in 2015, which included 24 children identified from a single center's prospectively maintained database.[21] Most patients underwent a 2-stage surgical approach. The largest proportion of patients (52%) received the implant for isolated microtia, followed by Goldenhar syndrome (16%). Following implantation, 13 patients (54%) had grade 2 or 3 local reactions on the Holgers Scale (redness, moistness, and/or granulation tissue) and 7 (29%) had grade 4 local reactions on the Holgers Scale (extensive soft-tissue reaction requiring removal of the abutment). Quality of life scores (Glasgow Children's Benefit Inventory [GCBI]; scoring range, -100 to 100) were obtained in 18 subjects/parents with a finale mean score change of +40 points. Audiologic testing indicated that the average performance of the device fell within the range of normal auditory perception in noisy and quiet environments.

Marsella (2012) reported on their center's experience with pediatric BAHA in all 47 children implanted, seven of which were younger than five years of age.[22] The functional gain was significantly better with BAHA than with conventional bone-conduction hearing aids. There was no significant difference in terms of functional outcome between the seven patients younger than age five and the rest of the patient cohort. Based on these findings, the study authors suggested that implantation of children at an age younger than five years can be conducted safely and effectively in such settings. However, the conclusions from this study were limited by the small number of children younger than five years of age and the limited power to detect a difference between younger and older children.

A 2008 review article noted that for children younger than age five years, other solutions (such as a bone conductor with transcutaneous coupling) should be utilized.[23] This recommendation is in agreement with the FDA clearance of the osseointegration implant only for children five years of age and older, and adults.

McDermott (2008) reported on the role of BAHAs in children with Down syndrome in a retrospective case analysis and postal survey of complication rates and quality of life outcomes for 15 children aged 2 to 15 years.[24] All patients were using their BAHA devices after a follow-up of 14 months. No fixtures were lost, and skin problems were encountered in three patients. All 15 patients had improved social and physical functioning as a result of better hearing.

Davids (2007) at the University of Toronto provided BAHA devices to children less than five years of age for auditory and speech-language development and retrospectively compared surgical outcomes for a study group of 20 children five years or younger and a control group of 20 older children.[25] Children with cortical bone thickness greater than 4 mm underwent a single-stage procedure. The interstage interval for children having 2-stage procedures was significantly longer in the study group to allow implantation in younger patients without increasing surgical or postoperative morbidity. Two traumatic fractures occurred in the study group versus four in the older children. Three younger children required skin site revision. All children were wearing their BAHA devices at the time of writing.

BAHA SOFTBAND AND ADHESIVE HEARING DEVICE USE IN CHILDREN

Nonrandomized Studies

The current evidence consists of small retrospective studies and comparative studies. Externally worn AOD sound processors appears to consistently be beneficial for children under age five years with bilateral aural atresia who are too young to receive an implantable device.[26-28]

A 2014 report compared use of the Softband in 16 children (ages ranging from three months to

six years) with bilateral aural atresia to 29 normal-hearing children (ages ranging from eight months to six years).[29] Auditory development was assessed at baseline, six months, and 12 months. The full text of the article was not available and the abstract did not provide data from the normal-hearing children for comparison. The authors concluded that the Softband was a suitable bridge to surgical implantation in infants and young children with bilateral atresia.

Ramakrishnan used the Glasgow Benefit Inventory (GBI) and Listening Situation Questionnaire to report quality of life findings in a retrospective cross-sectional survey administered to parents of 22 children (n=109 total participants), some with skull and congenital/chromosomal abnormalities from inherited syndromes that involve unilateral (hemifocal microsomia) or bilateral hearing impairment (Treacher-Collins Syndrome, n=4 of 22) due to microtia or aural atresia.[30] The youngest child utilizing an externally worn BAHA with Softband was six months of age. Overall, parents reported short-term satisfaction in the mean GBI scores for the children after three months of implanted BAHA or externally worn BAHA with Softband use. Despite the heterogeneous etiology of children in the study population, the authors suggest that the utility of BAHAs for children with syndromes and craniofacial anomalies is poorly recognized, resulting in delays in aid fitting and therefore in early hearing rehabilitation. In such cases, surgical reconstruction of the ear canal and middle-ear defects is not only technically challenging but also plagued by poor results (with a high rate of ear canal restenosis and limited functional hearing benefit). Hence, alternative treatment options such as Softband and BAHA may be of considerable benefit.

In 2010 Christensen reported on a retrospective chart review of 10 children (ages 6 months to 16 years) with bilateral conductive hearing loss.[31] Participants had been initially fit with a traditional bone-conduction hearing aid, then progressed first to the externally worn AOS with the Softband, then to the implanted BAHA. Functional gain was measured at 500 Hz, 1000 Hz, 2000 Hz, and 4000 Hz for each device. Both the external AOS and the implanted BAHA provided statistically significantly higher functional gain than the conventional BCHAs.

A number of the same authors for the Christensen study also reported the results of a retrospective chart review of 25 children aged 6 months to 18 years with craniofacial disorders and bilateral conductive hearing loss.

It is unknown whether some of the children in the 2010 study were also included in these results. The focus of this study was on functional as measure by comparison of aided (using the Baha Softband) and unaided soundfield audiometric thresholds. Soundfield thresholds were improved with the Baha amplification, with over 80% of the thresholds meeting significant target levels. The authors concluded that this demonstrated the benefit of the Baha for children with bilateral congenital conductive hearing loss.

Hol (2008) evaluated the validity of a BAHA with Softband (fitted unilaterally and bilaterally) in two young children with severe bilateral conductive hearing loss due to CAA.[32] In a small multicenter comparative study, 12 children (including the two children in the Hol, 2005 study) with bilateral CAA with a pure conductive hearing loss of around 60 dB HL were fitted with the BAHA with Softband.[33] These children were retrospectively compared to a reference group of eight children selected from a database of those who had a conventional bone conduction hearing aid for bilateral CAA. The authors reported the mean aided hearing threshold of the children with the BAHA with Softband compared to the reference group was 27 dB HL, ± 6 dB HL to 25 dB HL ± 6 dB HL, respectively. Further results compared psychological and language development in 5 of the 12 children available from the BAHA with Softband group.

ADVERSE EFFECTS OF BAHAS

Systematic Reviews

Hernández (2021) reported a retrospective chart review the frequency of cutaneous complications due to surgically implanted BAHAs.[34] Of the 88 patients identified (a total of 104 devices) with a minimum of six months of follow-up, 49 (55.7%) developed at least one episode of inflammatory or infectious skin reaction at the surgical incision site (mostly mild in severity), while 47 (53.4%) reported pain at the surgical site unrelated to clinically evident infection at some point during the follow-up.

Schwab (2020) completed a systematic review of adverse events associated with bone-conduction and middle-ear implants.[35] The 10 most frequently reported adverse events for bone conduction hearing implants included skin reactions (Holgers grade 1 to 3), skin revision surgery due to overgrowth or cellulitis, minor soft tissue/skin overgrowth, skin infection, surgical revision, reimplantation, failure to osseointegrate, and minor skin complications.

In 2016, Verheij published a systematic review on complications of tissue preservation surgical techniques with percutaneous BAHA devices including 18 studies with 381 devices.[36] The implantation techniques reported in the studies were as follows: punch method, four studies (81 implants); linear incision technique without soft tissue reduction, 13 studies (288 implants); and Weber technique, one study (12 implants). Indications for surgery were SSD (n=68), sensorineural hearing loss (n=4), mixed hearing loss (n=65), or CHL (n=66). The Holgers classification was used to grade soft tissue reactions (grade 0, no reaction; grade 2, red and moist tissue; grade 3, granulation tissue; grade 4, removal of skin-penetrating implant necessary due to infection). The incidence of Holgers 3 was 2.5% with the punch technique, 5.9% with the linear incision technique, and 0% with the Weber technique. Holgers 4 was reported in one patient implanted with the linear incision technique.

In 2014 Mohamad performed a systematic review focusing on the association between surgical technique and skin complications following BAHA implantation. Thirty randomized controlled trials and retrospective studies were included, which highlighted that the most common surgical techniques identified were full-thickness skin graft, dermatome and linear incision. The investigators reported that dermatome technique is associated with higher rate of skin complications and the use of a linear incision technique is associated with lower skin complications. However, the investigators concluded that the data to support these conclusions in limited and that higher quality studies are needed.[37]

In 2103 Kiringoda reported on a meta-analysis of complications related to BAHA devices. Included in the meta-analysis were 20 studies that evaluated complication in 2134 adult and pediatric patients who received a total of 2310 BAHA devices.[38] The quality of available studies was considered poor and lacking in uniformity. The most common complications related to BAHA devices were minor skin reactions. Holgers Grade 2 to 4 skin reactions were reported to occur from 2.4% to 38.1% in all studies. Zero to 18% of implants failed osseointegration in adult and mixed population studies while 0% to 14.3% failed osseointegration in pediatric population studies. Adult and mixed population studies reported revision surgery was required in 1.7% to 34.5% of cases while pediatric population studies reported required revision surgery in 0.0% to 44.4% of cases. Implant loss occurred in 1.6% to 17.4% in adult and mixed population studies and from 0.0% to 25% in pediatric studies.

Nonrandomized Studies

In 2016, Roplekar compared skin-related complications of the traditional skin flap method to the linear incision method performed by a single surgeon in 117 patients with at least one year of follow-up.[39] Twenty-one (24%) patients experienced skin-related complications in the skin flap group (12 skin overgrowths, eight wound infections, one numbness) and three (10%) patients experienced complications in the linear incision group (three wound infections).

Four 2014 retrospective studies reported specific complication rates related to BAHA implants. The rate of skin reaction (e.g., skin overgrowth, inflammation) ranged from 6% to 22%. Implant loss was 10-18% and were spontaneous while others required removal; the primary reasons for implant loss were loss of osseointegration, trauma, and soft tissue reactions or discomfort. In addition, a number of small studies reported the safety outcomes of various techniques for surgically implanting BAHA devices. These included skin flap versus full-thickness skin graft implantation[40], non-skin-thinning technique versus either flap or dermatome implantation[41], and techniques related to implant size[42, 43].

Section Summary: Safety and Adverse Events Related to BAHA Devices

The quality of available data for adverse events is generally poor with high heterogeneity. The most frequently reported complication from surgical procedures for BAHA insertion are adverse skin reactions, with an incidence of Holgers grade 2 to 4 reactions ranging from less than 2% to more than 34%, and implant loss ranging from less than 2% to more than 17%. There is some evidence of improvement in complication rates and severity with newer surgical techniques such as linear incision.

PARTIALLY IMPLANTABLE MAGNETIC BONE CONDUCTION HEARING AIDS

A small body of literature addresses outcomes associated with transcutaneous, partially implantable bone-anchored devices. The majority of studies use a within-subjects comparison of hearing thresholds with and without the device. The indications for partially implantable systems are the same as those for transcutaneous bone-anchored devices.

Systematic Reviews

Gutierrez (2024) published a SR comparing quality of life (QOL) outcomes of percutaneous and transcutaneous bone conduction devices (pBCD and tBCD, respectively).[44] A total of 52 articles with 1,469 patients were included. Six hundred eighty-nine patients were implanted with pBCDs, and the remaining 780 were implanted with tBCDs. Average Glasgow Benefit Inventory scores for the tBCD group (33.0, 95% confidence interval [22.7-43.3]) were significantly higher than the pBCD group (30.9 [25.2-36.6]) (Δ2.1 [1.4-2.8], $p < 0.0001$). Mean Glasgow Children's Benefit Inventory scores (Δ3.9 [2.0-5.8], $p = 0.0001$) and mean gain in Abbreviated Profile of Hearing Aid Benefit scores (Δ5.6 [4.8-6.4], $p < 0.0001$) were significantly higher among patients implanted with tBCDs than those implanted with pBCDs. Patients implanted with tBCDs also had significantly higher gains on the Speech (Δ1.1 [0.9-1.3], $p < 0.0001$), Spatial (Δ0.8 [0.7-0.9], $p < 0.0001$), and Qualities of Hearing (Δ1.2 [1.1-1.3], $p < 0.0001$) portions of the Speech, Spatial, and Qualities of Hearing Scale than those implanted with pBCDs. The authors conclude that patients implanted with transcutaneous devices had better QOL outcomes than those implanted with percutaneous devices.

Bezdjian (2017) published a systematic review of noncomparative studies that assessed outcomes and adverse events in patients with Sophono implants.[45] Thirteen articles were assessed for directness of evidence (DoE) and risk of bias (RoB) using predetermined criteria. Of these, eight studies (including 86 patients; 79.1% children) were considered to have high

enough quality for data extraction. These studies all had medium or low risk of bias and high directness of evidence. A pooled analysis of all studies showed an average unaided pure tone average of 63.70 dB and an aided pure tone average of 31.60 dB. Four studies reported unaided and aided sound reception thresholds in raw dB scores. A pooled analysis of these studies showed a mean unaided score of 66.90 dB and a mean aided score of 33.34. No intra-operative complications were reported and 29% of patients reported post-operative complications. Of these, three were serious adverse events. No implant loss occurred, except in one patient who requested explantation due to severe headaches. While there were improvements in auditory functions, no statistical analyses were reported.

In 2016, Dimitriadis reported on a systematic review of observational studies of the BAHA Attract device including 10 studies (total n=89 patients; range, 1 to 27 patients).[46] Seventeen (19%) of the patients were children, of whom five had unilateral sensorineural hearing loss and 4 had CHL. Of the 27 (45%) adults, 22 had unilateral sensorineural hearing loss and 11 (18%) had bilateral mixed hearing loss. Audiologic and functional outcome measures and the timing of testing varied greatly in the studies. Summary measures were not reported. In general, audiologic and functional outcomes measured pre- and postimplantation showed improvement, although statistical comparisons were lacking in some studies.

Randomized Studies

Gawecki (2022) completed a small randomized study that compared patients who received the Osia system (n=4) or the Baha Attract system (n=4) for bilateral mixed hearing loss.[47] After implantation, the mean gain in PTA was 42.8 ± 4.9 dB in the Osia group and 38.8 ± 8.5 dB in the Baha group. Patient ratings of hearing quality were better in the Osia group based on subjective Likert scores of sound loudness, sound distinctness, and hearing of own voice. Patient reported voice quality scores for reverberation were similar in the Osia and Baha groups. Both groups reported improved quality of life based on global Abbreviated Profile of Hearing Aid Benefit scores but there was a numerically larger improvement in the Osia group. Results for the Speech, Spatial and Qualities of Hearing Scale improved in both groups and were slightly better in the Baha group. The authors concluded that larger studies with longer follow-up are needed to evaluate differences in outcomes between these two systems.

Nonrandomized Studies

Kim (2022) compared the effects of the Osia system with the Baha Attract and Bonebridge systems in 67 patients with CHL or mixed hearing loss or single-sided deafness (SSD).[48] Patients who received the Osia system (n=17) were prospectively recruited and retrospectively compared with patients who received the Baha Attract or Bonebridge systems (n=50). Effective gains in bone conduction threshold at 2 kHz were 11.1 ± 14.9 dB in the Osia group compared to -2.7 ± 12.6 dB in the Baha Attract and Bonebridge group (combined) among patients with CHL or mixed hearing loss (p=0.01). Among patients with SSD, average functional gains at 4 kHz were 37.5 ± 8.9 dB in the Osia group, 21.7 ± 15.7 dB in the Baha Attract group, and 29.0 ± 13.0 dB in the Bonebridge group.

Iseri (2015) described a retrospective, single-center study from Turkey comparing 21 patients treated with a transcutaneous, fully implantable BAHA with 16 patients treated with a percutaneous device (the BAHA Attract).[49] Groups were generally similar at baseline, with most individuals undergoing BAHA placement for chronic otitis media. Operating time was longer in patients treated with the transcutaneous partially implantable devices (46 minutes vs 26 minutes, p<0.05). Three patients treated with percutaneous devices had Holger grade 2

skin reactions, and two had stopped using their devices. Mean thresholds for frequencies 0.5 to 4.0 kHz were 64.4 dB without the BAHA and 31.6 dB with the BAHA in the percutaneous device group, and 58.3 dB without the BAHA and 27.2 dB with the BAHA in the transcutaneous device group. Frequency-specific threshold hearing gains did not differ significantly between groups. Mean hearing gain measured by speech reception threshold was statistically significantly smaller in the percutaneous group (24 dB vs 36.7 dB, p=0.02).

There have been other, small nonrandomized studies that have assessed the outcomes of the BAHA Attract device, in comparison with other devices, or in single-center observational studies.[50-52] In addition, one case series of 34 patients has reported on complications of the BAHA attract device, where only three patients reported moderate to severe complications, two of which required removal of the magnet.[53]

In 2015, Denoyelle reported on a prospective trial of the Sophono device in children ages 5 to 18 years with uni- or bilateral congenital aural atresia with complete absence of the external auditory canal with pure CHL.[54] The study included a within-subject comparison of hearing results with the Sophono devices to those obtained with the Baha Softband preoperatively. All 15 patients enrolled were implanted (median age, 97 months). At six-month follow-up, mean aided AC pure-tone audiometry was 33.49 (mean gain, 35.53 dB), with a mean aided sound reception threshold of 38.2 (mean gain, 33.47 dB). The difference in AC pure tone average (PTA) between the Baha Softband and the Sophono device was 0.6 dB (confidence interval upper limit, 4.42 dB), which met the study's prespecified noninferiority margin. Adverse effects were generally mild, including skin erythema in two patients, which improved by using a weaker magnet, and brief episodes of pain or tingling in three patients.

The Otomag Sophono system has been studied in a number of very small (n=5 to 12) nonrandomized studies in pediatric patients.[50, 51, 55-61]

Similarly, the Bonebridge partially implantable system has also been studied in a number of small (n=5 to 44) case series, summarized in table 1.[62-68]

Table 1. Case Series Evaluating the Bonebridge Implant

Study	N	Patient Population	Main Hearing Results	Safety Outcomes
Seiwerth (2021)[69]	31	• Seven cases age <16 • 30 unilateral implantations • 1 bilateral implantation	• Mean sound-field threshold improvement at three and six months: 27 and 26 dB • WRS in quiet improved from 11% preoperatively to 74% three months postoperatively • Speech reception threshold in noise improved from -1.01 dB unaided to -2.69 dB best-aided	Not reported
Garcier (2021)[70]	24	• Adults with mixed hearing loss	• Average prosthetic gain in chronic otitis media vs. other etiologies: 43±4.8 dB and 50 ± 7.2, respectively • Abbreviated Profile of Hearing Aid Benefit (APHAB) questionnaire global score	No major complications. Local pain on the analogue visual scale was 3.23 ± 3.2 (n = 16

Study	N	Patient Population	Main Hearing Results	Safety Outcomes
			improved: 32 ± 10.2%	reporting) and manipulation difficulties were 3.1 ± 3.69
Bravo-Torres (2018)[71]	15	• Pediatric patients with bilateral CHL (microtia associated with external auditory canal atresia)	• Aided sound-field threshold improvement: 25.2 dB	Minor feedback (4), broken processors (4), mild skin redness (2) with one-month follow-up
Schmerber (2017)[72]	25	• SSD (n=12) • Bilateral CHL (n=7) • Bilateral mixed HL (n=6)	• SSD, in 5/7 patients speech reception threshold in noise lower with Bonebridge activated • CHL and mixed, average functional gain: 26 dB HL; mean % of speech recognition in quiet improved from 74% unaided to 95% aided	No complications, device failures, revision surgery, or skin injury reported with one year follow-up
Rahne (2015)[67]	11	• SSD (n=6; 1 sensorineural, 3 mixed, 2 conductive) • Bilateral CHL (n=2) • Bilateral mixed HL or mixed/sensorineural (n=3)	• Aided sound-field threshold improvement: 33.4 dB • WRS improved from mean of 10% unaided to 87.5% aided	One case of chronic fibrosing mastoiditis requiring mastoidectomy and antrotomy; no other complications
Laske (2015)[68]	9	• Adults with SSD and normal contralateral hearing	• Speech discrimination signal-to-noise improvement for aided vs unaided condition, sound presented to aided ear: 1.7 dB • Positive improvements on quality-of life questions	Not reported
Riss (2014)[62]	24	• Combined HL (n=9) • EAC atresia (n=12) • SSD (n=3)	• Average functional gain: 28.8 dB • Monosyllabic word scores at 65-dB sound pressure increased from 4.6 to 53.7 percentage points	Not reported
Manrique (2014)[63]	5	• Mixed HL (n=4) • SSD (n=1)	• PTA improvement: 35.62 dB (p=0.01) • Disyllabic word discrimination improvement: 20% (p=0.016)	No perioperative complications reported

Study	N	Patient Population	Main Hearing Results	Safety Outcomes
Ihler (2014)[64]	6	• Mixed HL (n=4) • CHL (n=2)	• PTA functional gain (average, 0.5-4.0 kHz): 34.5 dB • Speech discrimination at 65 dB improvement: o In quiet: 63.3 percentage points o In noise: 37.5 percentage points	Prolonged wound healing in one case
Desmet (2014)[65]	44	• All unilaterally deaf adults	• Statistically significant improvement on APHAB and SHHIA	Not reported

APHAB: Abbreviated Profile of Hearing Aid Benefit; CHL: conductive hearing loss; EAC: external auditory canal; HL: hearing loss; PTA: pure-tone average; SHHIA: Short Hearing Handicap Inventory for Adults; SSD: single-sided deafness; WRS: Word Recognition Score.

Section Summary: Partially Implantable Magnetic BAHA Devices

Studies of transcutaneous, partially implantable BAHAs have typically used a retrospective within-subjects comparison of hearing thresholds with and without the device, although there have been two small (27 and 15 participants) prospective studies. There was heterogeneity in the audiologic and functional outcome measures used in the studies and the timing of testing. Studies of partially implantable BAHAs have generally demonstrated within-subjects improvements in hearing.

PRACTICE GUIDELINE SUMMARY

AMERICAN ACADEMY OF OTOLARYNGOLOGY-HEAD AND NECK SURGERY

In 2021, the American Academy of Otolaryngology – Head and Neck Surgery (AAO-HNS) updated its consensus-based position statement on the use of bone conduction hearing devices.[73] It considers bone conduction hearing devices (BCHD) appropriate, and in some cases preferred, for the treatment of conductive and mixed hearing loss. BCHD may also be indicated in select patients with single-sided deafness. BCHD include semi-implantable bone conduction devices utilizing either a percutaneous or transcutaneous attachment, as well as bone conduction oral appliances and scalp-worn devices. The recommendation for BCHD should be determined by a qualified otolaryngology-head and neck surgeon. The statement indicates that the procedure should be performed by a qualified otolaryngologist-head and neck surgeon with devices which have been Food and Drug Administration (FDA)-approved, and "should adhere to the restrictions and guidelines specified by the appropriate governing agency, such as the Food and Drug Administration in the United States."

SUMMARY

There is enough research to show that unilateral or bilateral transcutaneous bone-conduction or bone-anchored hearing aid(s) improve net health outcomes when used as an alternative to air-conduction hearing aids in select patients. Clinical guidelines based on research recommend bone conduction hearing devices for the treatment of conductive or

mixed hearing loss and single-sided deafness. In addition, a binaural hearing benefit may be provided for patients with single-sided sensorineural deafness by the routing of signals to the hearing ear. Therefore, use of these devices is considered medically necessary for patients who meet the policy criteria.

There is not enough research to show that unilateral or bilateral transcutaneous bone-conduction or bone-anchored hearing aid(s) improve health outcomes for patients who do not meet the policy criteria, including but not limited to patients not meeting the age requirements and patients with bilateral sensorineural hearing loss. In addition, there are no evidence-based clinical practice guidelines that recommend these devices for patients who do not meet the criteria. Therefore, these devices are considered investigational for patients who do not meet the policy criteria.

Implant replacement, including replacement parts or upgrades, may be considered medically necessary only in the small subset of patients whose response to existing components is inadequate to the point of interfering with activities of daily living, which would include school and work; or when components are no longer functional.

Implant replacement, including replacement parts or upgrades to existing bone-anchored hearing aid components (for example, batteries, processor, headband or Softband) are considered not medically necessary when criteria are not met, including when requested for convenience or to upgrade to newer technology when the current components remain functional.

CODES

NOTE: The following CPT codes describe semi-implantable electromagnetic bone conduction hearing aids:

Codes	Number	Description
CPT	69710	Implantation or replacement of electromagnetic bone conduction hearing device in temporal bone*

Codes	Number	Description
	69711	Removal or repair of electromagnetic bone conduction hearing device in temporal bone

*****The Audiant™ bone conductor is a type of electromagnetic bone conduction hearing device. While this product is no longer actively marketed, patients with existing Audiant devices may require replacement, removal, or repair.

	69714	Implantation, osseointegrated implant, skull; with percutaneous attachment to external speech processor **
	69716	Osseointegrated implant insertion with magnetic transcutaneous attachment to a speech processor
	69717	Revision (including removal of existing device), osseointegrated implant, skull; with percutaneous attachment to external speech processor
	69719	Revision or replacement (including removal of existing device), osseointegrated implant, skull; with magnetic transcutaneous attachment to external speech processor, within the mastoid and/or involving a bony defect less than 100 sq mm surface area of bone deep to the outer cranial cortex
	69726	Removal, entire osseointegrated implant, skull; with percutaneous attachment to external speech processor
	69727	Removal, entire osseointegrated implant, skull; with magnetic transcutaneous attachment to external speech processor, within the mastoid and/or involving a bony defect less than 100 sq mm surface area of bone deep to the outer cranial cortex
	69728	Removal, entire osseointegrated implant, skull; with magnetic transcutaneous attachment to external speech processor, outside the mastoid and involving a bony defect greater than or equal to 100 sq mm surface area of bone deep to the outer cranial cortex
	69729	Implantation, osseointegrated implant, skull; with magnetic transcutaneous attachment to external speech processor, outside of the mastoid and resulting in removal of greater than or equal to 100 sq mm surface area of bone deep to the outer cranial cortex
	69730	Replacement (including removal of existing device), osseointegrated implant, skull; with magnetic transcutaneous attachment to external speech processor, outside the mastoid and involving a bony defect greater than or equal to 100 sq mm surface area of bone deep to the outer cranial cortex
	92622	Diagnostic analysis, programming, and verification of an auditory osseointegrated sound processor, any type; first 60 minutes
	92623	Diagnostic analysis, programming, and verification of an auditory osseointegrated sound processor, any type; each additional 15 minutes (List separately in addition to code for primary procedure)

**These codes describe implantation of the Baha®, Ponto™, and similar devices.

HCPCS	L8621	Zinc air battery for use with cochlear implant device and auditory osseointegrated sound processors, replacement, each
	L8624	Lithium ion battery for use with cochlear implant device or auditory osseointegrated device speech processor, ear level, replacement each
	L8625	External recharging system for battery for use with cochlear implant or auditory osseointegrated device, replacement only, each

Medical Policy Manual Surgery, Policy No. 132

Cryosurgical Ablation of Miscellaneous Solid Tumors Outside of the Liver

Effective: February 1, 2024

Next Review: November 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Cryoablation kills cells by freezing the tissue using a coolant that is circulated via a probe inserted into the tumor.

MEDICAL POLICY CRITERIA

Note: This policy does not address liver tumors (primary or metastatic). See Cross References.

I. Cryosurgical ablation may be considered **medically necessary** for the treatment of any of the following indications:
   A. Malignant dermatologic tumors
   B. Uveal melanoma
   C. Kidney tumors
   D. Prostate tumors
   E. Cervical intraepithelial neoplasia

F. Lung cancer when either of the following criteria is met:

1. For non-small cell lung cancer when the patient has early-stage (Stage I, and selected node negative Stage IIA) non-small cell lung cancer; or
2. The patient requires palliation for a central airway obstructing lesion.

II. Cryosurgical ablation is considered **investigational** as a treatment for all solid tumors not meeting Criterion I, including desmoid tumors and malignant or benign tumors of the breast (including fibroadenoma), pancreas, and bone; and for metastases outside of the liver or prostate.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical
- Treatment plan including treatment area.

BACKGROUND

Cryosurgical ablation (also called cryosurgery, cryotherapy, or cryoablation) kills cells (cancerous and normal) by freezing target tissues, most often by inserting a probe into the tumor through which coolant is circulated. Cryosurgery may be performed as an open surgical technique or as a closed procedure under laparoscopic or ultrasound guidance.

The goals of cryosurgery may include the following:

- Destruction or shrinkage of tumor tissue
- Controlling local tumor growth and preventing recurrence
- Palliating symptoms
- Extending survival duration for patients with certain tumors.

Potential complications associated with cryosurgery in any organ include the following:

- Hypothermic damage to normal tissue adjacent to the tumor (e.g., nerve damage)
- Structural damage along the probe track
- Secondary tumors if cancerous cells are seeded during probe removal.

REGULATORY STATUS

There are several cryoablation devices cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process for use in open, minimally invasive or endoscopic surgical procedures in the areas of general surgery, urology, gynecology, oncology, neurology, dermatology, proctology, thoracic surgery and ear, nose and throat. Examples include:

- Cryocare® Surgical System by Endocare;
- CryoGen Cryosurgical System by Cryosurgical, Inc.;
- CryoHit® by Galil Medical;
- IceRod® CX, IcePearl® 2.1 CX and IceFORCE® 2.1 CX Cryoablation Needles by Galil Medical;
- IceSense3™, ProSense™, and MultiSense Systems (IceCure Medical);
- SeedNet™ System by Galil Medical;
- Visica® System by Sanarus Medical;
- Visual-ICE® Cryoablation System by Galil;
- ERBECRYO 2® Cryosurgical Unit, ERBE USA Incorporated

EVIDENCE SUMMARY

In order to understand the impact of cryosurgical ablation on local or distant tumor recurrence and disease-free and overall survival in patients with solid tumors, randomized trials are needed that compare this technique with current standard treatments. The standard treatment for most solid tumors is surgical resection. For unresectable solid tumors, alternatives to resection depend on the tumor type and location, and may include thermal ablation, percutaneous ethanol injection, chemoembolization, chemotherapy, and radiation therapy.

Despite the weaknesses in the published clinical evidence, cryosurgical ablation has become a recognized standard of care for tumors of the kidney, liver (addressed in Ablation of Primary and Metastatic Liver Tumors, Surgery, Policy No. 204), prostate, and carefully selected patients with tumors of the lung.[1-51]

The following literature appraisal focuses on the investigational indications noted in medical policy criteria above.

BREAST TUMORS

The standard treatment for breast cancer is surgical excision by lumpectomy or mastectomy, with or without adjuvant radiation therapy, chemotherapy, and/or hormone therapy. Fibroadenomas, benign tumors of the breast, generally do not require treatment. If treated, they are typically surgically excised.

Systematic Reviews

One systematic review, by Zhao (2010), was found that included cryoablation along with other minimally-invasive thermal ablation techniques (i.e., radiofrequency, microwave, cryoablation and high-intensity focused ultrasound) for treatment of early-stage breast cancer.[52] Zhao reported that studies on cryoablation for breast cancer were primarily limited to pilot and feasibility studies conducted in the research setting. A wide range of 36-83% was reported for complete ablation of tumors. The authors concluded that, while promising, large randomized

controlled trials are needed to further evaluate patient selection criteria, techniques to ensure complete tumor ablation, and long-term outcomes compared with surgical excision of breast tumors.

Randomized Controlled Trials

There are no prospective, randomized controlled trials comparing survival and recurrence rates following cryoablation of breast tumors with surgical excision or, for unresectable tumors, with nonoperative therapies.

Nonrandomized Studies

The remaining nonrandomized evidence does not permit reliable conclusions concerning the impact of cryosurgical ablation on breast cancer survival or recurrence due to a number of methodological limitations, including: heterogeneous or unreported patient selection criteria, the use of varied cryoablation techniques, nonrandomized allocation of treatment, lack of an appropriate surgical excision control group for comparison, small subject population, and limited data on long-term outcomes.[53-66]

PULMONARY TUMORS

Systematic Reviews

Lee (2011) conducted a systematic review of endoscopic cryoablation of lung and bronchial tumors.[67] Included in the review were 15 case studies and one comparative observational study. Cryoablation was performed for inoperable, advanced lung and bronchial cancers in most studies. Some studies included patients with comorbid conditions and poor general health who would not be considered surgical candidates. Complications occurred in 11.1% of patients (10 studies) and consisted of hemorrhage, mediastinal emphysema, atrial fibrillation, and dyspnea. Within 30 days of the procedure, death from hemoptysis and respiratory failure, considered to be most likely related to disease progression, occurred in 7.1% of patients. Improvements in pulmonary function and clinical symptoms occurred in studies reporting these outcomes. One published review reported the outcomes of 15 case series and one comparative observational study for endoscopic cryotherapy of endobronchial tumors. Most studies were for inoperable, advanced lung and bronchial cancers. A critical analysis of the studies was not provided. However, the authors noted the significant limitations in the available evidence due to lack of control groups, lack of random treatment allocation, and heterogeneity in study methodologies, participants' characteristics (e.g., comorbid conditions, general health, cancer grade), treatment protocols, operative techniques, and outcome measures. Complications occurred in 11.1% of patients from ten studies and consisted of hemorrhage, mediastinal emphysema, atrial fibrillation, and dyspnea. Within 30 days of the procedure, death from hemoptysis and respiratory failure, considered to be most likely related to disease progression, occurred in 7.1% of patients. Improvements in pulmonary function and clinical symptoms occurred in studies reporting these outcomes. Because the studies in the review did not include control groups or compare outcomes of cryosurgery to alternative strategies for managing similar patients, no conclusions can be made on the net health outcomes of cryosurgery for lung cancer.

Randomized Controlled Trials

One preliminary randomized trial studied 36 female patients with NSCLC who also had epidermal growth factor receptor gene mutations.[68] All patients received six months treatment

with molecular target therapy gefitinib, an epidermal growth factor receptor-tyrosine kinase inhibitor. Patients were randomized to either an experimental group and underwent cryoablation prior to receiving gefitinib, or to a control group in which cryoablation was not performed. At one-year follow-up, the survival rate in the cryoablation group was significantly higher than that of the control group. The findings of this preliminary study suggest that cryoablation may improve the effects of gefitinib in this patient population. Additional larger, long-term randomized trials are needed to validate these findings.

Nonrandomized Studies

The Study of Metastatic Lung Tumors Targeted by Interventional Cryoablation Evaluation (SOLSTICE) study assessed the safety and local recurrence-free survival after cryoablation for treatment of pulmonary metastases. Callstrom (2020) published this multicenter, prospective, single-arm, phase 2 study in 128 patients with 224 lung metastases ≤3.5 cm.[69] Median tumor size was 1.0 cm. Local recurrence-free response was 85.1% at 12 months and 77.2% at 24 months. Secondary local recurrence-free response after retreatment with cryoablation for recurrent tumors was 91.1% at 12 months and 84.4% at 24 months. Overall survival at 12 and 24 months was 97.6% and 86.6%, respectively.

The ECLIPSE trial is prospective, multicenter trial of cryoablation for metastatic disease in the lungs, interim results at one-year follow-up were published in 2015.[70] The trial enrolled 40 patients with 60 metastatic lung lesions who were treated with cryoablation and had at least 12 months of follow-up. Outcomes included survival, local tumor control, quality of life, and complications. Local tumor control was achieved in 94.2% (49/52) of treated lesions, and one-year OS was 97.5% (39/40). There were no significant changes in quality of life over the 12-month study. The most common adverse event was pneumothorax requiring chest tube insertion in 18.8% (9/48 procedures). Five-year results of the trial were published by de Baère (2021), which reported disease-specific survival rates of 74.8% at three years and 55.3% at five years.[70] Five-year overall survival was 46.7% and there was no significant difference in quality-of-life measures.

BONE TUMORS

Systematic Reviews

Khanmohammadi (2023) published a systematic review of cryoablation for the palliation of painful bone metastases.[71] The review included 15 studies (n=376): ten case series and five prospective interventional studies. Of these, six were scored as “good,” six as “fair,” and three as “poor” according to the NIH Study Quality Assessment Tools. A total of 436 metastatic lesions were treated, mostly in the spine, pelvic bone, and ribs. All of the studies reported a statistically significant reduction in pain between one day and six months following the procedure.

A systematic review by Sagoo (2022) assessed percutaneous cryoablation of spinal metastases.[72] Eight studies, seven of which were retrospective, were included in the review, with a total of 148 patients and 187 treated lesions (3 cervical, 74 thoracic, 37 lumbar, and 17 sacrococcygeal). At one-month follow-up, the pooled mean difference in pain scores (1-10 scale) was 5.03 (95% confidence interval [CI] 4.24 to 5.82). Reported tumor control rates varied from 60% to 100% and complications were reported in 12 patients, three of which were grade III-V.

Lindquester (2020) published a systematic review evaluating percutaneous thermal ablation technologies for osteoid osteoma, which included 36 case-series (total n=1,798).[73] While the authors stated that the studies were evaluated for quality, the results of such an evaluation were not included in the publication. An overall success rate of 91.9% was reported, which included both technical and clinical success of the procedure as well as freedom from recurrence during follow-up, however median length of follow-up in these studies was not reported. The overall complication rate was 2.5% (95% CI 1.9% to 3.3%). No significant differences were found between radiofrequency and cryoablation, but only three of the 36 studies included cryoablation; most (32 studies) were for radiofrequency ablation.

Nonrandomized Studies

Cazzato (2022) published a review of 74 patients with spinal metastases who underwent cryoablation treatment at two academic medical centers.[74] Of these, 21 patients underwent treatment for curative purposes while 53 were treated for palliative purposes. Cryoablation was associated with a reduction in pain among those who presented with painful lesions. Local tumor control was achieved in 21 patients undergoing cryoablation with curative intent (mean follow-up of 25.9 ± 21.2 months).

Jennings (2021) reported on a multicenter, single-arm prospective study of 66 patients with metastatic bone disease who were treated with cryoablation, all of whom were not candidates for or had not benefited from standard therapy.[75] The primary endpoint was the change in pain score from baseline to week eight and patients were followed for 24 weeks. The mean decrease in pain score from baseline to week eight was 2.61 points (95% CI 3.45 to 1.78). Pain scores decreased further after the primary endpoint and reached clinically meaningful levels (more than a two-point decrease) after week eight. This study was limited by its lack of a comparator, potential for selection bias, and lack of blinding combined with subjective outcome measures.

Callstrom (2013) reported on 61 patients treated with cryoablation for pain from 69 tumors (size 1 to 11 cm) metastatic to the bone. Before treatment, patients rated their pain with a 4+ on a 1-to-10 scale using the Brief Pain Inventory, with a mean score of 7.1 for worst pain in a 24-hour period. The mean pain score gradually decreased after cryoablation to 1.4 ($p<0.001$) at 24 weeks for worst pain in a 24-hour period. A major complication of osteomyelitis was experienced by one (2%) patient.

Meller (2008) retrospectively analyzed a single-center experience with 440 bone tumor cryosurgery procedures performed between 1988 and 2002, two-thirds of them for primary benign-aggressive and low-grade malignant lesions, and one-third for primary high-grade and metastatic bone tumors.**[76]** At a median follow-up of seven years (range 3 to 18 years), the overall recurrence rate was 8%. Based on their data, the authors suggested that the ideal case for cryosurgery is a young adult with involvement of long bone, a benign-aggressive or low-grade malignant bone tumor, a good cavity with greater than 75%-thick surrounding walls, no or minimal soft-tissue component, and at least ±1 cm of subchondral bone left near a joint surface after curettage and burr drilling.

OTHER TUMORS

Cryoablation for the treatment of other solid tumors has not been well-studied.

Systematic Reviews

Keane (2014) reported on a systematic review of ablation therapies, including cryoablation, for locally advanced pancreatic cancer.[77] The review noted studies have demonstrated ablative therapies, including cryoablation, are feasible but larger studies are needed. No conclusions could be made on whether ablation resulted in better oncologic outcomes than best supportive care.

Tao (2012) reported on a systematic review of cryoablation for pancreatic cancer.[78] The authors identified 29 studies from the literature search and included five of these studies in the review. The five studies were all case series and considered to be of low quality. Adverse events, when mentioned in the studies, included delayed gastric emptying (0% to 40.9% in three studies), pancreatic leak (0% to 6.8% in four studies), biliary leak (0% to 6.8% in three studies), and one instance of upper gastrointestinal hemorrhage. Pain relief was reported in three studies and ranged from 66.7% to 100%. Median survival times reported in three studies ranged from 13.4 to 16 months. One-year total survival rates reported in two studies were 57.5% and 63.6%.

Nonrandomized Studies

The remaining published literature is limited to case series and retrospective reviews.[79-89] As discussed above, these studies do not permit reliable conclusions concerning the impact of cryoablation on health outcomes.

PRACTICE GUIDELINE SUMMARY

Clinical practice guidelines from U.S. professional associations consistently list cryoablation as a treatment option for uveal melanoma, certain NSCLC tumors, and for tumors of the kidney or prostate.[90-96]

No clinical practice guidelines or position statements based on research from U.S. professional societies were identified that specifically recommend cryoablation for the treatment of solid tumors other than those listed above, though some refer more generally to ablation procedures.[97 98]

SUMMARY

Cryosurgical ablation has become a recognized standard of care in the management of tumors of the skin, kidney and prostate, uveal melanoma, cervical intraepithelial neoplasia, and carefully selected patients with lung tumors. Therefore, this technique may be considered medically necessary in the treatment of these tumors when criteria are met.

There is not enough research to show that cryosurgical ablation can improve health outcomes for patients with solid tumors that do not meet policy criteria, including malignant or benign tumors of the breast (including fibroadenoma), pancreas, and bone; and for metastases outside of the liver or prostate. Therefore, cryosurgical ablation for these indications is considered investigational.

CODES

Codes	Number	Description
CPT	0581T	Ablation, malignant breast tumor(s), percutaneous, cryotherapy, including imaging guidance when performed, unilateral
	17260-17286	Destruction, malignant lesion (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery, surgical curettement)
	19105	Ablation, cryosurgical, of fibroadenoma, including ultrasound guidance, each fibroadenoma
	20983	Ablation therapy for reduction or eradication of 1 or more bone tumors (eg, metastasis) including adjacent soft tissue when involved by tumor extension, percutaneous, including imaging guidance when performed; cryoablation
	31641	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with destruction of tumor or relief of stenosis by any method other than excision (eg, laser therapy, cryotherapy)
	32994	Ablation therapy for reduction or eradication of 1 or more pulmonary tumor(s) including pleura or chest wall when involved by tumor extension, percutaneous, including imaging guidance when performed, unilateral; cryoablation
	50250	Ablation, open, 1 or more renal mass lesion(s), cryosurgical, including intraoperative ultrasound guidance and monitoring, if performed
	50542	Laparoscopy, surgical; ablation of renal mass lesion(s), including intraoperative ultrasound guidance and monitoring, when performed
	50593	Ablation, renal tumor(s), unilateral, percutaneous, cryotherapy
	55873	Cryosurgical ablation of the prostate (includes ultrasonic guidance and monitoring)
	57511	Cautery of cervix; cryocautery, initial or repeat
HCPCS	None

Sacral Nerve Neuromodulation (Stimulation) for Pelvic Floor Dysfunction

Effective: March 1, 2024

Next Review: December 2024
Last Review: January 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Sacral nerve neuromodulation involves the implantation of a permanent electrical stimulation device that modulates the neural pathways controlling bladder or rectal function.

MEDICAL POLICY CRITERIA

Note: Sacral nerve neuromodulation should be initiated with a *trial period* of sacral nerve neuromodulation (peripheral nerve stimulation test) with a *temporarily implanted* lead and may be followed by *permanent implantation*. This policy addresses these services as one combined episode beginning with the temporary placement.

I. Sacral nerve neuromodulation (including a *trial period* of sacral nerve neuromodulation [peripheral nerve stimulation test] with a *temporarily implanted* lead and, when used, the *permanent implantation*) may be considered **medically necessary** when one or more of the following criteria are met:

   A. For the treatment of urinary incontinence and non-obstructive retention in patients who meet **all** of the following criteria (1. – 3.):

1. There is a diagnosis of at least one of the following:
    a. Urge incontinence
    b. Urgency-frequency syndrome
    c. Non-obstructive urinary retention
    d. Overactive bladder
2. There is documented failure or intolerance to at least 2 conventional conservative therapies (e.g., behavioral training such as bladder training, prompted voiding, or pelvic muscle exercise training, pharmacologic treatment for at least a sufficient duration to fully assess its efficacy, and/or surgical corrective therapy); and
3. Incontinence is not related to a neurologic condition.

B. For the treatment of fecal incontinence in patients who meet **all** of the following criteria (1. - 5.):

1. There is a diagnosis of chronic fecal incontinence of greater than 2 incontinent episodes on average per week with duration greater than 6 months or for more than 12 months after vaginal childbirth;
2. There is documented failure or intolerance to conventional conservative therapy (e.g., dietary modification, the addition of bulking and pharmacologic treatment for at least a sufficient duration to fully assess its efficacy);
3. The condition is not related to an anorectal malformation (e.g., congenital anorectal malformation; defects of the external anal sphincter over 60 degrees; visible sequelae of pelvic radiation; active anal abscesses and fistulae) or chronic inflammatory bowel disease;
4. Incontinence is not related to another neurologic condition; and
5. The patient has not had rectal surgery in the previous 12 months, or in the case of rectal cancer, the patient has not had rectal surgery in the past 24 months.

II. Revision(s) or removal of an existing sacral nerve neuromodulation device may be considered **medically necessary** after the device has been placed.

III. Replacement of all or part of an existing sacral nerve neuromodulation device and/or generator is considered **medically necessary** when the existing device and/or generator is malfunctioning, cannot be repaired, and is no longer under warranty.

IV. Replacement of all or part of an existing sacral nerve neuromodulation device and/or generator is considered **not medically necessary** when Criterion III. is not met.

V. Sacral nerve neuromodulation for the treatment of urinary incontinence, non-obstructive retention, and fecal incontinence is considered **not medically necessary** when Criterion I. is not met, including but not limited to stress incontinence and urge incontinence due to a neurologic condition (e.g., detrusor hyperreflexia, multiple sclerosis, spinal cord injury, or diabetes with peripheral nerve involvement).

VI. Sacral nerve neuromodulation for the treatment of all other indications is considered **investigational**, including but not limited to chronic pelvic pain and constipation.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine whether the policy criteria are met. If these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Documented applicable Diagnosis/Diagnoses and any neurological diagnoses present
- Documented failure or intolerance to conventional conservative therapies attempted as detailed in criteria I.A.2. and I.B.2.
- Documentation of surgical history within the last 24 months as applicable to fecal incontinence

BACKGROUND

Sacral nerve neuromodulation (SNM), previously known as sacral nerve stimulation is defined as the implantation of a permanent device that modulates the neural pathways controlling bladder or rectal function. The SNM device consists of an implantable pulse generator (neurostimulator) that delivers controlled electrical impulses. The neurostimulator is attached to wire leads that connect to the sacral nerves, most commonly the S3 nerve root. A remote control is provided to the patient to adjust the stimulation level.

Treatment using SNM is one of several alternative modalities for patients with fecal or urinary incontinence who have failed behavioral (e.g., prompted voiding) and/or pharmacologic therapies.

Prior to implantation of the permanent device, patients undergo a peripheral nerve stimulation test to estimate potential response to SNM. This procedure is done under local anesthesia, using a test needle to identify the appropriate sacral nerve(s). Once identified, a temporary wire lead is inserted through the test needle and left in place for several days. This lead is connected to an external stimulator which is carried by patients in their pocket or on their belt. Patients then keep track of symptoms while the temporary device is functioning. The results of this test phase are used to determine whether patients are appropriate candidates for the permanent device. If patients show a 50% or greater reduction in incontinence frequency, they are deemed eligible for the permanent device. The permanent device is implanted with the patient under general anesthesia. An incision is made over the lower back and the electrical leads are placed in contact with the sacral nerve root(s). A second incision is made in the upper buttock where the neurostimulator is inserted and connected to the wire leads. The stimulator is turned on after the procedure is completed and the patient is provided a remote control to adjust the stimulation level. Manufacturers recommend the patients receive stimulation 24 hours per day, 7 days a week.

Newer generation stimulators have long life batteries (15-20 years) either requiring recharging weekly or are recharge free with an estimated recharge free life of 15 + years depending on level of stimulation.

REGULATORY STATUS

Axonics Sacral Neuromodulation System

In 2019, The Axonics Sacral Neuromodulation System received U.S. Food and Drug Administration (FDA) approval (PMA#: P190006) for the treatment of chronic fecal incontinence in patients who have failed or are not candidates for more conservative treatments. Product code: QON

In 2019, The Axonics Sacral Neuromodulation System received FDA approval (PMA#: P P180046) for the treatment of urinary retention and the symptoms of overactive bladder, including urge incontinence and significant symptoms of urgency-frequency alone or in combination, in patients who have failed or could not tolerate more conservative treatments. Product code: EZW

Axonic currently has two devices:

- The Axonics R15™ System which has a rechargeable with a battery designed to last 15 years or more.
- The Axonics F15™ System which has a long life battery that does not require recharging (15 -20 year battery life). FDA Approved 3/7/22 for above indications.

Axonics SNM Therapy is contraindicated for patients who have not demonstrated an appropriate response to test stimulation; or patients who are unable to operate the Axonics SNM Systems.

Medtronic Interstim® Sacral Nerve Stimulation™ system

In 1997, the Medtronic Interstim® Sacral Nerve Stimulation™ system received FDAapproval (PMA# P970004) for marketing for the indication of urinary urge incontinence in patients who have failed or could not tolerate more conservative treatments. In 1999 the device received FDA approval for the additional indications of urgency-frequency and urinary retention in patients without mechanical obstruction. Product Code: EZW

In 2006, the Medtronic Interstim® II System received FDA approval for treatment of intractable cases of overactive bladder and urinary retention. The new device is smaller and lighter than the original system and is reported to be suited for those with lower energy requirements or small stature. The device also includes updated software and programming options.

In 2011, the Medtronic InterStim System received FDA approval (PMA#: P080025) for the indication of chronic fecal incontinence in patients who have failed or could not tolerate more conservative treatments. Product Code: QON

In 2020, the Medtronic InterStim™ Micro system received FDA approval for above indications. This small device has a rechargeable battery designed to last 15 years. Recharging can be done 1x per week.

In 2022, the Medtronic InterStimX™ system received FDA approval for the above indications. This device does not require recharging and has a 15 year battery life when using low energy settings.

Virtis™ Sacral Neuromodulation System (Nuvectra)

In 2023, the Virtis™ Sacral Neuromodulation System (Nuvectra) was approved by the FDA for treatment of urinary retention and symptoms of overactive bladder, including urinary urge incontinence and significant symptoms of urgency-frequency in patients who have failed more conservative treatments.

Note: Sacral Neuromodulation devices are not currently approved by the FDA for treatment of chronic pelvic pain or constipation.

Note: Sacral nerve neuromodulation should be distinguished from pelvic floor stimulation. Pelvic floor stimulation refers to electrical stimulation of the pudendal nerve. This therapy is addressed in a separate medical policy (see Cross References).

EVIDENCE SUMMARY

Assessment of the safety and efficacy of sacral nerve modulation (SNM) as a treatment for urinary or fecal incontinence requires large, blinded, long-term randomized controlled trials to determine whether 1) the benefits of SNM outweigh any risks, and 2) whether SNM offers advantages over conventional conservative treatments. The appropriate control group(s) against which SNM should be compared is sham stimulation, on- versus off-phases in which patients act as their own controls, or conventional conservative therapies.

URINARY DYSFUNCTION

Urge Incontinence

Systematic Reviews

Initially, the policy for SNM as a treatment of urge incontinence was based on a 1998 BlueCross BlueShield Association Technology Evaluation Center (TEC) assessment.[1] Based on a multicenter RCT[2] conducted as part of the FDA approval process, the TEC Assessment concluded that SNM reduced urge incontinence compared with control patients.

Brazzelli performed a review of articles published between 1966 and 2003 which included four randomized controlled trials (RCT) and 30 case series.[3] The authors reported that about 80% of patients in the randomized trials achieved greater than 50% improvement in their main incontinence symptoms after SNM compared with about 3% of controls receiving conservative treatments. The case series, which were larger but methodically less reliable, showed similar results. Benefits were reported to persist three to five years after implantation. The authors noted that technical changes over time were associated with decreased complication rates.

Randomized Controlled Trials

No new RCTs for urge incontinence were identified since the above systematic reviews were published.

Nonrandomized Studies

Groen (2011) reported five year follow-up results for patients (n=60) after SNM treatment for refractory idiopathic urge urinary incontinence.[4] Success was defined as at least a 50% decrease in the number of incontinent episodes or pads used per day. The success rate was 52 of 60 (87%) at one month and gradually decreased to 37 (62%) at five years. The number of women who were completely continent was 15 (25%) at one month and 9 (15%) at five years. At the five-year follow-up, SNM was still used by 48/60 (80%) women. A total of 57 adverse events were reported in 32 of 60 (53%) patients. The most frequent adverse events were hardware-related or pain or discomfort. There were a total of 23 reoperations in 15 patients. In most cases, pain problems were managed conservatively.

Urinary Urgency/Incontinence/Frequency/Overactive Bladder

Systematic Reviews

No recent systematic reviews were identified.

Randomized Controlled Trials

In the multicenter randomized clinical study of 581 patients with a variety of urinary dysfunctions submitted to the FDA as part of the device approval process, 220 had significant urgency-frequency symptoms.[5] After six months of SNM therapy, 83% of patients with urgency-frequency symptoms reported increased voiding volumes with the same or reduced degree of frequency. At 12 months, 81% of patients had reached normal voiding frequency. Compared to a control group, patients with implants reported significant improvements in quality of life, as evaluated by the SF-36 health survey. The trial was well-designed, using standardized clinical and functional status outcomes measurements, and enrolled patients with severe urge incontinence who had failed extensive prior treatments. The magnitude of effect (approximately one-half of patients became dry, three-quarters experienced at least 50% reduction in incontinence) was fairly large, probably at least as great as with surgical procedures, and larger than expected from a placebo effect or conservative measures such as behavioral therapy or drugs. The therapy evaluation test, in which the device was turned off (ie, sham treatment was provided) and patients thus served as their controls, provided further evidence that the effect on incontinence was due to electrical stimulation and demonstrated that the effect of sacral nerve neuromodulation is reversible. The cohort analysis of the clinical trial provided some evidence that the effect of sacral nerve neuromodulation could be maintained for up to two years. There was a high rate of adverse events reported in this trial. Most were minor and reversible; however, approximately one-third of patients required surgical revision for pain at the operative sites or migration of the leads.

In 2016, Amundsen reported on a RCT comparing intradetrusor injection of onabotulinumtoxinA (n=192) with SNM (n=189) in women with refractory urgency urinary incontinence, defined as at least one supervised behavioral or physical therapy intervention and the use of a minimum of two anticholinergics (or inability to tolerate or contraindications to the medication).[6] In intention-to-treat analysis, onabotulinumtoxinA-treated patients had greater reductions in urge incontinence per day than SNM-treated patients: 3.9 vs 3.3 per day (mean difference: 0.63; 95% confidence interval [CI] 0.13 to 1.14, p=0.01). OnabotulinumtoxinA-treated patients had greater reductions in some overactive bladder-related quality of life questionnaire-related measures, although the clinical meaningfulness of the changes was uncertain. Patients in the onabotulinumtoxinA-treated group were more likely to have urinary tract infections (UTIs, 35% vs 11%; risk difference -23%, 95% CI -33% to -13%, p<0.001).

In 2014 Siegel published an industry-sponsored FDA-mandated postapproval randomized study and is known as the Insite trial.[7] This study compared SNM using a two-stage surgical procedure with standard medical therapy. Study inclusion criteria included a diagnosis of overactive bladder (OAB) (at least eight voids per day and/or at least two involuntary leaking episodes in 72 hours) and a failed trial of at least one anticholinergic or antimuscarinic medication. In addition, there needed to be at least one such medication that had not yet been attempted. Patients with neurologic diseases and with primary stress incontinence were excluded. A total of 70 patients were allocated to SNM and 77 to standard medical therapy. Of the 70 patients in the SNM group, 11 elected not to receive test stimulation with the tined lead and eight received the lead but did not receive a full system implant due to lack of response to a 14-day test stimulation period (response was defined as at least a 50% reduction in average leaks and/or voids). Patients in the medical treatment group tried the next recommended medication or restarted a discontinued medication. Therapeutic success was defined as at least a 50% improvement in average leaks/day or at least a 50% improvement in the number of voids per day or a return to fewer than eight voids per day. In an intention-to-treat analysis, the therapeutic success rate at six months was 61% in the SNM group and 42% in the standard medical treatment group; the difference between groups was statistically significant ($p=0.02$). Quality of Life (QOL) at six months was a secondary outcome. Several validated QOL scales were used, and all favored the SNM group compared with the standard medical treatment group ($p<0.002$ for all comparisons).

In 2014, Noblett published twelve-month follow-up results of the Insite trial. The analysis included patients included in the SNM group of initial RCT plus additional patients enrolled and implanted in the interim.[8] A total of 340 patients underwent test stimulation, 272 underwent implantation, and 255 completed 12 months of follow-up. In a modified completers' analysis, the therapeutic success rate was 82%. This modified completers' analysis included patients who were implanted and had either a baseline or 12-month evaluation, or withdrew from the trial due to a device-related adverse event or lack of efficacy. In an analysis limited to study completers, the therapeutic response rate was 85%. The Noblett analysis did not include data from the control group of patients receiving only standard medical therapy.

In 2014 Tang published the results of an RCT in which 240 women with OAB were randomized to receive tolterodine with (n=120) or without (n=120) sacral neuromodulation.[9] Participants were also divided into subgroups based on the presence or absence of urinary incontinence. The treatment period was three months; results were measured by voiding diaries and urodynamic parameters, in addition to psychological depression and anxiety scores. The group receiving SNM reported significantly greater improvements in the conditions of first desire to void, maximum cystometric capacity, daily average volumes, and daily single maximum voided volumes compared to the group receiving medication alone ($p=.001$). The SNM group also reported greater decreases in self-rated depression and anxiety scales ($p<0.001$). The authors concluded that combined treatment with SNM and tolterodine could improve the quality of life in women with OAB by decreasing voiding dysfunction symptoms and related depression and anxiety.

Nonrandomized Studies

Chartier-Kastler (2022) published 3-year results from a prospective, observational, multicenter study from France (SOUNDS).[10] Patients with overactive bladder (N=229) underwent InterStim implantation (either a first device or a replacement) and were followed for a mean of 33.7 ± 3.7 months. During the 3-year follow-up, average daily voids and leaks were

significantly reduced (all $p < 0.05$) and response (defined as ≥ 50% reduction in voids per day or return to normal voiding frequency) ranged from 72% to 86%. Quality of life scores were improved at all study visits. About half of the patients experienced adverse events, which were mostly minor, but surgical revision was required in 33% of patients. Lack of a control arm may limit the clinical applicability of these results.

Several groups have published results of the Axonics® Sacral Neuromodulation System for Urinary Urgency Incontinence Treatment (ARTISAN-SNM) study-a single arm, prospective, multicenter trial of the Axonics r-SNM System™.[11-13] All participants (n=129) were implanted with a tined lead and the rechargeable sacral neuromodulation system in a nonstaged procedure. Efficacy data were collected using a 3-day bladder diary, the validated International Consultation on Incontinence Questionnaire Overactive Bladder quality of life (ICIQ-OABqol) questionnaire and a participant satisfaction questionnaire. Pezzell (2021) published a two year follow-up analysis and reported that 93% of the participants (n = 121 Completers at two years) were therapy responders, of which 82% achieved ≥ 75% reduction in UUI episodes and 37% were dry (100% reduction).[13] Daily UUI episodes reduced from 5.6 ± 0.3 at baseline to 1.0 ± 0.2 at two years. Statistically significant improvements in ICIQ-OABqol were reported. Geynisman-Tan (2021) published a secondary analysis in Participants (n=124) at one year.[11] Participants were classified as responders (n=110) and non-responders (14) based on a ≥50% reduction in UUI episodes in a three-day period at one-month post-implant. Most participants reported being satisfied with the SNM treatment (68.5% were "very satisfied," 25.8% were "moderately satisfied," and 2.4% were "slightly satisfied). Twelve of the 14 "non-responders" continued to see improvements in symptom reduction from one month to one year; 9/14 (64%) were "responders" at one year with six reporting being "very satisfied" and one reporting being "moderately satisfied." McCrery (2020) reported at six-months that 90% of participants were therapy responders (≥50% reduction in UUI episodes compared to baseline).[12] With a mean (+ SE) reduction of 5.6 ± 0.3 at baseline to 1.3 ± 0.2. Participants experienced a clinically meaningful 34-point improvement on the ICIQ-OABqol questionnaire. There were no serious device related adverse events reported. The authors conclude that The Axonics r-SNM System™ demonstrates sustained safe and effective treatment for patients experiencing urinary urgency incontinence symptoms. They also report no unanticipated or serious device-related adverse events at two years.

Blok (2020) published the two year safety and efficacy outcomes using SNM for the treatment of Overactive Bladder (OAB) using the Axonics system.[14] Subjects (n=51) with confirmed OAB were implanted with the Axonics system using a nonstaged procedure. At two years 90% of test responders (defined as subjects who were responders at one month) to respond based on voiding diary criteria. Satisfaction with therapy was reported by 93% of subjects and 86% found their charging experience acceptable. Of the urinary incontinence Test Responders, 88% continued to be responders at two years, and 28% were completely dry. There were no unanticipated (AEs) or serious device-related AEs. The authors conclude that the Axonics System® provides sustained clinically meaningful improvements in OAB subjects at two years.

There has also been interest in the use of SNM as a treatment of interstitial cystitis, a condition characterized by painful urinary urgency and frequency.[15-17] These studies reported a decrease in both urgency/frequency and pain. These patients would be considered candidates for SNM therapy based on the presence of urgency and frequency alone.

Urinary Retention

Systematic Review

A 2009 Cochrane review[18] described eight randomized studies on implanted devices for urinary storage and voiding dysfunction in adults. In spite of methodologic problems (e.g., generally poor-quality studies), the evidence “seems clear that continuous stimulation offers benefits for carefully selected people with overactive bladder syndrome and for those with urinary retention but no structural obstruction.” The authors concluded that while some people benefit, more research is needed to improve patient selection, to carry out the implant, and to find why so many fail.

In 2014, the Agency for Healthcare Research and Quality published a comparative effectiveness review focused on chronic urinary retention treatments.[19] The authors identified the previously described Cochran review as providing “low-strength evidence that neuromodulation improves the rate at which patients with Fowler’s syndrome can be catheter free after treatment,” but noted that there were few studies overall, and most were small and had other methodologic limitations.

Randomized Controlled Trial

No new RCTs for urinary retention were identified since the above systematic review was published.

Complications of SNM for Urinary Dysfunctions

A large prospective series by White focused on complications associated with SNM in 202 patients with urge incontinence, urinary urgency, or urinary retention.[20] At a mean follow-up of 37 months (range, 7 to 84), 67 patients (30%) had experienced adverse events that required either lead or implantable pulse generator revisions. Complications included pain (3%), device malfunction secondary to trauma (9%), infection (4%), postoperative hematoma (2%), and lead migration (6%).In addition, 5% of patients underwent elective removal, 4% had device removal due to lack of efficacy, and 2% required removal due to battery expiration. At the last follow-up, 172 patients (85%) had functional implanted units.

Section Summary

Data from RCTs and case series with long-term follow-up provides sufficient evidence to conclude that SNM is effective and safe in selected patients with urge incontinence, overactive bladder, urgency-frequency syndrome, and non-obstructive urinary retention.

DEFECATION DYSFUNCTION

Fecal Incontinence

Systematic Reviews

In 2019, Simillis published a systematic review and meta-analysis of treatments for fecal incontinence (FI).[21] A total of 47 RCTs were included and 37 treatments were addressed. Overall, no treatment was ranked best or worst for any outcome. With respect to SNM, significant improvements compared to placebo were reported for incontinence scores.

A 2018 SR by Dulskas evaluated the literature on treatments for lower anterior resection syndrome.[22] The authors identified a total of 21 studies that met inclusion criteria, of which eight evaluated the use of SNM. Only one of the identified studies was determined not to be of

poor quality. Therefore, the authors concluded that high quality RCTs are needed to determine the efficacy of SNM.

A 2015 Cochrane review evaluated SNM for FI and constipation in adults.[23] This review included six trials assessing the effects of SNM for FI. Two parallel group trials found that SNM reduced the number of incontinence episodes when compared with optimal medical therapy or percutaneous tibial nerve stimulation. Three of the four included crossover trials found reductions in incontinence episodes during the SNM "on" period relative to the "off" period; in the other crossover trial, participants did not experience any episodes of FI during either period. The primary methodological quality issue noted was related to lack of clarity around randomization techniques and allocation concealment. The review authors concluded that there was limited evidence that SNM could improve continence in some patients with FI.

In 2016, the Agency for Healthcare Research and Quality published a comparative effectiveness review on treatments for FI.[24] There were 63 studies that met inclusion criteria for the review, and 53 surgical case series were reviewed for adverse events. There were 38 RCTs that assessed nonsurgical treatments and 12 that reviewed surgical interventions, including five studies of SNM. Regarding SNM, the authors concluded that the evidence was "insufficient because all five studies had moderate or high risk of bias, and none assessed the same treatment-outcome combination."

In 2013, Thin published a SR of randomized trials and observational studies on SNM for treating FI.[25] A total of 61 studies met eligibility criteria; including at least 10 patients, having a clear follow-up interval and reporting the success rate of therapy based on a 50% or greater improvement in fecal incontinence episodes. Only two of the studies were RCTs.[26, 27] and 50 were prospective case series. Data from two studies with long-term follow-up could be pooled to calculate median success rates using an intention-to-treat analysis. These median success rates were 63% in the short term (no more than 12 months' follow-up), 58% in the medium term (12 to 36 months), and 54% in the long term (>36 months). The per-protocol short-, medium-, and long-term success rates were 79%, 80%, and 84%, respectively.

In 2011, Maeda published a SR of studies on complications following permanent implantation of a SNM device for FI and constipation.[28] The authors identified 94 articles. The vast majority of studies addressed FI. A combined analysis of data from 31 studies on SNM for fecal incontinence reported a 12% suboptimal response to therapy (149 of 1,232 patients). A review of complications reported in the studies found that the most commonly reported complication was pain around the site of implantation, with a pooled rate of 13% (81/621 patients). The most common response to this complication was repositioning the stimulator, followed by explantation of the device and reprogramming. The second most common adverse event was infection, with a pooled rate of 4% (40/1025 patients). Twenty-five of the 40 infections (63%) led to explantation of the device.

In 2011, Tan published a meta-analysis of randomized trials and observational studies published between 2000 and 2008 on SNM for treating FI.[29] They identified a total of 34 studies that reported on at least one of their outcomes of interest and clearly documented how many patients underwent temporary and permanent SNM. Only one of these studies was an RCT; this was the study by Tjandra discussed earlier.[26] In the 34 studies, a total of 944 patients underwent temporary SNM and 665 subsequently underwent permanent SNM implantation. There were 279 patients who did not receive permanent implantation, and 154 of these were lost to follow-up. Follow-up in the studies ranged from 2 weeks to 35 weeks. In a

pooled analysis of findings of 28 studies, there was a statistically significant decrease in incontinence episodes per week with SNM compared to maximal conservative therapy (weighted mean difference: -6.83; 95% CI -8.05 to -5.60, p<0.001). Fourteen studies reported incontinence scores, and when these results were pooled, there was also a significantly greater improvement in scores with SNM compared to conservative therapy (weighted mean difference: -10.57, 95% CI -11.89 to -9.24, p<0.001).

A 2016 systematic review by Bielefeldt focused on the adverse events associated with SNM treatment of FI.[30] A literature search of PubMed and Embase was performed for studies that included at least five patients with fecal incontinence treated with SNM. The researchers additionally searched the FDA's Manufacturer and User Device Experience (MAUDE) database for reports from 2005 to October 2015. There were 45 articles included in the review that described distinct patient cohorts and provided information about adverse events. These included a total of 1,953 patients and a median follow-up time of 27 months. There were two studies with a total of 201 that provided the most detailed information.[31, 32] In these two studies, approximately 20% of the patients had their devices explanted by the end of follow-up and a substantial number required additional surgeries. There were five more studies that reported adverse events with less detail, and these reported a significantly lower incidence of such events. Information on infectious complications was reported in 44 studies with 1,953 patients, and the pooled rate of these was 5.1%. There were 39 studies with 1,810 patients that reported explant rates, with an average rate of 10.0%. Increases in explant rates were seen with increased follow-up duration. An overall re-operation rate of 18.6% was seen, based on data from 1,784 patients. According to the MAUDE database, there was an average of ten incidents per month related to the Interstim device in 2005. This rose to approximately 100 incidents per month within the next three years and stabilized until the year prior to FDA approval of the device as a treatment for fecal incontinence, and have since tripled. From August 1 - October 31, there were 1,684 problem reports received by the FDA, with 652 reports mentioning gastrointestinal issues as indications for SNM treatment and 278 reports specifically referring to fecal incontinence or bowel dysfunction. Most adverse events were reported within two years after device implantation.

In 2015, a systematic review was published that evaluated the impact of SNM on clinical symptoms and gastrointestinal physiology in patients with FI.[33] There were 81 studies included in the review, and the clinical outcomes assessed included frequency of fecal incontinence episodes, fecal incontinence severity score, and treatment success rates. A meta-analysis of the data from these studies was not possible, as most lacked a comparison group. Following SNM device implantation, 'perfect' continence was reported in 13% to 88% of patients. The majority of studies found a reduction in incontinence episodes per week (mean, -7.0; range, -24.8 to -2.7) and Wexner scores. The studies did not demonstrate any consistent, statistically significant effects of SNM on physiological parameters or identify any clinicophysiological factors that predicted success.

Randomized Controlled Trials

No new RCTs for FI were identified since the above systematic review was published.

Nonrandomized studies

Picciariello (2022) published a retrospective study to assess the long-term effectiveness of SNM treatment in patients with FI.[34] Of the patients (n=58) who met the inclusion criteria, 36 (58%) participated in the study the remainder (n=22; 38%) were lost to follow-up. The authors

report that 17 (27%) of patients included still experience efficacy with SNM, after a median follow-up of 13 years. The authors suggest that very long-term outcome further deteriorates with time compared with the 60–70% success rate reported at five years.

Jottard (2021) published the 6-month follow-up data for efficacy, clinical outcomes and ease of use of the Axonics rechargeable SNM (ArSNM) system in patients (n=15) with FI.[35] Patients were implanted with the SNM device using a single-stage procedure. At four weeks, 13 participants (87%) were test responders based on ≥50% reduction in FI episodes as documented on their bowel diary. Weekly FI episodes decreased from a median of 8 (5.8-20.3) at baseline to a median of 1.5 (0.4-4.5) at four weeks (p = 0.001), and 1.5 (0-2.6) at six months (p = 0.001), corresponding to 75% and 79% reduction in weekly FI episodes. Of the 13 subjects having ≥50% reduction in FI episodes at four weeks, 12 (PP = 92%) were therapy responders at six months. There were no unanticipated device or procedure-related adverse events. The authors conclude that the The ArSNM system provides safe and effective therapy in patients with FI at six months.

Desprez (2020) published results of a study that retrospectively analyzed prospectively collected data and found that long-term efficacy with SNM was maintained for at least 10 years post-implantation in approximately half of the patients treated for FI.[36] A similarly designed study by De Meyere (2020) in a single-center in Belgium demonstrated that the efficacy of sacral nerve stimulation in patients with fecal incontinence or low anterior resection syndrome was maintained for at least five years.[37]

Leo (2020) reported medium- and long-term outcomes following sacral nerve stimulation for FI.[38] This prospective observational study included 256 patients with medium-term results and, of those, 185 were followed up for long term outcomes. At the six-month follow-up, 65.2% (167/256) of patients showed a reduction of more than 50% in their St Marks fecal incontinence score and at the medium-term and long-term follow-ups it was 60.4% (142/235) and 62.1% (115/185), respectively. There was a reduction in median St Mark's score from baseline at six months ($p<0.00001$), which was maintained at the medium-term (110 months) and long-term (132 months) follow-ups. Twelve patients had lack of efficacy at the first postoperative follow-up, which was resolved with surgical correction in three patients and resulted in removal in the remainder. Of the 256 initial patients, 61 reported complications. This resulted in device removal for complications in 11 patients (4.2%), revisional surgery in 14 (5.4%), successful conservative treatment in 36 (14%), and a change of their SNS stimulation parameters in 51 (19.9%). Fourteen patients experienced wound infection/implant rejection.

In 2017, Koh reported on outcomes following SNM at a single Scottish center.[39] Of a total of 83 patients undergoing temporary SNM testing, 52 patients were permanently implanted. There were four failures, one removal due to cancer, seven infections, one lead migration, and three reports of post-operative pain or numbness.

Irwin (2017) assessed morbidity following SNM implantation for FI. Seventy-five patients were evaluated, 61 received insertion of a temporary SNM, and 40 received a permanent SNM.[40] Significant reduction in the Cleveland Clinic Incontinence Scores (14 pre-SNM to 9 post-SNM) and improvements in Role Physical, General Health, Vitality, Social Functioning, Role Emotional, Mental Health, and Mental Health Summary measures were reported.

Rice (2016) compared the commonly used staging procedure for evaluating candidacy for implantation of SNM to an office-based evaluation.[41] In this retrospective study, a total of 86 patients were evaluated, with 45 in the office-based evaluation group and 41 in the staged

group. The primary outcome was >50% improvement in Wexner score, resulting in patients progressing to permanent implantation. There was no significant difference in the primary outcome between groups or in the mean three-month Wexner score. Infection was significantly more likely in the staged group.

Patton (2016) evaluated medium-term outcomes from SNM patients at a single institution.[42] Of the 166 patients that underwent preliminary nerve stimulation testing, 112 had a permanent device implanted, and an additional 15 patients received a device without an initial testing phase for a total of 127 patients with SNM devices. The mean follow-up was 2.7 years (range, two months to 8.5 years), and 14 patients had the device removed and four had died, leaving 109 patients. Of these, 91 (83%) responded to the follow-up survey. There were significant improvements from baseline in St Mark's continence score (from 10.3 to 14.4, $p<0.01$), bowel control score, and fecal incontinence quality of life measures. Complications from the device included 12 infections, five of which required surgery, 17 lead dislodgements, and five rotated SNM devices that required repositioning.

Duelund (2016) published the results of a two-center prospective registry study that included 164 FI patients treated with SNM between 2009 and 2013.[43] The median follow-up in the study was 22 months (range, 1 to 50 months). There were improvements in Wexner incontinence scores and VAS impact on daily life. During follow-up, additional surgeries were required in 19.5% of patients. The most common complication was repositioning of the device due to pain or migration in 12.1% of patients, and infections leading to explantation were reported for 3% of patients. The same group also evaluated the effects of bilateral versus unilateral SNM for fecal incontinence treatment, and found no significant differences between groups.[44]

Altomare (2014) reported long-term outcomes (minimum of 60-month follow-up, median of 84-month follow-up) in patients implanted with a sacral nerve stimulator for FI.[45] Patients were identified in a European registry and surveyed. Long-term success was defined as maintaining the temporary stimulation success criteria, i.e., at least 50% improvement in the number of fecal incontinence episodes (or fecal incontinence symptom score) at last follow-up, compared with baseline. A total of 272 patients underwent permanent implantation of an SNM device and 228 were available for follow-up. A total of 194 of the 272 (71.3%) implanted patients maintained improvement in the long term.

Hull (2013) reported outcomes in 72 patients (60% of the 120 implanted patients) who had completed a five-year follow-up visit.[31] Sixty-four (89%) of the patients who contributed bowel diary data at five years had at least a 50% improvement from baseline in weekly incontinent episodes and 26 of the 72 patients (36%) had achieved total continence. It is uncertain whether outcomes differed in the 40% of patients who were missing from the five-year analysis.

Other case series have reported the experiences of patients with FI who were treated with sacral neuromodulation. These series are not summarized in depth here because methodological limitations do not permit conclusions on the safety and effectiveness of SNM for fecal incontinence. These limitations included patients with a variety of etiologies of fecal incontinence, including obstetric injury, spinal cord injury, prior surgery, sacral malformation, or idiopathic incontinence, lack of a comparator, and a wide range of follow-up periods (e.g., two months to 9.5 years). Thus, it is difficult to determine the complication rates or the durability of any benefits initially reported.

Section Summary

With longer term results from two randomized controlled trials, prospective case series, and a pooled analysis of data from the RCTs and observational studies, evidence is considered sufficient to conclude that sacral nerve neuromodulation/stimulation improves outcomes when used for the treatment for chronic fecal incontinence in well-selected patients who have failed conservative therapy.

Constipation

Systematic Review

Pauwels (2021) published a SR evaluating the different modalities of neurostimulation and their effect on chronic functional constipation in adults.[46] Seventeen studies were included on SNM. Although multiple uncontrolled retrospective and prospective studies demonstrated positive effects of SNM in constipation, the 3 RCTs included in the analysis demonstrated no significant improvements in outcomes.

Pilkington (2017) published a SR on behalf of the NIHR CapaCiTY working group, Pelvic floor Society that assessed outcomes of sacral nerve stimulation in adults with chronic constipation.[47] Seventy articles were included, with a total of 375 patients. Morbidity rates were heterogeneous and varied from 13 to 34%. Device removal rates were also heterogenous and ranged from 8 to 23%. Harms were inconsistently reported. Treatment success was reported between 57 and 87%. Reviewers concluded that the quality of studies was poor and therefore although the results were positive in favor of sacral nerve stimulation for chronic constipation, they urged caution.

The 2015 Cochrane review of SNM for fecal incontinence and constipation, described earlier, included two studies assessing SNM as a constipation treatment.[23] One trial, which included only two participants, found that the participants experienced a greater number of bowel movements per week when the device was on. The other trial, a larger randomized trial by Dinning, found that SNM did not affect the frequency of bowel movements.[48] The study included patients aged 18 to 75 years with slow transit constipation. Potentially eligible patients completed a three-week stool diary and, in order to continue participating, they needed to indicate in the diary that they had complete bowel movements less than three days per week for at least two of the three weeks. Patients with metabolic, neurogenic or endocrine disorders known to cause constipation were excluded. There were 57 patients that met eligibility criteria and had temporary percutaneous nerve evaluation (PNE), and 55 underwent permanent implantation. In random order, patients received active stimulation or sham stimulation. The primary outcome measure, determined by stool diaries, was a bowel movement with feelings of complete evacuation more than two days per week for at least two of three weeks; it was only assessed in phase 2. Compared with sham stimulation, 16 of 54 patients (29.6%) met the primary outcome during stimulation and 11 of 53 patients (20.8%) met it during sham stimulation; the difference was not statistically significant (p=0.23). Other outcomes did not differ significantly by group. The review authors concluded that SMN did not improve constipation symptoms and there were some adverse events associated with its use.

In 2013, Thomas published a systematic review of controlled and uncontrolled studies evaluating sacral nerve stimulation for treatment of chronic constipation.[49] The authors identified 11 case series and two blinded cross-over studies. Sample sizes in the case series ranged from 4 to 68 patients implanted with a permanent SNM device; in 7 of the 11 studies,

fewer than 25 patients underwent SNM implantation. Among the two cross-over studies, one included two patients implanted with an SNM device. The other, a 2012 study by Knowles and colleagues, temporary stimulation was evaluated in 14 patients.[50] Patients were included if they were diagnosed with evacuatory dysfunction and rectal hyposensitivity and had failed maximal conservative treatment. Patients were randomized to two weeks of stimulation with the SNM device turned on and two weeks with the SNM device turned off, in random order. There was no wash-out period between treatments. The primary efficacy outcome was change in rectal sensitivity and was assessed using three measures of rectal sensory thresholds. The study found a statistically significantly greater increase in rectal sensitivity with the device turned on in two of the three measures. Among the secondary outcome measures, there was a significantly greater benefit of active treatment on the percentage of successful bowel movements per week and the percentage of episodes with a sense of complete evacuation. In addition to its small sample size, the study was limited by the lack of a wash-out period between treatments i.e., there could have been a carry-over effect when the device was used first in the “on” position. Moreover, the authors noted that the patients were highly selected; only 14 of the approximately 1800 patients approached met the eligibility criteria and agreed to participate in the study.

Randomized Controlled Trials

One RCT has been published since the 2015 Cochrane review. This double-blind crossover trial, by Zerbib, included 36 patients (34 women) with refractory constipation, defined as at least two of the following criteria: fewer than three bowel movements per week, sensation of incomplete evacuation on more than a quarter of attempts, or straining to evacuate on more than a quarter of attempts.[51] This study defined a positive response to therapy as a more than 50% improvement in symptoms and/or at least three bowel movements per week. Of the 36 patients, 20 responded to the initial peripheral nerve evaluation and had a permanent stimulator implanted. Positive responses were seen in 12 of the patients during the active stimulation period and 11 of the patients during the sham stimulation period. Adverse events noted by the researchers included device-related pain in five patients and wound infection or hematoma in three patients, leading to device removal in two patients. SNM did not have a significant effect on colonic transit time. The authors concluded that the results of the study did not support the placement of SNM devices in patients with refractory constipation. The improvements seen with sham stimulation highlight the importance of control groups for comparison in studies of this technology.

Additionally, longer-term follow-up results to the study by Dinning[48] were published in 2016.[52] There were 53 patients that entered long-term follow-up, with one patient death. Adverse events or patient dissatisfaction lead to 44 patients withdrawing from the study by the end of the second year. Because of this, only ten patients met the primary outcome measure after one year, and only three patients met this measure after two years. There was no difference in colonic isotope retention at 72 hours at one-year follow-up.

Nonrandomized Studies

A 2019 report by Widmann analyzed a prospective database of fecal incontinence and constipation patients treated with SNM therapy. A total of 101 patients underwent test stimulation, 79 received permanent implantation, and 57 were still receiving SNM at the end of follow-up. The five-year success rate was 88.2% (95% CI 80.1 to 97.0%) for fecal incontinence and 31.2% (95% CI 10.2 to 95.5%) in patients with isolated constipation. Complications

necessitation reinterventions were reported in 24 patients. Battery replacement was reported in 23 patients, and the median battery life was 6.2 years.

In 2017, Maeda published a prospective multicenter study.[53] Of the 62 patients who underwent test stimulation, 45 proceeded to permanent implantation and 18 were followed up through 60 months. Fourteen patients reported improved Cleveland Clinic constipation score, which was sustained at 60 months. Ten patients submitted a bowel diary. Analysis of these showed significantly increased defecations per week and reduced sensation of incomplete emptying. Device-related adverse events were reported in 61% of patients.

In 2010, Maeda published a retrospective review of 38 patients with constipation who received permanent SNM after a successful trial period.[54] The study focused on reportable events, defined as suboptimal outcomes (lack of or loss of efficacy) or adverse events. The authors did not report detailed criteria for temporary or permanent placement of an SNM device. At the time of chart review, a mean of 25.7 months had elapsed since implantation. A total of 58 reportable events were identified in 22 of the 38 (58%) patients. A median of two (range 1-9) events per patient were reported; 26 of 58 events (45%) were reported in the first six months after device implantation. The most common reportable events were lack or loss of efficacy (26 of 58 events, 45%), and pain (16 events, 28%). Twenty-eight (48%) of the events were resolved by reprogramming. Surgical interventions were required for 19 (33%) of the events, most commonly permanent electrode replacement (14 events). Three of 38 (8%) patients discontinued use of the device due to reportable events.

A prospective registry study published in 2016 evaluated the effects of SNM on antigrade continence enema use in pediatric patients with severe constipation.[55] There were 22 patients below age 21 included; 55% were male and the median age was 12 years. The median frequency of antigrade continence enema use dropped from seven per week to one per week at 12 months. The Fecal Incontinence Severity index improved after six months, while other outcomes, including laxative use, Gastrointestinal Symptom Scale, and Fecal Incontinence Quality of Life Scale did not change. Ten children received cecostomy/appendicostomy closure within two years.

Several small case series were identified that focused on patients with slow transit constipation.[56-59] While promising results were reported, these case series are inadequate to permit scientific conclusions due to methodological limitations such as lack of lack of randomization and blinding, and lack of an adequate comparison group.

Section Summary

Only three controlled cross-over studies are available; one study was very small and had only two patients, the second study had methodological limitations, and the third and largest study showed no statistical difference between sham and stimulation. In addition, there are several, mainly small, case series. There is insufficient evidence to permit scientific conclusions about the efficacy and safety of sacral nerve neuromodulation/stimulation for patients with constipation.

Chronic Pelvic Pain

Systematic Review

Tirlapur assessed the effectiveness of tibial and sacral nerve stimulation in the treatment of bladder pain syndrome (BPS) and chronic pelvic pain (CPP).[60] Authors included randomized

and prospective quasi-randomized controlled studies vs. sham nerve stimulation treatment or usual care of patients with CPP and BPS who underwent sacral or tibial nerve stimulation were included. Three studies with 169 patients treated with tibial nerve stimulation were included: two for CPP and one for BPS. There were improvements in pain, urinary and quality of life scores. There were no reported data for sacral nerve stimulation. Authors concluded that due to the quality of the literature, a large multi-centered clinical trial investigating the effectiveness of electrical nerve stimulation to treat BPS and CPP is recommended.

Nonrandomized studies

Several case series have evaluated SNM for treating chronic pelvic pain. For example, in 2012 Martelluci reported on 27 patients with chronic pelvic pain (at least six months) who underwent testing for SNM implantation[61]. After a four-week temporary stimulation phase, 16 of 27 patients (59%) underwent implantation of an Interstim device. In the 16 implanted patients, mean pain on a visual analogue scale (VAS) was 8.1 prior to implantation and 2.1 at the six- and 12-month follow-ups. An earlier study by Siegel reported on 10 patients and stated that 9 of the 10 experienced a decrease in pain with SNM.[62]

Section Summary

Data from several small case series with heterogenous patients represents insufficient evidence that sacral nerve neuromodulation/stimulation is safe and effective for treating chronic pelvic pain. RCTs are needed, with sham control groups, to assess the efficacy of neuromodulation/stimulation as a treatment of chronic pelvic pain.

PRACTICE GUIDELINE SUMMARY

AMERICAN UROLOGICAL ASSOCIATION AND THE SOCIETY OF URODYNAMICS, FEMALE PELVIC MEDICINE & UROGENITAL RECONSTRUCTION

The joint American Urological Association (AUA) and The Society of Urodynamics (SUFU) guidelines for non-neurogenic OAB in adults (updated in 2019) considers SNM an option for third-line treatment in carefully selected patients who failed conservative therapies and are characterized by severe OAB symptoms or those not considered candidates for pharmacologic therapy.[63] The strength of evidence was given a Grade C defined as low quality/low certainty based on observational studies that are inconsistent, small, or have other limitations that potentially confound interpretation of the data.

AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS

A 2015 practice bulletin on urinary incontinence (replaced practice bulletin number 63, 2005; reaffirmed in 2018) from the American College of Obstetricians and Gynecologists (ACOG) stated, “sacral neuromodulation may be considered for patients with recalcitrant urinary urge incontinence who have failed other conservative measures, including bladder training, pelvic floor physical therapy with biofeedback, and pharmacologic treatment.”[64]

A 2019 ACOG practice bulletin (No. 210) on fecal incontinence included the following Level B (based on limited or inconsistent scientific evidence) recommendation: “sacral nerve stimulation can be considered as a surgical treatment option for women with fecal incontinence with or without anal sphincter disruption who have failed conservative treatments.”[65]

AMERICAN COLLEGE OF GASTROENTEROLOGY

The 2014 clinical guideline on the management of benign anorectal disorders, including fecal incontinence, from the American College of Gastroenterology (ACG) found that "sacral nerve stimulation should be considered in [fecal incontinence] who do not respond to conservative therapy (strong recommendation, moderate quality of evidence)."[66] The 2021 updated ACG guidelines continue the recommendation for sacral nerve stimulation in patients with fecal incontinence refractory to medical therapy.[67] Additionally, due to a lack of evidence supporting efficacy and the risk of adverse events and complications, the 2021 ACG Panel states that sacral nerve stimulation "cannot be recommended in patients with constipation of any type".

AMERICAN SOCIETY OF COLON AND RECTAL SURGEONS

In 2015, the American Society of Colon and Rectal Surgeons released a clinical practice guideline for the treatment of fecal incontinence.[68] They stated that "sacral neuromodulation may be considered as a first-line surgical option for incontinent patients with and without sphincter defects (Grade of Recommendation: Strong, based on moderate-quality evidence, 1B)."

In 2016, the Society released a clinical practice guideline for the management of constipation.[69] They stated "sacral neuromodulation may be an effective treatment for patients with chronic constipation and successful peripheral nerve evaluation test when conservative measures have failed; however, it is not currently approved by the US Food and Drug Administration for this condition in the United States (Grade of Recommendation: Weak, based on moderate quality evidence, 2B)."

SUMMARY

There is enough research to show that sacral nerve neuromodulation/stimulation (SNM) can improve health outcomes and quality of life in some patients with urinary incontinence, non-obstructive urinary retention, overactive bladder or fecal incontinence. Therefore, SNM, including temporary and the potential permanent implantation, may be considered medically necessary for these conditions when the policy criteria are met.

A SNM device may require revision or removal after it has been placed. In these cases, revision may be medically appropriate to allow for the proper functioning of the device. Therefore, revision(s) to an existing sacral nerve neuromodulation device or removal of the device may be considered medically necessary after the device has been placed.

In certain situations, a SNM device may no longer be able to perform its basic function due to damage or wear. When a stimulator is out of its warranty period and cannot be repaired adequately to meet the patient's medical needs, replacement of the device may be medically appropriate. Therefore, replacement of all or part of SNM device and/or generator may be considered medically necessary when device replacement Criteria are met.

When a SNM device is in its warranty period or can be repaired or adapted adequately to meet the patient's medical needs, replacement of the device is not medically appropriate. Therefore, replacement of all or part of a sacral nerve neuromodulation device and/or

generator is considered not medically necessary when device replacement Criteria are not met.

Sacral nerve neuromodulation/stimulation is considered not medically necessary for the treatment of urinary incontinence, non-obstructive urinary retention, and fecal incontinence in patients who do not meet criteria, including for individuals with urinary stress incontinence, or urge incontinence due to neurologic conditions such as multiple sclerosis, spinal cord injury, diabetes-related peripheral nerve conditions, and detrusor hyperreflexia because the procedure is not considered clinically effective or appropriate for these individuals.

There is not enough research to show that sacral nerve neuromodulation/stimulation (SNM) improves health outcomes for people with conditions other than urge incontinence, non-obstructive urinary retention, overactive bladder and fecal incontinence. Therefore, SNM is considered investigational for other conditions, including but not limited to chronic constipation and chronic pelvic pain.

CODES

NOTE: HCPCS code C1823 is NOT the correct code to use for reporting these services. Please refer to the codes listed below for guidance.

Codes	Number	Description
CPT	0786T	Insertion or replacement of percutaneous electrode array, sacral, with integrated neurostimulator, including imaging guidance, when performed
	0787T	Revision or removal of neurostimulator electrode array, sacral, with integrated neurostimulator
	0788T	Electronic analysis with simple programming of implanted integrated neurostimulation system (eg, electrode array and receiver), including contact group(s), amplitude, pulse width, frequency (Hz), on/off cycling, burst, dose lockout, patient-selectable parameters, responsive neurostimulation, detection algorithms, closed-loop parameters, and passive parameters, when performed by physician or other qualified health care professional, spinal cord or sacral nerve, 1-3 parameters
	0789T	Electronic analysis with complex programming of implanted integrated neurostimulation system (eg, electrode array and receiver), including contact group(s), amplitude, pulse width, frequency (Hz), on/off cycling, burst, dose lockout, patient-selectable parameters, responsive neurostimulation, detection algorithms, closed-loop parameters, and passive parameters, when performed by physician or other qualified health care professional, spinal cord or sacral nerve, 4 or more parameters
	64561	Percutaneous implantation of neurostimulator electrode array; sacral nerve (transforaminal placement) including image guidance, if performed
	64581	Open implantation of neurostimulator electrode array; sacral nerve (transforaminal placement)

Codes	Number	Description
	64585	Revision or removal of peripheral neurostimulator electrode array
	64590	Insertion or replacement of peripheral, sacral, or gastric neurostimulator pulse generator or receiver, requiring pocket creation and connection between electrode array and pulse generator or receiver
	64595	Revision or removal of peripheral, sacral, or gastric neurostimulator pulse generator or receiver, with detachable connection to electrode array
	64596	Insertion or replacement of percutaneous electrode array, peripheral nerve, with integrated neurostimulator, including imaging guidance, when performed; initial electrode array
	64597	Insertion or replacement of percutaneous electrode array, peripheral nerve, with integrated neurostimulator, including imaging guidance, when performed; each additional electrode array (List separately in addition to code for primary procedure)
	64598	Revision or removal of neurostimulator electrode array, peripheral nerve, with integrated neurostimulator
	95970	Electronic analysis of implanted neurostimulator pulse generator/transmitter (eg, contact group[s], interleaving, amplitude, pulse width, frequency [Hz], on/off cycling, burst, magnet mode, dose lockout, patient selectable parameters, responsive neurostimulation, detection algorithms, closed loop parameters, and passive parameters) by physician or other qualified health care professional; with brain, cranial nerve, spinal cord, peripheral nerve, or sacral nerve, neurostimulator pulse generator/transmitter, without programming
	95971	;with simple spinal cord, or peripheral nerve (eg, sacral nerve) neurostimulator pulse generator/transmitter, programming by physician or other qualified health care professional
	95972	;with complex spinal cord, or peripheral (eg, sacral nerve) neurostimulator pulse generator/transmitter programming by physician or other qualified health care professional
HCPCS	C1767	Generator, neurostimulator (implantable), nonrechargeable
	L8678	Electrical stimulator supplies (external) for use with implantable neurostimulator, per month
	L8679	Implantable neurostimulator, pulse generator, any type
	L8680	Implantable neurostimulator electrode, each
	L8681	Patient programmer (external) for use with implantable programmable neurostimulator pulse generator, replacement only
	L8682	Implantable neurostimulator radiofrequency receiver
	L8683	Radiofrequency transmitter (external) for use with implantable neurostimulator radiofrequency receiver
	L8684	Radiofrequency transmitter (external) for use with implantable sacral root neurostimulator receiver for bowel and bladder management, replacement
	L8685	Implantable neurostimulator pulse generator, single array, rechargeable, includes extension
	L8686	Implantable neurostimulator pulse generator, single array, non- rechargeable, includes extension
	L8687	Implantable neurostimulator pulse generator, dual array, rechargeable, includes extension
	L8688	Implantable neurostimulator pulse generator, dual array, non-rechargeable, includes extension
	L8689	External recharging system for battery (internal) for use with implantable neurostimulator

Medical Policy Manual Surgery, Policy No. 137

Orthognathic Surgery

Effective: May 1, 2024

Next Review: December 2024
Last Review: April 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Orthognathic surgery involves the surgical manipulation of the facial skeleton, particularly the maxilla and mandible, to restore the proper anatomic and functional relationship in patients with dentofacial skeletal anomalies.[1]

MEDICAL POLICY CRITERIA

Notes:

- This policy does not address the surgical management of sleep apnea, which is addressed in a separate medical policy (see Cross References). Also, this policy does not address temporomandibular joint (TMJ) surgical interventions, which may require pre-authorization.
- Member contracts for covered services vary. Member contracts may have specific language defining congenital and developmental anomalies. Member contract language takes precedence over medical policy. A congenital anomaly is defined as an anomaly that is present at birth (e.g., cleft palate). Developmental anomalies are conditions that develop some time after birth.

I. Orthognathic surgery for the treatment of obstructive sleep apnea may be considered **medically necessary** when the criteria in Surgery, Policy No. 166 are met.

II. Orthognathic surgery to treat conditions other than obstructive sleep apnea may be considered **medically necessary** to correct jaw and craniofacial deformities when all of the following Criteria (A-D) are met:

A. Significant functional impairment that is documented to be directly attributable to jaw and craniofacial deformities and to include one or more of the following:

1. Chewing-induced trauma secondary to malocclusion; or
2. Significantly impaired swallowing and/or choking due to inadequate mastication secondary to malocclusion; or
3. Significant speech abnormalities (e.g., sibilant distortions or velopharyngeal distortion) which have not responded to speech therapy and are secondary to malocclusion; or
4. Loss of masticatory or incisive function due to malocclusion or skeletal abnormality; or
5. Airway restriction; and

B. Significant over- or underjet as documented by one of the following:

1. In mandibular excess or maxillary deficiency, a reverse overjet of 3mm or greater; or
2. In mandibular deficiency, an overjet of 5mm or greater; or
3. Open bite of 4mm or greater; or
4. Deep bite of 7mm or greater and/or palatal impingement of the mandibular teeth on the palatal tissue; or
5. Less than six posterior teeth in functional opposition to other teeth secondary to a developmental or congenital growth abnormality (as opposed to a consequence of the loss of teeth); and

C. The functional impairment and over- or underjet are not correctable with non-surgical treatment modalities (e.g. orthodontics) and;

D. The following documentation is required to determine medical necessity for orthognathic surgery:

1. Clinical record of history and physical performed demonstrating medical necessity of orthognathic surgery and when appropriate, any other pertinent diagnostic findings; and
2. Intra-oral and extra-oral photographs; and
3. Cephalometric and panoramic radiographs with either a written report or a summary of radiographic findings in the clinical record (e.g. cephalometric tracings).

III. Reduction of the masseter muscle and bone may be considered **medically necessary** as a component of orthognathic surgery only when there is clinical documentation of the presence of masseteric hypertrophy.

IV. Orthognathic surgery is considered **cosmetic** when Criteria are not met, including but not limited to when used for improvement of appearance.

V. Genioplasty is considered **cosmetic** when performed in conjunction with orthognathic surgery for the sole purpose of improving appearance and/or profile.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

SUMMARY

Orthognathic surgery improves health outcomes including functional impairments for some people with dentofacial skeletal anomalies that are not correctable with non-surgical treatment modalities. Therefore, orthognathic surgery may be considered medically necessary when policy Criteria are met.

The reduction of the masseter muscle and bone improves health outcomes for some people with masseteric hypertrophy when performed as a component of orthognathic surgery. Therefore, reduction of the masseter muscle and bone may be considered medically necessary when policy Criteria are met.

In all other situations, it is unclear how orthognathic surgery improves health outcomes or corrects functional impairments. Therefore, orthognathic surgery is considered cosmetic when policy Criteria are not met including but not limited to for the sole purpose of improving appearance.

CODES

Codes	Number	Description
CPT	21085	Impression and custom preparation; oral surgical splint
	21110	Application of interdental fixation device for conditions other than fracture or dislocation, includes removal
	21120	Genioplasty; augmentation (autograft, allograft, prosthetic material)
	21121	Genioplasty; sliding osteotomy, single piece
	21122	Genioplasty; sliding osteotomies, two or more osteotomies (e.g., wedge excision or bone wedge reversal for asymmetrical chin)
	21123	Genioplasty; sliding, augmentation with interpositional bone grafts (includes obtaining autografts)

Codes	Number	Description
	21125	Augmentation, mandibular body or angle; prosthetic material
	21127	Augmentation, mandibular body or angle; with bone graft, onlay or interpositional (includes obtaining autograft)
	21141	Reconstruction midface, LeFort I; single piece, segment movement in any direction (e.g., for Long Face Syndrome), without bone graft
	21142	Reconstruction midface, LeFort I; two pieces, segment movement in any direction, without bone graft
	21143	Reconstruction midface, LeFort I; three or more pieces, segment movement in any direction, without bone graft
	21145	Reconstruction midface, LeFort I; single piece, segment movement in any direction, requiring bone grafts (includes obtaining autografts)
	21146	Reconstruction midface, LeFort I; two pieces, segment movement in any direction, requiring bone grafts (includes obtaining autografts) (e.g., ungrafted unilateral alveolar cleft)
	21147	Reconstruction midface, LeFort I; three or more pieces, segment movement in any direction, requiring bone grafts (includes obtaining autografts) (e.g., ungrafted bilateral alveolar cleft or multiple osteotomies)
	21150	Reconstruction midface, LeFort II; anterior intrusion (e.g., Treacher-Collins Syndrome)
	21151	Reconstruction midface, LeFort II; any direction, requiring bone grafts (includes obtaining autografts)
	21154	Reconstruction midface, LeFort III (extracranial), any type, requiring bone grafts (includes obtaining autografts); without LeFort I
	21155	Reconstruction midface, LeFort III (extracranial), any type, requiring bone grafts (includes obtaining autografts); with LeFort I
	21159	Reconstruction midface, LeFort III (extra and intracranial) with forehead advancement (e.g., mono bloc), requiring bone grafts (includes obtaining autografts); without LeFort I
	21160	Reconstruction midface, LeFort III (extra and intracranial) with forehead advancement (e.g., mono bloc), requiring bone grafts (includes obtaining autografts); with LeFort I
	21188	Reconstruction midface, osteotomies (other than LeFort type) and bone grafts (includes obtaining autografts)
	21193	Reconstruction of mandibular rami, horizontal, vertical C, or L osteotomy; without bone graft
	21194	Reconstruction of mandibular rami, horizontal, vertical C, or L osteotomy; with bone graft
	21195	Reconstruction of mandibular rami and/or body, sagittal split; without internal rigid fixation
	21196	Reconstruction of mandibular rami and/or body, sagittal split; with internal rigid fixation
	21198	Osteotomy, mandible, segmental;
	21206	Osteotomy, maxilla, segmental (e.g., Wassmund or Schuchard)
	21208	Osteoplasty, facial bones; augmentation (autograft, allograft, or prosthetic implant)
	21209	Osteoplasty, facial bones; reduction
	21210	Graft, bone; nasal, maxillary or malar areas (includes obtaining graft)
	21215	Graft, bone; mandible (includes obtaining graft)
	21230	Graft; rib cartilage, autogenous, to face, chin, nose or ear (includes obtaining graft)
	21295	Reduction of masseter muscle and bone (eg, for treatment of benign masseteric hypertrophy); extraoral approach

Codes	Number	Description
	21296	Reduction of masseter muscle and bone (eg, for treatment of benign masseteric hypertrophy); intraoral approach
CDT	D7940	Osteoplasty – for orthognathic deformities
	D7941	Osteotomy; mandibular rami
	D7943	Osteotomy; mandibular rami with bone graft; includes obtaining the graft
	D7944	Osteotomy; segmented of subapical – per sextant or quadrant
	D7945	Osteotomy; body of mandible
	D7946	LeFort I (maxilla – total)
	D7947	LeFort I (maxilla – segmented)
	D7948	LeFort II or LeFort III (osteoplasty of facial bones for midface hypoplasia or retrusion); without bone graft
	D7949	LeFort II or LeFort III; with bone graft
	D7950	Osseous, osteoperiosteal, or cartilage graft of the mandible or facial bones – autogenous or nonautogenous, by report
	D7995	Synthetic graft – mandible or facial bones, by report
	D7996	Implant – mandible for augmentation purposes (excluding alveolar ridge), by report

Magnetic Resonance (MR) Guided Focused Ultrasound (MRgFUS) and High Intensity Focused Ultrasound (HIFU) Ablation

Effective: November 1, 2022

Next Review: August 2023
Last Review: September 2022

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Magnetic resonance (MR) guided focused ultrasound (MRgFUS) and high-intensity focused ultrasound (HIFU) concentrate high-energy ultrasound waves via probe on a single location to cause coagulative necrosis.

MEDICAL POLICY CRITERIA

I. High-intensity focused ultrasound (HIFU) may be considered **medically necessary** as a local treatment for prostate cancer when all of the following (A.-D.) criteria are met:
   A. For the treatment of radiation recurrence (see Policy Guidelines); and
   B. The patient is a candidate for local therapy (see Policy Guidelines); and
   C. Transrectal ultrasound guided (TRUS) biopsy positive; and
   D. In the absence of metastatic disease.

II. High-intensity focused ultrasound (HIFU) is considered **investigational** for all other indications not meeting Criterion I.

III. Magnetic resonance (MR) guided focused ultrasound (MRgFUS) may be considered **medically necessary** for either of the following indications:

A. Medicine-refractory essential tremors; or

B. Pain palliation in an adult (greater than or equal to 18 years) with metastatic bone cancer for whom radiotherapy has failed or who are not candidates for radiotherapy.

IV. Magnetic resonance (MR) guided focused ultrasound (MRgFUS) is considered **investigational** for all other indications not meeting Criterion III., including but not limited to treatment of the following:

A. Uterine fibroids; and

B. All tumors, including but not limited to brain, breast, prostate and renal; and

C. Tremor-dominant Parkinson's disease.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

CANDIDATE FOR LOCAL THERAPY

According to National Comprehensive Cancer Network (NCCN) guidelines for prostate cancer (version 1.2023), in the presence of radiation therapy recurrence (see below), a candidate for local therapy includes:[1]

- Biopsy positive
- Studies negative for distant metastatic disease
- Life expectancy > 5y

RADIATION RECURRENCE

NCCN guidelines for prostate cancer (version 1.2023) cite radiation therapy recurrence as either 1) a positive digital rectal exam (DRE), or 2) Radiation Therapy Oncology Group - American Society for Therapeutic Radiology and Oncology (RTOG-ASTRO) Phoenix Consensus biochemical failure.

RTOG-ASTRO Phoenix Consensus PSA recurrence is further defined as:

1.) PSA increase by 2 ng/mL or more above the nadir PSA is the standard definition for biochemical failure after EBRT with or without hormonal therapy; and
2.) A recurrence evaluation should be considered when PSA has been confirmed to be increasing after radiation even if the increase above nadir is not yet 2 ng/mL, especially in candidates for salvage local therapy who are young and healthy.

Retaining a strict version of the ASTRO definition allows comparison with a large existing body of literature. Rapid increase of PSA may warrant evaluation (prostate biopsy) prior to meeting the Phoenix definition, especially in younger or healthier men.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical
- Treatment plan including treatment area
- For essential tremors, clinical documentation must demonstrate medicine-refractory symptoms
- For prostate cancer treatment, clinical documentation must also demonstrate results from transrectal ultrasound guided (TRUS) biopsy
- For pain palliation bone metastases, clinical documentation that radiotherapy has failed for the patient or the patient is not a candidate for radiotherapy

BACKGROUND

Magnetic resonance (MR) guided focused ultrasound (MRgFUS) and high-intensity focused ultrasound (HIFU) are proposed as less invasive approaches than surgery for treatment of localized prostate cancer, uterine fibroids, and pain palliation of bone metastases. Broadly, these devices use an integrated imaging system to take measurements, confirm the treatment area, and monitor thermal destruction in real time.

MRgFUS is a noninvasive treatment that combines focused ultrasound and magnetic resonance imaging (MRI). The ultrasound beam penetrates through the soft tissues and, using MRI for guidance and monitoring, the beam can be focused on targeted sites. Ultrasound causes a local increase in temperature in the target tissue, resulting in coagulation necrosis while sparing the surrounding normal structures. Ultrasound waves from each sonication are focused at a focal point that has a maximum focal volume of 20 nm in diameter and 15 nm in height/length. This causes a rapid rise in temperature (to approximately 65°C-85°C), which is sufficient to achieve tissue ablation at the focal point. In addition to providing guidance, the associated MRI can provide online thermometric imaging that provides a temperature “map” to confirm the therapeutic effect of the ablation treatment and allow for real-time adjustment of the treatment parameters.

HIFU focuses high-energy ultrasound waves on a single location, which increase the local tissue temperature to over 80°C. This causes a discrete locus of coagulative necrosis of approximately 3×3×10 mm. In the treatment of prostate cancer, HIFU is a minimally invasive localized option. The surgeon uses a transrectal probe to plan, carry out, and monitor ablative treatment in a real-time sequence with a combination of ultrasound and MRI imaging.

REGULATORY STATUS

Devices have received U.S. Food and Drug Administration (FDA) approval via the *De Novo* and Premarket Application (PMA) processes:

High-Intensity Focused Ultrasound

The Sonablate® 450 (SonaCare Medical) is the first high-intensity ultrasound system for prostate tissue ablation to receive FDA approval, and therefore underwent the *De Novo* application process, obtaining clearance in 2015. Shortly thereafter, Ablatherm Integrated Imaging® (EDAP TMS) received PMA approval. In June 2018, EDAP received 510(k) clearance for its Focal-One® HIFU device designed for prostate tissue ablation procedures. This device fuses magnetic resonance and 3D biopsy data with real-time ultrasound imaging, allowing urologists to view detailed images of the prostate on a large monitor and direct high-intensity ultrasound waves to ablate the targeted area.

Magnetic Resonance-Guided Focused Ultrasound

The ExAblate® 2000 System (InSightec, Inc.) received premarket approval (PMA) from the FDA for the indications: “ablation of uterine fibroid tissue in pre- or peri- menopausal women with symptomatic uterine fibroids who desire a uterine sparing procedure,” and for palliation of pain associated with tumors metastatic to bone.[2]

For uterine fibroids, the FDA approval letter states that patients must have a uterine gestational size of less than 24 weeks and those patients must have completed childbearing.

In the initial safety and efficacy studies, the FDA limited MRI-guided focused ultrasound to 33% of fibroid volume with a maximum treatment time of 120 minutes. Guidelines were later modified to allow up to 50% treatment volume, 180-minute maximum treatment time, and a second treatment if within a 14-day period.

The ExAblate 2000 treatment is contraindicated for use in women who have MRI-related issues, such as metallic implants, or sensitivity to MRI contrast agents; obstructions in the treatment beam path, such as a scar, skin fold, or irregularity, bowel, pubic bone, intrauterine device, surgical slips, or any hard implants; and fibroids that are close to sensitive organs such as the bowel or bladder or are outside the image area.

The ExAblate® 2100 System also received approval through the PMA process.[3] It includes several modifications to the previous system including enhanced sonication and a detachable cradle, and only certain cradle types can be used for palliation of pain associated with metastatic bone cancer. Approval remains limited to treatment of patients with metastatic bone cancer who failed or are not candidates for radiation therapy; or, in patient with symptomatic uterine fibroids with a uterine size of less than 24 weeks and those who have completed childbearing.

In October 2012, the FDA granted PMA approval for ExAblate® System, for pain palliation due to metastatic bone cancer.[4] For pain palliation, the intended use of the device is in adult patients with metastatic bone cancer who failed or are not candidates for radiation therapy. The device was evaluated through an expedited review process. The FDA required a post-approval study with 70 patients to evaluate the effectiveness of the system under actual clinical conditions.

In July 2016, the FDA granted premarket approval (PMA) of the ExAblate® Neuro System for the treatment of essential tremor in patients who have not responded to medication (beta-

blockers or anticonvulsant drugs).[5] This PMA outlined required pending studies for the device, including investigational treatment with the ExAblate Neuro in 75 patients to be evaluated at two-, three-, four- and five-years post-operative.

In December 2018, the FDA granted premarket approval (PMA) of the ExAblate Model 4000 (Neuro) for the treatment of tremor-dominant PD with medication-refractory tremor.[6] This PMA outlined required post-approval study, including a prospective, multi-center, new enrollment, long-term safety and effectiveness study in 50 patients. The study is designed to evaluate the long-term safety of the device when used to treat patients who have failed medication.

FDA product codes: NRZ, POH.

MRgFUS is also being investigated for the treatment of other tumors, including breast, prostate, brain, and desmoid tumors as well as nonspinal osteoid osteoma.

EVIDENCE SUMMARY

HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU)

Prostate Cancer

Given significant uncertainty in predicting the behavior of individual localized prostate cancers, and the substantial adverse effects associated with definitive treatments, investigators have sought a therapeutic middle ground. The latter seeks to minimize morbidity associated with radical treatment in those who may not actually require surgery while reducing tumor burden to an extent that reduces the chances for rapid progression to incurability. Locally directed therapies, also termed *focal treatment* includes several ablative methods, one of which is high-intensity focused ultrasound (HIFU). The overall goal of any focal treatment is to minimize the risk of tumor progression and preserve erectile, urinary, and rectal functions by reducing damage to the neurovascular bundles, external sphincter, bladder neck, and rectum.

Maestroni (2021) published a systematic review (SR) of studies evaluating the safety and cancer control rates of HIFU following failure of External Beam Radiation Therapy (EBRT).[7] Data from 1241 patients across 13 publications were included in the analysis. The mean age of the patients was 68.6 years (range 53 to 83 years, SD ±6.11). Of those included in the analysis, 38.3% of the patients were on androgen-deprivation therapy at the time of salvage HIFU, and 24.71% continued the therapy after the treatment. PSA nadir was 1.1 ng/mL (SD ±3.39). The time to which PSA nadir was reached was not reported in all series. Limited to these series, PSA nadir was achieved in a mean time of 11.7 weeks (SD ±9.1). Mean follow-up was 24.3 months after salvage HIFU treatment, ranging from 3 to 168 months. Overall survival (OS) was 85.2% at five years. One study reported OS of 72% at seven years.

Valle (2021) published a SR comparing the efficacy and toxicity of salvage radical prostatectomy (RP), HIFU, cryotherapy, stereotactic body radiotherapy (SBRT), low-dose-rate (LDR) brachytherapy, and high-dose-rate (HDR) brachytherapy in the management of locally recurrent prostate cancer.[8] Two- and five-year recurrence-free survival (RFS) rates and crude incidences of severe genitourinary (GU) and gastrointestinal (GI) toxicity were endpoints of interest. A total of 150 studies were included for analysis. Significant heterogeneity between studies was found within each modality, and covariates differed between modalities, necessitating adjustment. Adjusted five-year RFS ranged from 50% after cryotherapy to 60%

after HDR brachytherapy and SBRT, with no significant differences between any modality and RP.

A SR of functional and oncological outcomes of focal therapy in patients with localized prostate cancer was published by Hopstaken (2021).[9] Seventy-two studies on eight different modalities to deliver focal therapy in 5827 patients were assessed including 27 studies reporting on high-intensity focused ultrasound (HIFU). One of these studies was considered IDEAL stage 1 study; the majority (n=23) were considered stage 2 studies. One large retrospective study (n=1032) stated as IDEAL stage 4. There were no RCTs assessing the effectiveness of HIFU. Studies of HIFU reported a median of 95% pad-free patients and a median of 85% patients with no clinically significant cancer (CSC) in the treated area and the treatment was well-tolerated.

Ingrosso (2020) published a SR with meta-analysis on nonsurgical therapeutic strategies in patients with radiorecurrent prostate cancer.[10] The review addressed the clinical outcomes and toxicity profiles of treatments including HIFUS, brachytherapy, external beam radiotherapy, and cryotherapy. Thirteen of the 64 case-series studies were publications reporting HIFUS as the salvage treatment. Among the treatments studied, biochemical control rates were lowest for patients treated with HIFU (58%, 95% confidence interval [CI] 47–68%). The prevalence of incontinence was highest among patients treated with HIFU (28%, 95% CI 19–38%; I2 = 89.7%). The authors concluded that good efficacy and tolerability was found after local treatment of radiorecurrent prostate cancer, but that high-quality data from prospective trials are needed to validate the long-term outcomes of these strategies for the treatment of intraprostatic recurrence after previous radiotherapy.

A 2020 SR by Khoo also evaluated 15 studies (14 case series and one comparative study) reporting outcomes after focal salvage brachytherapy (five studies), cryotherapy (seven studies) and HIFU (three studies) in the treatment of localized non-metastatic radiorecurrent prostate cancer.[11] Rates of biochemical disease-free survival (BDFS), metastasis, conversion to second-line therapies, and adverse events were assessed and median follow-up ranged from 10 to 56 months. At three years, BDFS ranged from 61% to 71.4% after brachytherapy, 48.1–72.4% after cryotherapy and 48% after HIFU. The authors note high heterogeneity in patient selection, individual treatment protocols and outcome reporting. Additional studies comparing the treatment modalities is recommended.

As a salvage treatment, that is, for recurrent disease following initial therapy, Crouzet (2017) reported that HIFU is associated with cancer-specific (CSS) and metastasis-free survival (MFS) of at least 80% at seven years in a study of over 400 men.[12] Morbidity rate for grade III/IVa complications was 3.6%. Smaller studies with shorter-duration of follow-up are in general agreement[1, 13-16], however, patient selection criteria is an important predictor of treatment outcomes[17-20]. While this is still an area of investigation, there may be limited treatment for this population of men with recurrent disease. Current practice guidelines based on research recommend HIFU in the presence of radiation recurrence for carefully selected patients (e.g., no metastases, and good candidate for local therapy).[1]

Primary Treatment of Prostate Cancer

As a primary treatment, evidence for HIFU is still accumulating. Data in the published literature are available for shorter follow-up times than in salvage treatment studies (e.g., two years).[13, 16, 21]

Bakavicius (2022) published a SR of data from studies with at least 50 patients published 2010 to 2020 that evaluated focal HIFU therapy as a primary treatment for localized prostate cancer.[22] Data from 20 publications were included in the final analysis consisting of one randomized feasibility study (Hamdy 2018),[23] ten prospective development studies, and nine retrospective case series (total N=4209). Across all studies, clinically significant in-field recurrence and out-of-field progression were detected in 22% and 29% patients, respectively. The authors conclude intermediate- and long-term outcomes are needed from high-quality comparative trials evaluating the HIFU in comparison to standard of care.

Bates (2021) published a SR that evaluated studies published from January 2000 to June 2020 on focal therapy as a treatment for histologically proven, clinically localized prostate cancer compared to standard management.[24] Focal therapy interventions included HIFU, vascular targeted photodynamic therapy, laser ablation, thermal ablation, focal brachytherapy, radiofrequency waves, microwave ablation, focal external-beam radiotherapy, and irreversible electroporation. The comparator intervention included any standard management option such as radical prostatectomy, external beam radiotherapy, whole gland brachytherapy, and active surveillance/monitoring. Overall, five articles reporting on four primary comparative studies (one RCT and three retrospective nonrandomized comparative studies; N=3961) and 10 eligible systematic reviews were identified. One retrospective study comparing focal HIFU with robotic radical prostatectomy found no significant difference in treatment failure at three years, with better continence and erectile function recovery with HIFU. Regarding the included systematic reviews, virtually all concluded that there was insufficient high certainty evidence to make definitive conclusions regarding the clinical effectiveness of focal therapy. The authors conclude that the "certainty of the evidence regarding the comparative effectiveness of focal therapy as a primary treatment for localized prostate cancer was low, with significant uncertainties" and that "until higher certainty evidence emerges...focal therapy should ideally be performed within clinical trials or well-designed prospective cohort studies."

Uterine Fibroids

Tsai (2021) published a SR with meta-analysis of studies comparing the outcome of HIFU and conventional surgery (myomectomy and hysterectomy) for the treatment of uterine myomas.[25] The review included 10 studies inclusive of one RCT, six prospective studies and three retrospective studies with sample sizes ranging from 39 to 1353 (total N = 4217). HIFU improved uterine myoma symptoms compared with conventional surgery at six months (MD −1.61; 95% confidence interval [CI], −2.88 to −0.33) and 12 months (MD −2.44; 95% CI, −3.68 to −1.20) after treatment as well as quality-of-life score at six (MD 2.14; 95% CI, 0.86–3.42) and 12 (MD 2.34; 95% CI, 0.82–3.86) months after treatment compared to the surgery group. Overall, nine studies, including RCTs and non-RCTs had moderate risk of bias and one study had serious risk of bias. Three studies reported the incidence of skin burns in the HIFU group. Considerable heterogeneity was observed across the studies with respect to treatment techniques, outcomes, and timepoints of assessment of outcomes. Patients with more than three uterine myomas or larger myomas were not included in any of the studies and four studies recruited patients with only certain types of uterine myoma, which limits the generalizability of observations.

Barnard (2017) published preliminary results from Fibroid Interventions: Reducing Symptoms Today and Tomorrow trial, a parallel RCT and cohort study comparing MRgFUS with fibroid embolization to treat uterine fibroids.[26] For the RCT, patients were randomized to uterine artery embolization (UAE; n=22) or to MRgFUS (n=27). Patients and investigators were not

blinded. Women who did not want to be randomized were enrolled in the cohort study; 16 underwent UAE and 16 underwent MRgFUS. After six weeks of follow-up, there were no differences between groups in fatigue, hot flashes, discomfort urinating, vaginal discharge, or constipation. Recovery was significantly faster in the MRgFUS group, as measured by the first day back to work and the first day back to normal. Medication use (ie, opioids, nonsteroidal anti-inflammatory drugs, acetaminophen or aspirin, nausea medication, bowel medication) was also significantly lower in the MRgFUS group. Analyses combining the RCT and cohort patients showed similar results. The MRgFUS procedure took significantly longer than the UAE procedure. A trial limitation was the inability to recruit more patients. Long-term follow-up results were reported by Laughlin-Tommaso (2019).[27] Patients in both the RCT and cohort studies had follow-up for up to three years. The primary outcome assessed was reintervention for uterine fibroids within three years; secondary outcomes included change in anti-Mullerian hormone levels and standardized measures of quality of life, pain, sexual function, and fibroid symptoms. Among the women in the MRgFUS arm (n=43), 13 (30%) had a second fibroid procedure compared to 5 (13%) women in the UAE arm (hazard ratio [HR], 2.81; 95% confidence interval [CI], 1.01 to 7.79). Both quality of life and pain scores improved in both arms, however there was a larger improvement in the UAE arm. There was a significantly greater absolute decrease in anti-Mullerian hormone levels at 24 months in the UAE arm compared to the MRgFUS arm.

A 2017 SR published by the Agency for Healthcare Research and Quality (AHRQ) on the management of uterine fibroids included evaluation studies of HIFUS.[28] Outcomes following HIFUS were symptoms (two studies, N=53), sexual function (one study, n=50), and fibroid characteristics (five studies, N=216). The duration of follow-up studied ranged from less than one to 24 months. The conclusion of the review was that HIFU reduced fibroid size, but strength of evidence is low because of short followup and poor quality of overall study design. Evidence related to patient reported outcomes is insufficient.

Other Indications

HIFU has been investigated as a treatment for other indications, such as adenomyosis[29] and thyroid disorders,[30, 31] but these are generally small, noncomparative studies. Systematic reviews of HIFU in the treatment of malignant lesions of the hepatobiliary system,[32] pancreas,[33] and benign thyroid nodules[34, 35] have concluded that although volumetric reduction or complete ablation was achieved with HIFU, additional studies are needed to determine the added benefit and long-term outcomes of the technology either alone or as a combination therapy on net health outcomes in these patient populations.

MAGNETIC RESONANCE (MR) GUIDED FOCUSED ULTRASOUND (MRGFUS)

Essential Tremors

Systematic Reviews

Miller (2021) published a meta-analysis that evaluated the efficacy of MRgFUS for treating medication-refractory essential tremor (ET) with a focus on long-term trends and the durability of the response.[36] Data from patients with comorbid conditions such as Parkinson’s disease, were not included. Twenty-one studies (N=395) were included; 17 were prospective studies, three were retrospective, and one was the RCT published by Elias (2016) discussed below. Hand tremor scores decreased from a weighted mean pre-operative value of 19.2±5.0 to 7.4±5.0 after three months. Over time, the hand tremor score values gradually increased:

8.3±5.3 after 12 months and 9.1±5.4 after 36 months. The pooled standardized mean difference of hand tremor scores compared to pre-treatment values was 2.68 (95% CI, 1.94 to 3.41) at three months (five studies), 2.44 (95% CI, 1.97 to 2.91) at the 12-month time point (seven studies), and 2.18 (95% CI, 1.50 to 2.86) at the 24-month time point (three studies). Clinical Rating Scale for Tremor scores were reported through 12 months. The pooled standardized mean difference in Clinical Rating Scale for Tremor (CRST) scores compared to pre-treatment values was 1.86 (95% CI, 1.51 to 1.21) at the three-month time point (eight studies) and 2.24 (95% CI, 1.55 to 2.94) at the 12-month time point (six studies). Six studies reported Quality of Life in Essential Tremor Questionnaire (QUEST) scores as a quality-of-life measure. The pooled pre-treatment QUEST score was 48.2±22.4, which improved to 24.9±18.2 at three months. Additionally, a single study detailed a mean 23.8±19.6 QUEST score at 36 months follow-up, an increase of 2.2 over 30 months.

A SR of 29 studies (N = 617) on MRgFUS in the treatment of ET was published by Agrawal (2021).[37] Studies that reported outcomes in patients with tremors secondary to any other causes, such as drug-induced tremor, trauma, psychogenic tremor, or co-morbid Parkinson disease and dystonia were excluded. The ventral intermediate nucleus of the thalamus is the common target region. Of the 29 studies, only one (Elias 2016, below) was a RCT, the remaining were observational studies. Pre- and post- procedure changes in the CRST score, hand score, disability and quality of life scores were evaluated. A significant difference was observed in the pooled standard mean difference between pre- and post-operative total CRST score ($p < 0.001$), hand score ($p < 0.05$), and disability at 12 months ($p < 0.01$), although the number of included studies ranged from five to nine for the assessed outcomes. Disability, assessed by the CRST Part C at three months after MRgFUS, was reported by five studies in which the pooled standard mean difference was −2.66 with 95% CI: −3.53 to −1.79 ($p = 0.08$). Disability at 12 months after MRgFUS was reported by eight cohorts and the pooled standard mean difference was −4.54 (95% CI: −8.95 to −0.12, $p < 0.01$). More than one third of patients developed sonication related complications, amongst which head pain and dizziness were the most common. The pooled proportion of ataxia, which included gait disturbance and hand ataxia, was 50% at the short-term was found to be as high as 31% at three years post-treatment. No hemorrhage, seizure or trajectory related complications were reported.

Giordano (2020) conducted a systematic review with meta-analysis to compare unilateral MRgFUS to unilateral and bilateral DBS for medication-refractory ET.[38] Forty-five studies published between 1996 and 2019 were identified. Thirty-seven studies (n=1202) evaluated DBS and eight studies (n=477) evaluated MRgFUS. Fifteen studies had a retrospective study design, while 30 were prospectively designed. Means and standard deviations were calculated for each intervention and differences between groups were compared where appropriate. The average percentage improvement in tremor severity was significantly improved in the pooled DBS group (60.1%±9.7%) compared to the MRgFUS group (55.6%±8.2%, $p<0.001$). Subgroup analyses demonstrated that the improvement in tremor severity was significantly greater with the bilateral DBS (61.2%±5.2%) compared to both unilateral DBS (56.4%±9.7%) and MRgFUS; there was no significant difference between unilateral DBS and MRgFUS. MRgFUS was associated with significantly improved quality of life compared to DBS (61.9%±7.9% vs 52.5%±16.2%, $p<0.001$). There were 517 complications reported in the DBS group and 484 complications reported in the MRgFUS group. The most common adverse events reported with DBS were lead-related complications (11.4%) and speech disturbances (11.1%). For MRgFUS, adverse events of sensory nature (36.7%) and gait disturbances/muscle problems (34.4%) were most common. Limitations of the review included the different scales used in

studies to measure tremor severity and quality of life. There was only one retrospective study that directly compared DBS and MRgFUS.

A technology assessment was published by Health Quality Ontario (2018).[39] The literature search, conducted through April 2017, identified nine studies for inclusion: four single cohort studies, two retrospective chart reviews, two uncontrolled prospective studies, and an RCT. The RCT compared MRgFUS with sham treatment, the chart reviews compared MRgFUS with deep brain stimulation and radiofrequency thalamotomy. Study quality was evaluated using the GRADE system. The RCT was rated high quality, the uncontrolled comparative studies were rated very low quality, and the remaining studies were rated low quality. All studies reported tremor severity as an outcome. Pooling of results was not conducted due to heterogeneity in study designs, analyses, and outcomes across the studies. Reviewers determined that, overall, MRgFUS decreased tremor severity and improved QOL. The high-quality RCT by Elias (2016) is discussed below.

Mohammed (2018) conducted a meta-analysis evaluating the use of MRgFUS to treat medicine-refractory essential tremors.[40] The literature search, conducted through August 2017 identified 9 studies (total n=160 patients) for inclusion, eight of which were also evaluated in the Ontario technology assessment. Pooled analyses found significant improvements in the mean percentage change in Clinical Rating Scale for Tremor scores (62.2%) and Quality of Life in Essential Tremor scores (46.5%). Complications included nausea, vomiting, and ataxia, which decreased during the 12-month follow-up.

Randomized Controlled Trials

A high-quality double-blind, sham-controlled randomized trial by Elias (2016)[41] was identified by the systematic reviews above. Trial selection criteria included patients with moderate or severe postural or intention tremor of the hand (≥2 on the Clinical Rating Scale for Tremor) and refractory to at least two medical therapies. Patients were excluded if they had a neurodegenerative condition, unstable cardiac disease, coagulopathy, risk factors for deep-vein thrombosis, severe depression or cognitive impairment or if they had undergone a previous brain procedure (transcranial magnetic stimulation, deep-brain stimulation, stereotactic lesioning, or electroconvulsive therapy). Patients were randomized to MRgFUS thalamotomy (n=56) or sham treatment (n=20). Outcomes were tremor severity, improvement, and QOL, measured at three months postprocedure. Patients in the treatment group were followed for an additional 12 months. Mean score for hand tremor improved significantly from baseline in the treatment group (47%) compared with the sham group (0.1%) at three months. Change in mean functional improvement score from baseline differed significantly in the MRgFUS group (62%) compared with the sham group (3%) at three months. Change in Quality of Life in Essential Tremor Questionnaire scores also differed significantly in the treatment group compared with the sham group, with the largest improvements experienced in the psychosocial domain. The improvements in hand tremor score, functional improvement, and QOL were maintained at 12 months in the MRgFUS group.

Chang (2018) published results from 67 patients who participated in the open-label extension of the RCT.[42] Because nine patients from the original trial received additional treatment during the two-year follow-up, they were excluded from the analysis. Improvements in tremor and disability scores were maintained at the two-year follow-up (tremor, 19.8±4.9 [baseline] to 8.8±5.0 [at two years]; disability, 16.4±4.5 [baseline] to 6.5±5.0 [at two years]).

Nonrandomized Studies

Several nonrandomized studies (n=11 to 15) reported results from trials implementing MRgFUS as a treatment for essential tremor and many were included in the systematic reviews discussed above.[43-46]

Parkinson's Disease

Ge (2021) published a SR of data from RCTs comparing MRgFUS to sham procedure in the treatment of Parkinson's Disease (PD).[47] The available data from RCTs consisted of the trials by Bond (2017) and Martinez-Fernandez (2020) below, in which the blinded phase lasted for four months three months, respectively. The MRgFUS group showed significant improvement in limb tremor on the treated side (SMD: - 1.20; 95% CI: - 2.06, - 0.34) and the ability to perform daily activities (SMD: - 0.86; 95% CI: - 1.41, - 0.32) compared to the sham group, however, no other treatment effects were found. Dizziness was more common in the treatment group (OR: 4.68; 95% CI: 1.20, 18.23) and symptoms such as hemiparesis, ataxia, dysmetria, speech impairment, and anxiety were found only in the treatment group in both studies. Heterogeneity in patient selection (asymmetric motor symptoms vs. tremor-dominant PD) surgical target site (dorsolateral subthalamic nucleus or ventral intermediate thalamus), and assessed outcomes, as well as small sample sizes, and limited follow-up times are limitations to the available data. Larger, longer-term trials are needed to determine the role of MRgFUS in the treatment of Parkinson's disease.

Martinez-Fernandez (2020) published the results of a RCT of 40 patients with asymmetric PD with predominant motor features randomly assigned to focused ultrasound subthalamotomy (n=27, active treatment) or sham procedure (n=13, control).[48] The lesion site was targeted to the dorsolateral subthalamic nucleus and immediately dorsally to impinge on the pallidothalamic tract and adjusted according to clinical effects. The primary efficacy outcome was between-group difference in the change from baseline in the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) motor score and the primary safety outcome was procedure-related complications, both assessed at four months post-procedure. MDS-UPDRS III score for the more affected side decreased from 19.9 at baseline to 9.9 in the active-treatment group (least-squares mean difference, 9.8 points; 95% confidence interval [CI], 8.6 to 11.1) and from 18.7 to 17.1 in the control group (least-squares mean difference, 1.7 points; 95% CI, 0.0 to 3.5); between group difference = 8.1 (95% CI, 6.0 to 10.3; $p < 0.001$). Adverse events in the active-treatment group were dyskinesia in the off-medication state in six patients and in the on-medication state in six, which persisted in three and one, respectively, at four months; weakness on the treated side in five patients, which persisted in two patients at four months; speech disturbance in 15 patients, which persisted in three at four months; facial weakness in three patients, which persisted in one at four months; and gait disturbance in 13 patients, which persisted in two at four months. In six patients in the active-treatment group, some of these deficits were present at 12 months.

A double-blind, sham-controlled, randomized pilot trial by Bond (2017) assessed the safety and efficacy of unilateral MRgFUS thalamotomy in patients with tremor-dominant PD.[49] Adult patients over 30 years with idiopathic PD were included if their subtype was tremor-dominant that was deemed medication-refractory, severe, and disabling. A total of 27 patients were randomized (2:1) to MRgFUS thalamotomy (n=20) or a sham procedure (n=7) at two centers. The lesion target described in the study was the ventral intermediate thalamus. The primary efficacy outcome was change from baseline (on-medication state) to three months after post-procedure in the hand tremor subscore in the Clinical Rating Scale for Tremor (CRST). On-medication median tremor scores improved 62% (IQR, 22%-79%) from a baseline of 17 points

(IQR, 10.5-27.5) following MRgFUS thalamotomy and 22% (IQR, -11% to 29%) from a baseline of 23 points (IQR, 14.0-27.0) after sham procedures (Wilcoxon p= 0.04). The most common thalamotomy-related adverse events reported for all 26 patients treated were finger paresthesia (39%), ataxia (35%), and orofacial paresthesia (27%). Paresthesia and ataxia persisted to one year in 19% and 4% of patients, respectively. Eight severe adverse events were reported in four patients, and three were thalamotomy-related (two patients with persistent mild hemiparesis and one patient had an associated persistent mild ataxia). After unblinding at three months, six of the seven patients who received sham procedures crossed over to undergo open-label treatment with MRgFUS. Limitations to the study include small sample size, comparison to a sham treatment instead of an alternative surgical procedure and lack of long-term follow-up.

Uterine Fibroids

There are several approaches that are currently available to treat symptomatic uterine fibroids: hysterectomy; abdominal myomectomy; laparoscopic and hysteroscopic myomectomy; hormone therapy; uterine artery embolization; and watchful waiting. Hysterectomy and various myomectomy procedures are considered the gold standard treatment. Comparisons to these procedures in well-designed prospective randomized clinical trials are needed to determine whether MRI-guided high-intensity focused ultrasound ablation (MRgFUS) results in the same or better health outcomes with respect to long-term treatment effects, recurrence rates and impact on future fertility and pregnancy. The focus of this review is therefore on randomized controlled trials.

Systematic Reviews

A SR with meta-analysis published by Xu (2021) assessed re-intervention rates of myomectomy, uterine artery embolization (UAE), and MRgFUS for the treatment of uterine fibroids across 31 studies (N = 42,103).[50] Shorter-term (12-month) pooled re-intervention rate estimations of MRgFUS, UAE, and myomectomy were 0.12 (95%CI, 0.04–0.20; I2=89.1%; p = 0.000), 0.07 (95%CI, 0.06–0.09; I2=14.2%; p = 0.324), and 0.06 (95%CI, 0.01–0.11; I2=95.1%; p = 0.000), respectively. Twenty-four-month: 0.14 (95%CI, 0.07–0.21), 0.08 (95%CI, 0.01–0.17; I2=75.7%; p = 0.016), and 0.10 (95%CI, 0.04–0.16; I2=76.0%; p = 0.002), and 36-month: 0.22 (95%CI, 0.11–0.32; I2=86.3%; p = 0.002), 0.14 (95%CI, 0.05–0.23; I2=94.7%; p = 0.000), and 0.09 (95%CI, 0.05–0.13; I2=0.0%; p = 0.508), respectively. Longest-term (60-month) estimations of the pooled re-intervention rates for MRgFUS, UAE, and myomectomy were 0.49 (95%CI, 0.21–0.77; I2=96.5%; p = 0.000), 0.21 (95%CI, 0.17–0.25; I2=84.1%; p = 0.000), and 0.19 (95%CI, 0.15–0.24; I2=53.7%; p = 0.071), respectively. No evidence of publication bias was found. In sum, estimations of the pooled 12-month, 24-month, 36-month and 60-month re-intervention rates of MRgFUS were 12%, 14%, 22% and 49%, which were the highest rates across all interventions assessed. Myomectomy had the lowest re-intervention rate.

In the 2017 AHRQ review of management of uterine fibroids summarized above, of the six studies assessing HIFU for fibroid ablation, only one fair quality pilot study (n=20) used magnetic resonance imaging (MRI) guidance.

A SR published by Gizzo (2013) identified 38 uncontrolled studies with a total of 2,500 patients (mean age 43.67 years) who underwent MRgFUS for treatment of uterine fibroids.[51] All of the published studies included women older than age 18 years with symptomatic uterine fibroids, and most excluded patients who desired future pregnancies. The authors of the systematic

review did not pool study findings, noting there was no uniform consensus regarding the parameters for evaluating treatment results and considerable variety in the inclusion criteria and follow-up periods. The review confirms the continued absence of published randomized controlled trials on MRgFUS for uterine fibroids.

Clark (2014) published a review of the evidence regarding the role of MRgFUS in the treatment of fibroids and its impact upon future fertility and reproductive outcomes.[52] The authors identified 35 reports of pregnancy after MRgFUS in the available literature; however, additional studies are needed to evaluate the impact of MRgFUS upon future fertility and reproductive outcomes.

Randomized Controlled Trials

A pilot sham-controlled RCT with 20 patients was published by Jacoby (2015). The study was designed to determine the feasibility of a full scale randomized study evaluating MRgFUS for treatment of uterine fibroids.[53] The study included premenopausal women with symptomatic uterine fibroids. Women who were pregnant or had a desire for future fertility were excluded. Patients were randomized to MRgFUS with the ExAblate 2000 system (n=13) or a sham treatment in which no thermal energy was delivered (n=7). The investigators did not specify primary outcomes. The sample size of 20 was selected, not to have sufficient statistical power, but to assess the feasibility of a larger trial. All patients assigned to the MRgFUS group and six of seven in the placebo group received their allocated treatment and all treated patients completed three months of follow-up. Patients were unblinded at three months and given the sham group was given the option of active treatment.

Quality of life outcomes included the Uterine Fibroid Symptom and Health Related Quality of Life Questionnaire (UFS-QOL), which has subscales including the Symptom Severity Score (SSS) and Health Related Quality of Life (HRQL) score. Other measure was the Medical Outcomes Study (MOS), which has a Mental Component Summary (MCS) and Physical Component Summary (PCS). At both the 4- and 12-week follow-ups, there were no statistically significant differences (at the $p<0.05$ level) between the MRgFUS and sham groups in the SSS, HRQL, PCS, or MCS. Change in uterine and fibroid volume, however, differed significantly between groups at 12 weeks. Uterine volume decreased by 17% in the MRgFUS group and by 3% in the sham group ($p=0.04$). Total fibroid volume decreased 18% in the MRgFUS group and did not change in the sham group ($p=0.03$). The authors concluded that women are willing to participate in a sham-controlled RCT of MRgFUS and that larger trials are feasible.

Nonrandomized Studies

The “pivotal” study which led to FDA approval of the ExAblate® 2000 device was included in the AHRQ report discussed above.[54, 55] Additional study outcomes have been subsequently reported from this same study, although interpretation of any such results is limited by the weak strength of the evidence from the original trial. For example, Taran (2009) failed to report on the original primary outcome measure and instead reported findings on a different quality of life measure.[56] The different measures were subject to a multiple comparison bias; a large number of statistical comparisons were done for secondary outcomes, and p-values were not adjusted for increased risk of chance statistical findings.

Another nonrandomized study compared two variations on the MRgFUS procedure.[57] Patients were either treated with the original protocol (33% of fibroid volume with a maximum treatment

time of 120 minutes, n=96) or modified protocol (50% treatment volume, 180 minutes maximum treatment time, and a second treatment if within a 14-day period, n=64). Interpretation of these results was limited by 49% loss to follow-up; 55 patients (57%) from the original treatment protocol completed follow-up. Only 21 patients (33%) from the modified protocol group were evaluable at 12-month follow-up.

A prospective registry of pregnancies after MRgFUS was maintained by the manufacturer of the ExAblate device. A 2008 article reported that there were 54 known pregnancies a mean of eight months after treatment.[58] They included 8 pregnancies from clinical trials designed for women who did not desire pregnancy, 26 pregnancies after commercial treatment, and 20 pregnancies in 17 patients from an ongoing study of MRgFUS in women trying to conceive. Twenty-two of the 54 pregnancies (42%) resulted in deliveries, 11 were ongoing beyond 20 weeks at the time the article was written. There were 14 miscarriages (26%) and seven elective terminations (13%). Among the 22 live births, the mean birth weight of live births was 3.3 kg, and the vaginal delivery rate was 64%. The article provides initial information on the impact of MRgFUS for uterine fibroids on pregnancy; findings suggest that fertility may be maintained but that the number of cases is too small to draw definitive conclusions. Moreover, the study does not address the possible impact of MRgFUS treatment on the ability to become pregnant.

Other non-comparative, prospective and retrospective case series have been published; however, conclusions concerning health outcomes cannot be reached from these studies due to small study populations, high rate of loss to follow-up, and failure to control for bias which could impact treatment results.[59-66]

Although results from these trials contribute to the body of evidence on MRgFUS, interpretation of such results is limited by the lack of a comparative treatment group, the absence of which does not allow for the comparison of the relative treatment effect of MRgFUS with standard medical alternatives. In addition, there is insufficient evidence on the long-term treatment effects, recurrence rates, and impact on future fertility and pregnancy.

Section Summary

There is insufficient evidence regarding the use of MRgFUS as a treatment of uterine fibroids compared to other established procedures. Evidence from randomized controlled trials is lacking and conclusions concerning the safety and efficacy of MRgFUS cannot be drawn from nonrandomized studies due to methodological limitations such as an inability to isolate treatment effects. Systematic review of long-term follow-up results indicate that there is a lower reintervention rate and greater improvement in symptoms after uterine artery embolization compared to MRgFUS. Questions remain regarding the durability of MRgFUS treatment or the impact of this treatment upon future fertility.

Palliative Treatment of Bone Metastases

The principal outcomes for treatment of pain are symptom relief and improved functional level. Relief of pain is a subjective outcome and can be influenced by nonspecific effects, placebo response, the natural history of the disease, and regression to the mean. Therefore, RCTs are important to control for nonspecific effects and to determine whether any treatment effect provides a significant advantage over the placebo/sham treatment or other treatments. Appropriate comparison groups depend on the condition being treated and may include placebo/sham stimulation, or medical or surgical management.

Therefore, the assessment of the safety and efficacy of MRgFUS treatment for bone metastases requires large, long-term, randomized controlled trials comparing this technique with the current standard of care for the condition being treated.

Systematic Reviews

Baal (2021) conducted a systematic review (SR) of studies published between 2007 and 2019 evaluating MRgFUS treatment for painful bone metastases.[67] A total of 33 studies were reviewed, inclusive of three noted as randomized control trials, six retrospective studies, and 24 prospective studies (N=1082). The 2014 RCT by Hurwitz discussed below appears to be the only RCT reporting clinical outcomes in a full publication; one randomized trial evaluated molecular outcomes and one RCT was published only as a conference abstract. Overall, thirteen studies were available in abstract form only. The median study sample size was 21 patients (range 5 to 140) with a median follow-up period of three months (range, 1 to 12 months). The median age of patients was 60 years (22 studies including one study on a pediatric study population, range 4.3–69). Efficacy was assessed by treatment response (complete response or partial response [≥ 2-point improvement in pain score]) and the mean difference in pain scores (10-point VAS [visual analog scale] or NRS [numeric rating scale]) from baseline to month one/month three. The pooled proportion of patients with a treatment response to MRgFUS was 79% (95% confidence interval [CI], 73% to 83%; based on 20 studies [N=636]). The pooled one-month and three-month mean difference from baseline in pain scores were -3.8 (95% CI, -4.3 to -3.3) and -4.4 (95% CI, -5.0 to - 3.7), respectively (based on 20 studies [N=543]). Across 26 studies (N=799), seven high-grade adverse events were observed (one deep vein thrombosis, two cases of grade 3 skin burn, and four fractures). Approximately 11.8% of patients experienced sonication-related pain during MRgFUS treatment. The analysis was limited by a lack of a pooled comparator and heterogeneity of data with respect to populations (eg, type of primary cancer), reported data, and treatment details. Most studies had follow-up periods that were limited to three months.

A SR with meta-analysis by Han (2021) included 15 studies (N = 362) inclusive of the 2014 RCT by Hurwitz and a matched-pair study by Lee (2017) described below and.[68] The studies were conducted in China (n = 112), the United States (n = 112), Israel (n = 38), Italy (n = 23), France (n = 17), Netherlands (n = 15), Canada (n = 21), Japan (n = 10), South Korea (n = 5), and the United Kingdom (n = 9). Most of the included studies were single-arm clinical studies. The quality of studies was assessed by the MINORS score, a validated instrument for assessment of quality in non-randomized surgical studies ranging from 0-24. The mean MINORS score was 14.6 (range: 9–24). Lack of blinding and control groups were found in most of the studies, which contributed to risk of bias in study quality evaluations, however no evidence of publication bias was found. All but one paper included in the study used 10-point scales to assess pain and the data of the one paper using a 100-point scale was transformed into a 10-point scale for comparison purposes. Compared with baseline, pain was significantly improved at 0 to 1 week (mean reduced pain scores = 2.54 [95% CI: 1.92–3.16, $p < 0.01$] and at 1 to 5 weeks (3.56 [95% CI: 3.11–4.02, $p < 0.01$]), and at 5 to 14 weeks (4.22 [95% CI: 3.68–4.76, $p < 0.01$]). Pain outcomes were not assessed at all timepoints across trials and heterogeneity was high in all timeframes; nine studies (N = 268) assessed pain at 0 to 1 week (I^2 = 98.7%), 10 trials (N = 291) assessed at 1 to 5 weeks (I^2 = 98.2%), and nine trials (N = 289) assessed pain at 5 to14 weeks (I^2 = 99.7%). The overall complete response rate, defined as a pain score of 0 with no medication increase was 0.36 (95% CI: 0.24–0.48) and the partial response rate, defined as a drop of 2 on a 10-point scale without an increase in pain medications or a drop of 25% in pain medication without increase in the reported pain score,

was 0.47 (95% CI: 0.36–0.58), and no response (no drop of score and no changes in medication use) rate was 0.23 (95% CI: 0.13–0.34). Among the 14 studies (N = 352) reporting complications, 93 (26.4%) patients had minor complications and five (1.42%) had major complications.

A SR by Gennaro (2019) evaluated multiple thermal ablation techniques for relief of bone pain due to metastatic disease, including MRgFUS, radiofrequency ablation, microwave ablation and cryoablation.[69] The review included 11 papers and reported a mean reduction in pain scores of 26% to 91% at four weeks and 16% to 95% at 12 weeks. The authors noted that MRgFUS was associated with a higher rate of adverse events than the other modalities. All techniques achieved pain relief at one and three months in up to 91% and 95% of patients respectively. Across all modalities, the number of minor complications ranged from 0 to 59 (complication ratio 0–1.17), and the number of significant adverse effects ranged from 0 to 4 (complication ratio 0–0.04). Specific to MRgFUS, only the RCT by Hurwitz (2014, below) reported complications, which are summarized below.

Randomized Controlled Trials

Hurwitz (2014) published results from a randomized trial that evaluated the safety and efficacy of MRgFUS on palliation of pain due to bone metastases.[70] The study was included in the SRs discussed above and included patients age 18 years and older with at least three months of life expectancy who had bone metastases that were painful, despite radiotherapy treatment, or who were unsuitable for or declined radiotherapy. Patient-rated tumor pain on a numeric rating scale (NRS) at four or higher on a 10-point scale and up to five painful lesions were inclusion criteria, however, only one lesion was treated and it had to cause at least two points greater pain on the NRS than any other lesion. In addition, targeted tumors needed to be device accessible.

Study participants were randomized in a 3:1 ratio to active (n=122) or sham (n=39) MRgFUS treatment. Ten patients in the treatment group and four in the sham group did not receive the allocated treatment. An additional 26 patients in the treatment group and 23 in the sham group did not complete the three-month follow-up. A much larger proportion of the placebo group dropped out; 17 (49%) of 35 who were treated decided to have rescue MRgFUS treatment after lack of response to placebo. A modified intention-to-treat analysis was used that included patients who had at least one MRgFUS or placebo sonication. Missing values were imputed using the last observation carried forward method.

The primary efficacy end point, assessed at three months, was a composite outcome comprised of change in baseline in worst NRS score and morphine equivalent daily dose (MEDD) intake. Patients were considered responders if their worst NRS score decreased by at least two points and if their MEDD intake did not increase more than 25% from baseline to three months. NRS score and MEDD intake separately were reported as secondary outcomes.

Seventy-two (64%) of 112 patients in the MRgFUS group and seven (20%) of 35 patients in the control group were considered responders, as previously defined. The difference between groups was statistically significant (p=0.01), favoring active treatment. When the two measures comprising the primary end point were analyzed separately, there was a statistically significant difference between groups in change in worst NRS score and a nonsignificant difference in change from baseline in pain medication. The NRS score decreased by a mean (SD) of 3.6 (3.1) points in the MRgFUS group and by a mean of 0.7 (2.4) in the placebo group (p<0.01). Change in MEDD was only reported in a figure. Fifty-one (46%) patients in the MRgFUS group

and one (3%) in the placebo group experienced at least one adverse event (AE). Most AEs were transient, and the most common was sonication pain, experienced by 36 (32%) patients in the MRgFUS group. In 17 (15%) patients, sonication pain was severe; three patients did not complete treatment due to pain. The most clinically significant AEs that lasted more than a week were third-degree skin burns in one patient (associated with noncompliance with the treatment protocol) and fracture in two patients (one of which was outside the treatment location). Potential limitations of the trial included a nonconventional primary outcome measure and the small initial size of the sham group. Moreover, a large number of sham patients (66%) did not complete the three-month follow-up; the authors did state that this low completion rate was due to lack of response to placebo treatment. Additional randomized studies are required to isolate the treatment effect of MRgFUS upon pain and better characterize the benefit and length of symptom relief with MRgFUS in patients with bone metastases.

Nonrandomized Studies

Lee (2017) published the results of a matched-pair study of MRgFUS or conventional radiation therapy (RT) as a treatment for patients with painful bone metastasis.[71] A total of 63 patients (21 MRgFUS and 42 RT-treated) were matched 1:2 by age, sex, primary cancer, pretreatment pain score, and treated site. All patients were followed for at least three months post-treatment. Mean numerical rating scale (NRS) for the MRgFUS-treated group was significantly lower at one week post-treatment (2.5 versus 4.8, $p < 0.0001$), two weeks (2.1 versus 3.6, $p < 0.05$) and three months (1.0 versus 2.3, $p < 0.05$) post-treatment compared to the RT-treated group, however, no significant difference was found at one or two month timepoints. Mean morphine-equivalent daily dose change from baseline did not differ between groups. At one week post-treatment, 71% of the MRgFUS and 26% of the RT- treated patients had experienced a treatment response (successful pain palliation), a statistically significant difference ($p<0.001$). No statistically significant group difference in response rate were found at subsequent timepoints. No adverse events above grade 2 were observed for either group. This study was limited by small sample size and short-term follow-up.

Examples of nonrandomized trials include four small (n=11 to 31), nonrandomized prospective studies evaluating MRgFUS for the treatment of bone metastases, the majority of which are industry-sponsored.[72-75] Although none reported any treatment-related adverse effects, and all reported improvements in pain and two reported decreases in analgesic use, independent verification of treatment effects with larger groups of patients is needed. At present, results from these trials are not sufficient to reach conclusions regarding the impact of MRgFUS in palliation of pain related to bone metastases due to methodological limitations such as lack of an appropriate control group for comparison.

In addition, there have been several small case series published on the use of MRgFUS for treatment of bone metastases. However, these series did not compare the safety and efficacy of this treatment to other treatment options.

Other Tumors

MRgFUS is also being studied for several other clinical applications, including the treatment of benign and malignant tumors. As with MRgFUS treatment for uterine fibroids and bone metastases, randomized controlled trials comparing this technique with the current standard of care for the condition being treated are required in order to assess the efficacy of this treatment approach.

Breast Tumors

Nonrandomized Studies

No controlled studies evaluating MRgFUS for treating breast cancer have been identified in the published literature. Evidence is limited to small case series, examples of which include six feasibility studies that describe preliminary results only[76-81] Fibroadenoma, ductal carcinomas, adenocarcinomas, and lobular carcinomas were treated. The adverse effects profile includes a few second-degree skin burns, and protocols maintain a roughly 1cm distance between the tumor margin and the skin or rib cage. Residual tumor in the treated area appears to be a problem, with authors recommending treatment of the entire tumor plus 1 cm of surrounding tissue, as is done in lumpectomy. No long-term outcome studies are available. As with uterine fibroids, interpretation of these results is limited by the lack of a comparative treatment group. A 2016 case series by Merckel[82] included ten patients with early-stage invasive breast cancer who underwent MRgFUS prior to surgical resection. Ablation was confirmed histopathologically in six of these patients. The investigators concluded that MRgFUS is safe and feasible. A noted limitation is the long procedure time (average, 145 minutes), due to waiting time after contrast injection and time to find a proper magnetic resonance navigator signal.

Brain Cancer

Nonrandomized Studies

Evidence on MRgFUS in brain cancer is similarly restricted to case series, which include a report of initial findings in three patients.[83] The authors reported that it was possible to focus an ultrasound beam into the brain transcranially, and they believe that thermal ablation without overheating the brain is possible; however, substantial technical barriers to using MRgFUS for treating brain tumors remain. Larger and longer comparative trials are needed to establish the use of MRgFUS for treating this indication.

Prostate Cancer

Nonrandomized Studies

Ghai (2021) conducted a phase II trial to evaluate the safety and efficacy of transrectal MRgFUS treatment for intermediate-risk prostate cancer in 44 men, 36 with grade group (GG) 2 and eight with GG 3 disease.[84] The primary efficacy endpoint was the presence of residual disease at the treatment site at five months post- procedure. The International Prostate Symptom Score (IPSS) and International Index of Erectile Function-15 (IIEF-15) score were assessed at six weeks and five months, and multiparametric MRI and targeted biopsy of the treated area was obtained at five months post-procedure. Ninety-three percent of patients (95% CI: 82, 98) were free of clinically significant prostate cancer, defined as (≥6 mm GG 1 disease or any volume ≥GG 2 disease) at the five-month biopsy. Median IIEF-15 and IPSS scores were not significantly different at baseline compared to five months (IIEF-15 score at baseline, 61 [IQR, 34–67] and at five months, 53 [IQR, 24–65.5], p = 0.18; IPSS score at baseline, 3.5 [IQR, 1.8–7] and at five months, 6 [IQR, 2–7.3], p = 0.43). Seven percent (95% CI, 2.4 to 18.2) had residual disease at five months after ablation. No major treatment-related adverse events were reported, however, 16 patients reported dysuria; five patients required antispasmodics for bladder spasm in the first week; two patients had urinary retention; and one patient had severe pelvic pain. Study limitations include the short follow-up time to assess

efficacy; however, a biopsy at a 24-month follow-up is planned, which will address persistence and recurrent prostate cancer.

Small (n=1 to 5) feasibility studies regarding the use of MRgFUS in patients with biopsy-proven prostate cancer have demonstrated that the procedure may be performed in this patient population.[85-87] At least one study was conducted using the ExAblate® 2100 System, which is not FDA approved for this indication. Larger and longer comparative trials are needed to establish the use of MRgFUS for treating prostate cancer.

Other tumors

Several studies have investigated the use of MRgFUS for nonspinal osteoid osteoma.[88-90] Arrigoni (2021) conducted a propensity score-matched retrospective study to compare treatment with radiofrequency ablation and MRgFUS.[89] A total of 116 patients were treated (61 with radiofrequency ablation and 55 with MRgFUS). After propensity score matching, both radiofrequency ablation and MRgFUS treatment resulted in a significant reduction in pain from baseline as measured by VAS (8.9 to 0.02 and 8.8 to 0.54, respectively). There was no statistically significant difference between the mean values of both groups after the treatment. Four cases of relapse (one with radiofrequency ablation and three with MRgFUS) were observed. Arrigoni (2019) prospectively enrolled children into a study to evaluate MRgFUS treatment for osteoid osteoma.[88] The primary clinical endpoint was defined as the absence of pain (evaluated on the Faces Pain Scale-Revised) at the first follow-up study one week after the procedure. A total of 33 children were included in the study and treated with MRgFUS. The mean pain score at baseline was 7.6; the score at week one after the procedure significantly improved in all children (mean score, 0.21). Complete absence of pain was reported in 32 of 33 (97%; 95% CI, 84 to 100) of patients at week one. At the 24-month follow-up visit, imaging results confirmed the complete disappearance of bone edema around all lesions. Geiger (2014) prospectively enrolled patients into a study to evaluate MRgFUS treatment for osteoid osteoma.[90] Clinical success was evaluated based on pain reduction (evaluated on a VAS) through 12 months. At the 12-month follow-up, complete clinical success was achieved in 90% of the 29 patients enrolled (mean VAS, 0±0 points); partial success was achieved in the remaining patients (mean VAS, 5±0 points).

PRACTICE GUIDELINE SUMMARY

AMERICAN CONGRESS OF OBSTETRICS AND GYNECOLOGISTS

A practice bulletin from American Congress of Obstetrics and Gynecologists (ACOG) considered MRgFUS as an alternative to hysterectomy as a treatment of uterine fibroids, but did not specifically recommend its use, stating:[91]

> Whereas short-term studies show safety and efficacy, long-term studies are needed to discern whether the minimally invasive advantage of MRI-guided focused ultrasound surgery will lead to durable results beyond 24 months. Protocols for treating larger leiomyoma volumes are being studied.

AMERICAN COLLEGE OF RADIOLOGY

The 2017 American College of Radiology (ACR) Appropriateness Criteria guidelines regarding the treatment of uterine fibroids mention the use of MRgFUS indicating that, “(t)o date, there is

little long-term information on the efficacy of [MRgFUS] technology."[92] However, the MRgFUS approach is not recommended as treatment for fibroids.

AMERICAN UROLOGICAL ASSOCIATION

In 2017, the American Urological Association (AUA) published a joint guideline (with the American Society for Radiation Oncology [ASTRO], and the Society of Urologic Oncology [SUO] regarding clinically localized prostate cancer.[93] Nearly all recommendations regarding HIFU as a treatment for prostate cancer were Expert Opinion, that is, the committee did not have sufficient evidence to grade the strength of the evidence. Additionally, the following recommendation was made:

> *Clinicians should advise localized prostate cancer patients considering HIFU that tumor location may influence oncologic outcome. Limiting apical treatment to minimize morbidity increases the risk of cancer persistence. (Moderate Recommendation; Evidence Level: Grade C)*
>
> Grade C (RCTs with serious deficiencies of procedure or generalizability or extremely small sample sizes or observational studies that are inconsistent, have small sample sizes, or have other problems that potentially confound interpretation of data).

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN) guideline for prostate cancer (version 1.2023) include high-intensity focused ultrasound ablation as a recommended treatment option in the presence of radiation recurrence in a manner that is consistent with the policy criteria. (Category 2B: Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate).[1]

The NCCN Guideline on adult cancer pain (version 2.2022) does not include ultrasound ablation specifically in pain management algorithms, however, the guideline states:[94]

> Image-guided ablation of bone lesions has proven successful in pain management, especially for those failing to achieve adequate analgesia without intolerable effects. Several small studies also have demonstrated the palliative effects of HIFU treatment of bone lesions.

SOCIETY OF OBSTETRICIANS AND GYNAECOLOGISTS OF CANADA

In 2015, the Society of Obstetricians and Gynaecologists of Canada published a clinical practice guideline entitled "Management of Uterine Fibroids in Women with Otherwise Unexplained Fertility."[95] The guideline states that there are no studies comparing MRgFUS with myomectomy or in women with fibroids who have infertility as their primary complaint, and thus additional data are needed before the treatment is offered to this patient population.

SUMMARY

HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU) ABLATION

It appears that high-intensity focused ultrasound (HIFU) ablation may improve overall health outcomes for select men with localized recurrent prostate cancer. Clinical guidelines based

on research recommend HIFU for specific patient populations. Therefore, high-intensity focused ultrasound may be considered medically necessary to treat localized prostate cancer when policy criteria are met. Due to a lack of research and clinical practice guidelines, HIFU is considered investigational for all other indications that do not meet the policy criteria.

MAGNETIC RESONANCE (MR) GUIDED FOCUSED ULTRASOUND (MRGFUS)

Movement Disorders

Medicine-Refractory Essential Tremor

It appears that Magnetic Resonance-guided focused ultrasound (MRgFUS) may help those with medicine-refractory essential tremor. At least one high quality randomized study and several large systematic reviews of MRgFUS use specifically in the treatment of essential tremor have demonstrated improvement in symptoms with MRgFUS treatment and improved overall quality of life. Therefore, MRgFUS may be considered medically necessary for medicine-refractory essential tremors when policy criteria are met.

Parkinson's Disease

There is not enough research to know if or how well Magnetic Resonance-guided focused ultrasound (MRgFUS) works to treat people with Parkinson's Disease. There is evidence that the use of MRgFUS in the treatment of Parkinson's Disease is associated with high rates of adverse events. No evidence-based clinical practice guidelines recommend MRgFUS for the treatment of Parkinson's Disease. Therefore, treatment of Parkinson's Disease with MRgFUS is considered investigational.

Palliative Treatment of Bone Metastases

It appears that Magnetic Resonance-guided focused ultrasound (MRgFUS) may provide effective palliation of pain due to bone metastases in adults. Evidence-based clinical practice guidelines note the success of image-guided ablation in pain management, especially for those failing to achieve adequate analgesia without intolerable effects Therefore, pain palliation of bone metastases with MRgFUS may be considered medically necessary when policy criteria are met.

Uterine Fibroids

The evidence for MRgFUS in individuals who have uterine fibroids includes a pilot RCT, nonrandomized comparative studies, and case series. The pilot RCT (N=20 patients) reported some health outcomes, but its primary purpose was to determine the feasibility of a larger trial. It did not find statistically significant differences in quality of life outcomes between active and sham treatment groups, but did find lower fibroid volumes after active treatment. The pivotal Food and Drug Administration trial was not randomized, the clinical significance of the primary outcome was unclear, and there were no follow-up data beyond one year. The limited nature of this evidence-base raises concerns about the reliability and validity of reported findings. In particular, the durability of any early treatment effect with MRgFUS given the potential for regrowth of treated fibroids, is not clearly understood. Therefore, treatment of uterine fibroids with MRgFUS is considered investigational.

Other Tumors and Other Indications

(MRI)-guided focused ultrasound (MRgFUS) is being investigated for use in several applications that are not currently approved by the FDA. There are some preliminary reports of safety and efficacy in small numbers of patients; however, this evidence is insufficient, and the impact of MRgFUS on health outcomes remains unknown. Due to the lack of evidence from well-designed randomized controlled trials, the use of MRgFUS for the treatment of any condition is considered investigational when policy criteria are not met.

CODES

NOTE: There are no specific CPT codes for the use of magnetic resonance–guided high-intensity ultrasound ablation in certain cancers. In these situations an unlisted code would be used based on the anatomic location of the metastasis being treated (eg, 23929 for the clavicle) or perhaps one of the radiation oncology unlisted codes (eg, 77299 or 77499).

Codes	Number	Description
CPT	0071T	Focused ultrasound ablation of uterine leiomyomata, including MR guidance; total leiomyomata volume of less than 200 cc of tissue
	0072T	;total leiomyomata volume greater or equal to 200 cc of tissue
	0398T	Magnetic resonance image guided high intensity focused ultrasound (MRgFUS), stereotactic ablation lesion, intracranial for movement disorder including stereotactic navigation and frame placement when performed
	23929	Unlisted procedure, shoulder
	55880	Ablation of malignant prostate tissue, transrectal, with high intensity-focused ultrasound (HIFU), including ultrasound guidance
	58578	Unlisted laparoscopy procedure, uterus
	58579	Unlisted hysteroscopy procedure, uterus
HCPCS	C9734	Focused ultrasound ablation/therapeutic intervention, other than uterine leiomyomata, with magnetic resonance (MR) guidance

Date of Origin: *October 2004*

Medical Policy Manual Surgery, Policy No. 145

Automated Percutaneous and Percutaneous Endoscopic Discectomy

Effective: November 1, 2023

Next Review: July 2024
Last Review: September 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Automated percutaneous and percutaneous endoscopic discectomy are techniques used to remove spinal disc material for treatment of herniated discs.

MEDICAL POLICY CRITERIA

Note: This policy does *not* address intradiscal electrothermal annuloplasty (IDET), percutaneous intradiscal radiofrequency thermocoagulation (PIRFT), or laser discectomy and radiofrequency disc decompression which are considered in separate medical policies (see Cross References below).

Automated percutaneous and percutaneous endoscopic discectomy are considered **investigational** as techniques for intervertebral disc decompression in patients with back pain and/or radiculopathy related to disc herniation in the lumbar, thoracic, or cervical spine.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

1. Percutaneous Intradiscal Electrothermal Annuloplasty, Radiofrequency Annuloplasty, and Biacuplasty, Surgery, Policy No. 118
2. Decompression of Intervertebral Discs Using Laser Energy (Laser Discectomy) or Radiofrequency Energy (Nucleoplasty), Surgery, Policy No. 131
3. Image-Guided Minimally Invasive Spinal Decompression (IG-MSD) for Spinal Stenosis, Surgery, Policy No. 176

BACKGROUND

Back pain or radiculopathy related to herniated discs is an extremely common condition and a frequent cause of chronic disability. Surgical decompression is often considered when the pain is unimproved with conservative therapy and is clearly neuropathic in origin, resulting from irritation of the nerve roots.

This policy addresses automated percutaneous and percutaneous endoscopic removal of disc material as minimally invasive alternatives to open surgical excision for disc decompression. Automated percutaneous discectomy involves placement of a probe within the intervertebral disc and aspiration of disc material using a suction cutting device. Endoscopic discectomy involves the percutaneous placement of a working channel under image guidance, followed by visualization of the working space and instruments through an endoscope, and aspiration of disc material. Endoscopic discectomy may also be referred to as arthroscopic discectomy.

REGULATORY STATUS

The Stryker DeKompressor® Percutaneous Discectomy Probe (Stryker), Herniatome Percutaneous Discectomy Device (Gallini Medical Devices), and the Nucleotome® (Clarus Medical) are examples of percutaneous discectomy devices that received clearance from the U.S. Food and Drug Administration (FDA) through the 510(k) process. Both have the same labeled intended use, i.e., “for use in aspiration of disc material during percutaneous discectomies in the lumbar, thoracic and cervical regions of the spine.”

A variety of endoscopes and associated surgical instruments have received marketing clearance through the FDA’s 510(k) process.

EVIDENCE SUMMARY

The primary beneficial outcomes of interest for treatment of spinal pain are relief of pain and improved function. Both outcomes are subjective and can be influenced by nonspecific effects, placebo response, and the variable natural history of the disease. Therefore, large, blinded, randomized controlled trials (RCTs) with long-term follow-up are necessary to establish the safety and efficacy of automated percutaneous and percutaneous endoscopic discectomy compared with open surgical discectomy, the current standard of care for surgical removal of damaged intervertebral disc material. These comparisons are necessary to determine whether any beneficial treatment effects of percutaneous and endoscopic discectomy outweigh any risks and provide a significant advantage over conventional open discectomy techniques.

AUTOMATED PERCUTANEOUS DISCECTOMY (APD)

Systematic Reviews

Several systematic reviews (SRs) have been published since 2007.[1-7] Four comparative trials have been published on APD, two comparing APD to chymopapain chemonucleolysis[8, 9] and two comparing APD to microdiscectomy[10, 11]. These trials suggested that APD produced inferior results to either of the established procedures, though the patient selection criteria may have been inappropriate in the Revel (1993) trial[8]. The authors of the systematic reviews reached similar conclusions, that while there is considerable evidence of efficacy for conventional surgical discectomy, there is insufficient evidence on percutaneous discectomy techniques including APD to draw firm conclusions. “Trials of automated percutaneous discectomy and laser discectomy suggest that clinical outcomes following treatment are at best fair and certainly worse than after microdiscectomy, although the importance of patient selection is acknowledged.[1]” A 2015 network meta-analysis found that percutaneous discectomy was one of the least effective treatment strategies for sciatica of 21 assessed.[12]

The four RCTs reviewed in the SRs had several methodological limitations including small size, high loss to follow-up, inadequate randomization procedure, between-group heterogeneity, and other significant design flaws. For example, the LAPDOG study was initially designed to recruit 330 patients, but only was able to recruit 36 patients for reasons that were not readily apparent to the authors.[11] Of the evaluable 27 patients, 41% of the percutaneous discectomy patients and 40% of the conventional discectomy patients were assessed as having successful outcomes at six months. The authors concluded that this trial was unable to enroll sufficient numbers of patients to reach a definitive conclusion. The authors stated, “It is difficult to understand the remarkable persistence of percutaneous discectomy in the face of a virtually complete lack of scientific support for its effectiveness in treated lumbar disc herniation.”

In a 2013 review for their practice guideline[13], the American Society of Interventional Pain Physicians noted that “the available literature on Dekompressor illustrates the common shortcomings of observational studies of interventions. Even though Dekomporssor may be considered a new interventional modality, the early studies were published approximately eight years ago. Consequently, one would expect that the technique’s continued use would be supported by more recent, high quality evaluations. Even though all the studies are of moderate quality, they lack scientific rigor because of their observational, albeit prospective, design. Further, these studies do not include sufficiently large numbers of patients.”

Randomized Controlled Trials

No RCTs were identified after the search dates of the systematic review.

ENDOSCOPIC DISCECTOMY

Systematic Reviews

Li (2022) published a systematic review comparing endoscopic discectomy to non-endoscopic discectomy for the treatment of symptomatic lumbar disc herniation.[14] A total of 25 studies were added, with 20 studies comparing endoscopic discectomy to non-endoscopic discectomy and five studies comparing percutaneous endoscopic transforaminal discectomy (PETD) to percutaneous endoscopic interlaminar discectomy (PEID). Operation time was longer and intraoperative blood loss volume was lower for microendoscopic discectomy (MED) compared to open discectomy. Complication rates were lower for percutaneous endoscopic lumbar discectomy (PELD) compared to fenestration discectomy and also for full-endoscopic discectomy compared to microscopic discectomy. The authors reported that there are some

potential advantages to endoscopic discectomy procedures, however more high quality randomized trials with large sample sizes are needed.

Zhang (2022) published a systematic review comparing percutaneous transforaminal endoscopic discectomy (PTED) to open lumbar discectomy in patients with lumbar disc herniations.[15] Nine studies were included in the review with a total of 1679 patients. There were no significant difference in excellent rates (OR = 1.47, 95% CI: 0.94-2.28, P= 0.09), reoperation rates (OR = 0.96, 95% CI: 0.50-1.84, P = 0.90), length of operation (SMD = -17.97, 95% CI: -54.83-18.89, P = 0.34], and the amount of intraoperative blood loss (SMD = -128.05, 95% CI: -258.67-2.57, P = 0.05), respectively. There were significant differences in complication rates (OR = 0.22, 95% CI: 0.14-0.33, P < 0.001), length of incision (SMD = -2.76, 95%CI: -2.88--2.65, P < 0.001), and length of hospital stay (SMD = -5.19, 95%CI: -5.36--5.01, P < 0.001), respectively. The authors concluded that PTED shows better outcomes for complication rate, incision size, and length of hospital stay compared to standard discectomy, however there was heterogeneity in inclusion criteria, baseline characteristics, and follow-up time in the included studies. Additionally, comparisons for each outcome were not equal and some comparison of outcomes had relatively small numbers of trials.

Zhang (2022) published a systematic review of nine, nonrandomized trials evaluating the safety and efficacy of percutaneous endoscopic cervical discectomy (PECD) in patients with cervical disc herniation.[16] The pooled results demonstration that VAS scores at one week follow-up and at last follow-up (varying times) were significantly lower than baseline VAS scores. The authors also reported pooled results showing decreased operative time and hospital stays for PECD compared to anterior cervical discectomy and fusion (ACDF). There is a need for high quality randomized trials with long-term follow-up and comparison to standard of care procedures, such as ACDF, to establish the clinical utility of PECD in patients with cervical disc herniation.

Zhao (2022) published a systematic review comparing PELD to MED and traditional open surgery for the treatment of lumbar disc herniation.[17] A total of 6467 cases across 33 studies were included in the review which assessed several outcomes such as blood loss, recovery time, VAS for pain, ODI, and revision or recurrence rates. PELD showed superior results compared to MED in some outcomes (e.g., blood loss, postoperative bed time, hospital stay duration), but show inferior results in other outcomes like revision and recurrence rates. Other outcomes were similar across groups including operation times, postoperative VAS for leg pain, and operation success. Additional studies are needed to demonstrate superior efficacy and outcomes for PELD compared to existing standards of care.

Bai (2022) published a systematic review with meta-analysis of 14 studies (N=2,528) comparing PELD to other surgical approaches to lumbar disc herniation (LDH).[18] Outcomes evaluated were success rate, recurrence rate, complication rate, operation time, hospital stay, blood loss, visual analog scale (VAS) score for back pain and leg pain, 12-item Short Form Health Survey (SF12) physical component score and mental component score, Japanese Orthopaedic Association Score, and Oswestry Disability Index. PELD had favorable clinical outcomes for PELD compared to other surgical approaches, including shorter operation time (weight mean difference, WMD=-18.14 minutes, 95% CI -25.24, -11.05; p<0.001) and hospital stay (WMD = -2.59 days, 95% CI -3.87, -1.31; p<0.001), less blood loss (WMD = -30.14 ml, 95% CI -43.16, -17.13; p<0.001), and improved SF12- mental component score (WMD = 2.28, 95% CI 0.50, 4.06; p=0.01) and physical component score (WMD = 1.04, 95% CI 0.37, 1.71; p=0.02). No significant difference between the PELD group and other surgical group was found

in success rate, complication rate, or other clinical outcomes assessed. PELD was associated with a significantly higher rate of recurrent disc herniation (relative risk [RR] = 1.65, 95% CI 1.08, 2.52; p=0.02).

Chen (2020) published a SR with meta-analysis comparing complication rates of surgical treatments of symptomatic lumbar disc herniation which included discectomy/microdiscectomy (OD/MD), MED, PELD, percutaneous laser disc decompression (PLDD), and tubular discectomy.[19] The review included 17 RCTs and 20 cohort studies. Overall complication rates of 16.8% and 16.1%, 21.2%, 5.8%, 8.4%, and 25.8% were found for RCTs evaluating OD/MD, MED, PELD, PLDD, and tubular discectomies, respectively. Moderate-quality evidence was found suggesting that, compared to OD/MD, PELD had a lower risk of overall complications (RR = 0.52, 95% CI 0.29-0.91) and high-quality evidence suggesting a lower risk of Type I complications (RR = 0.37, 95% CI 0.16-0.81). Compared with the data from cohort studies, there was low-quality evidence reported suggesting a higher risk of reherniations (RR = 1.67,95% CI 1.05-2.64) and reoperations (RR = 1.75, 95% CI 1.20-2.55) for PELD compared to OD/MD.

A SR with meta-analysis published by Xu (2020) evaluated mid- and long-term outcomes in single-level lumbar disc herniation treated with PELD or MED.[20] One prospective RCT and eight retrospective nonrandomized comparative studies were included (PELD N=468, MED N=516). Although no difference between groups within 24 months were found, at 24 months postoperative, significantly better outcomes were found in the PELD group compared to MED for low back pain visual analog scale score and Oswestry Disability Index (ODI) score (OR=-0.856, 95% CI -1.488 to -0.224, p=0.008; OR=-0.425, 95% CI -0.724 to -0.127, p=0.005). No significant differences were found in complication, recurrence, or reoperation rates at any timepoint reported.

Yu (2019) compared PTED to MED in a SR of eight comparative studies with a total of 805 patients.[21] Hospital stay, time in bed, incision length were shorter with PTED, but there were not differences between the interventions in surgical time or intraoperative blood loss. Visual Analogue Scale (VAS) back and leg pain scores were similar between groups at most time points, with the exception of lower leg pain VAS score at one week in the PTED group.

A meta-analysis by Alvi (2018) included 14 RCTs or quasi-randomized trials (total n=1,707), and compared OD/MD to minimally invasive procedures including percutaneous discectomy, percutaneous endoscopic discectomy (PED), and tubular discectomy (TD) for lumbar disc herniation.[22] All of the studies were determined to have a serious risk of bias and were judged to be of low or very low quality. No differences were seen between groups for VAS score. ODI score was lower for TD than for other procedures at one year (mean difference 1.17, 95% confidence interval [CI] 0.10 to 2.24, p=0.03), and at last follow-up, ODI scores were worse with OD/MD compared to TD and PED (mean difference 2.61, 95% CI 0.88 to 4.65, p=0.03). Open procedures were also associated with longer hospital stays and greater blood loss. TD was associated with a greater rate of complications and recurrent herniations than the other procedures, while MD/OD had significantly lower rates of recurrent herniations and revision surgery than TD or PED.

A meta-analysis by Ding (2018) compared PTED to fenestration discectomy (FD) in patients with lumbar disc herniation.[23] There were 17 studies included in the analysis, and all were retrospective studies. There were 733 patients who had PTED and 657 who had FD. There was no difference between groups for VAS score, but the PTED group had shorter operation,

bed rest, and hospitalization times (all p<0.00001), less bleeding (p<0.00001), and a lower postoperative ODI score (p=0.02). Long-term outcomes were not assessed in this study.

Phan (2017) published a SR comparing full endoscopic discectomy (FED) and MED with open discectomy for the treatment of lumbar disc herniation.[24] A database search through February 2016 identified 23 studies for inclusion. FED was favorable compared with open discectomy in surgery duration, hospital length of stay (LOS), and blood loss. MED was favorable compared with open discectomy in LOS and blood loss. Both endoscopic procedures were comparable to open discectomy as measured on a VAS for leg pain and ODI score. In terms of patient satisfaction, FED was more favorable than open discectomy and MED was comparable to open discectomy. The authors concluded that FED and MED are safe alternatives to other procedures, but more RCTs are needed to investigate and validate these as options for discectomies.

Li (2016) published a SR comparing FED with traditional discectomy surgery.[25] The search was conducted in January 2015 and resulted in the inclusion of four RCTs and two non-RCTs. FED for herniation (both cervical and lumbar) was favorable compared with traditional discectomy in operative duration, blood loss, length of stay, and return to work days. Clinical outcomes were comparable between FED and traditional discectomy. The authors concluded FED is effective, but larger RCTs with long-term follow-up are needed.

A 2016 meta-analysis identified nine RCTs (total n=1,092 patients) that compared endoscopic to open discectomy for lumbar disc herniation.[26] Endoscopic discectomy resulted in clinical outcomes similar to open discectomy, but had significantly greater patient satisfaction, lower intraoperative blood loss, and shorter hospital lengths of stay.

He (2016) reported results from another meta-analysis of five RCTs (n=501 patients) comparing outcomes from MED and open discectomy for patients with lumbar herniation.[27] Pooled analysis found no difference in VAS, ODI, or complication between the two groups. MED was associated with less blood loss, shorter length of hospital stay, and longer operation time.

A Cochrane review (2014) of literature through 2013 evaluated 11 studies of minimally invasive discectomy compared with microdiscectomy/open discectomy. Seven of the studies reviewed[10, 28-33] were rated as having a high risk of bias and the remaining four studies[34-37] were rated as having a low risk of bias. Included in the review were eight RCTs or quasi-RCTs that evaluated percutaneous endoscopic lumbar discectomy.[38] Also included were three studies on transmuscular tubular microdiscectomy and automated percutaneous lumbar discectomy. The review concluded that minimally invasive discectomy may be inferior in terms of relief of leg pain, low back pain, and rehospitalization; however, differences in pain relief appeared to be small and may not be clinically important. In addition, potential advantages of minimally invasive discectomy are a lower risk of surgical site infection and shorter hospital stay. Because of these potential advantages, the authors concluded that more research was needed to define the indications for minimally invasive discectomy.

Smith (2013) published a SR of MED for lumbar disc herniation.[39] A search was conducted for controlled trials published after the 2007. The Gibson and Waddel (2007) Cochrane review through September 2012 identified four RCTs. None of the studies found a significant difference in ODI scores compared with open discectomy or microdiscectomy. In the largest study, which included 240 patients, Teli (2010) reported an increase in the number of severe complications in the microendoscopic discectomy group.[36] In another large study with 112

patients Garg (2011) found a shorter hospital stay with no significant changes in ODI or complication rates but recommended that microendoscopic discectomy should not be attempted without appropriate training.[28] The two other trials included in the review were small, with 22[29] and 40[30] patients.

Randomized Controlled Trials

The following is a summary of randomized or quasi-randomized trials that were not included in the above systematic reviews.

Cervical disc decompression

Ruetten (2009) compared anterior endoscopic discectomy with anterior cervical discectomy and fusion (ACDF) in 120 patients with mediolateral cervical disc herniations.[40] The duration of pain ranged from 4 to 128 days. The mean operating time was 32 minutes for the endoscopic discectomy compared to 62 minutes for ACDF. In the endoscopic discectomy group, bone resection was required to reach the epidural space or the foramen in 55% of cases. At 24 months, 103 patients (86%) were available for follow-up examinations. The revision rate was 6.1% for ACDF and 7.4% for endoscopic discectomy; these were not significantly different. Excluding four patients who were revised by ACDF, 85 patients (85.9%) had no arm pain; there were no significant differences in clinical outcomes between the two groups. Advantages and disadvantages of the anterior endoscopic approach were discussed, including a difficult learning curve.

Lumbar disc decompression

Gadradj (2022) published the results of a RCT in 613 patients who underwent percutaneous transforaminal endoscopic discectomy (PTED, n=179) or conventional open microdiscectomy (n=309) for the treatment of lumbar disc herniation.[41] The primary outcome was self-reported leg pain measured by a 0-100 visual analogue scale and secondary outcomes included complications, reoperations, self-reported functional status as measured with the Oswestry Disability Index, visual analogue scale (VAS) for back pain, health related quality of life, and self-perceived recovery. At 12 months post-procedure, VAS scores for leg pain were lower in the PTED group (median 7.0, IQR 1.0-30.0) compared to the open microdiscectomy group (16.0, 2.0-53.5) (between group difference 7.1, 95% CI 2.8 to 11.3). Within one year, nine (5%) in the PTED group compared with 14 (6%) in the open microdiscectomy group had repeated surgery. This study was limited by lack of blinding.

Ran (2021) published the results of a RCT in 68 patients with highly migrated lumbar disc herniation who were randomized to computerized tomography (CT) navigation percutaneous spinal endoscopy (n=35) or open discectomy (n=33).[42] Although at one week post-procedure, VAS sores for back pain were significantly lower in the endoscopic group (1.30 ± 1.07 versus 2.44 ± 0.72, p< 0.01), at 12 months post-procedure, VAS scores were not statistically different between groups (0.58 ± 0.90 versus 0.75 ± 0.84, p=0.58). Limitations to the study design include unclear allocation concealment, apparent lack of blinding, and no power calculations reported.

Wang (2019) compared PTED to MED in a trial of 90 patients with lumbar disc herniation at a single center in China.[43] Patients in the PTED group had significantly better surgical and immediate postoperative outcomes (length of surgical incision, bleeding, postoperative bedridden time and hospital stay), while the MED group had shorter surgical time. Both groups

improved from baseline on low back pain VAS scores at three days, three months, and six months. Both groups also improved on ODI scores and there were no differences between groups postoperatively or up to six months after surgery.

Gibson (2017) published a RCT comparing transforaminal endoscopic discectomy (TED) with microdiscectomy.[44] Patients with single-level lumbar prolapse and radiculopathy were randomized to TED under conscious sedation (n=70) or to microdiscectomy under general anesthesia (n=70). Both procedures resulted in comparable improvements in outcomes (ODI scores, VAS back pain, VAS leg pain, SF-36 scores) at three months, one year, and two years compared with baseline. The trial noted limitations including being non-blinded.

Hussein (2014) reported the outcomes of 200 patients randomized to either microendoscopic lumbar discectomy (n=95) or to a control group in which patients underwent open lumbar discectomy (n=90).[45] The patients and investigators were not blinded to the treatment assignments. By eight years follow-up, data was available for 185 patients; 15 patients were lost to follow-up, 10 due to subsequent same-level fusion, three due to death unrelated to surgery, and two who did not response to telephone calls. Relief of leg pain was statistically significant for both groups, with no significant between-group difference. Back pain was significantly improved in the endoscopic group throughout the entire follow-up period. However, in the control group the significant improvement in back pain following surgery deteriorated over time; by eight years follow-up, back pain scores in this group had worsened significantly from preoperative scores. There were no serious complications in either group.

Nonrandomized Studies

Yu (2021) published the results of a retrospective multicenter study that followed patients for two years after receipt of transforaminal percutaneous endoscopic discectomy (n=632) and microendoscopic discectomy (n=421) for lumbar disc herniation.[46] Mean blood loss ($p<0.001$) and mean duration of hospital stay ($p=0.018$) were significantly less with transforaminal percutaneous endoscopic lumbar discectomy compared to microendoscopic discectomy. Rates of complications, recurrence, and revisions were similar in both groups. Visual analogue pain scores did not differ between groups after the first postoperative day. At 1 month postoperatively there was a significant difference in ODI scores between groups ($p=0.016$) in favor of transforaminal percutaneous endoscopic discectomy, but there was no difference at other time points.

Song (2021) published a retrospective single-center study that compared percutaneous endoscopic lumbar discectomy (n=306) and microendoscopic discectomy (n=116) in patients undergoing same day ambulatory surgery for lumbar disc herniation.[47] Mean blood loss and mean duration of hospital stay were significantly less with percutaneous endoscopic lumbar discectomy (both $p<0.001$ compared to microendoscopic discectomy). After three years of follow-up, visual analogue pain scores for the back were also significantly lower in the percutaneous endoscopic lumbar discectomy group compared to the microendoscopic discectomy group ($p=.001$) but there was no difference between groups in pain scores for the legs ($p=0.224$). Overall recurrence rates ($p=0.201$) and ODI scores ($p=0.220$) were also similar between groups.

PRACTICE GUIDELINE SUMMARY

AMERICAN SOCIETY OF INTERVENTIONAL PAIN PHYSICIANS (ASIPP)[13]

In 2013, a task force of the ASIPP published updated guidelines for interventional techniques in the management of chronic spinal pain. The evidence for APD and for percutaneous lumbar discectomy was rated as limited for short- and long-term relief based on all observational studies. An evidence rating of “limited” is defined as evidence insufficient to assess effects on health outcomes because of limited number or inadequate power of studies, large and unexplained inconsistency between higher-quality trials, important flaws in trial design or execution, gaps in the chain of evidence, or lack of information on important health outcomes. The ASIPP concluded that this technique may be performed when indicated, but did not provide patient selection criteria. Nor was the recommendation graded; the authors indicated only that this recommendation was based on “individual experience and the large amount of literature.” Therefore, this recommendation is not considered evidence-based.

NORTH AMERICAN SPINE SOCIETY (NASS)[48]

The 2014 practice guidelines from the NASS on the diagnosis and treatment of lumbar disc herniation with radiculopathy recommended that endoscopic percutaneous discectomy or automated percutaneous discectomy could be considered for the treatment of these patients. Both recommendations were grade C recommendations (poor quality evidence). However, a separate recommendation stated that evidence is insufficient to recommend for or against use of automated percutaneous discectomy compared with open discectomy.

THE AMERICAN SOCIETY OF PAIN AND NEUROSCIENCE (ASPN)[49]

ASPN (2022) published clinical guidance for interventional treatments for low back pain. The guideline states that discectomy procedures (such as percutaneous and endoscopic disc procedures) have favorable safety and efficacy profiles for the treatment of lumbar disc herniation with persistent radicular symptoms; however, it is stated that further research is needed to evaluate complications rates in order for these procedures to supplant classic open microdiscectomy.

SUMMARY

There is not enough research to show that automated percutaneous or percutaneous endoscopic discectomy improves health outcomes for people with back pain and/or radiculopathy related to disc herniation in the lumbar, thoracic, or cervical spine. Therefore, automated percutaneous or percutaneous endoscopic discectomy is considered investigational for people with back pain and/or radiculopathy related to disc herniation in the lumbar, thoracic, or cervical spine.

CODES

NOTE: CPT code 62287 specifically describes a percutaneous aspiration or decompression procedure of the lumbar spine. This code does not distinguish between an aspiration procedure (addressed in this policy) and a laser decompression procedure (addressed in separate medical policies). Also, note that this code is specifically limited to the lumbar region. Although the majority of percutaneous discectomies are performed on lumbar vertebrae, the FDA labeling of the Stryker DeKompressor Percutaneous Discectomy Probe includes the thoracic and cervical vertebrae.

Codes	Number	Description
CPT	62287	Decompression procedure, percutaneous, of nucleus pulposus of intervertebral disk, any method utilizing needle based technique to remove disc material under fluoroscopic imaging or other form of indirect visualization, with discography and/or epidural injection(s) at the treated level(s), when performed, single or multiple levels, lumbar
	62380	Endoscopic decompression of spinal cord, nerve root(s), including laminotomy, partial facetectomy, foraminotomy, discectomy and/or excision of herniated intervertebral disc, 1 interspace, lumbar
	64999	Unlisted procedure; nervous system
HCPCS	C2614	Probe, percutaneous lumbar discectomy

Date of Origin: *October 2005*

Medical Policy Manual Surgery, Policy No. 147

Ovarian, Internal Iliac, and Gonadal Vein Embolization, Ablation, and Sclerotherapy

Effective: July 1, 2023

Next Review: April 2024
Last Review: May 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Embolization involves occlusion of blood flow through the ovarian, internal iliac, and gonadal veins with coils, foam, or a chemical sclerosant as a treatment of pelvic congestion syndrome or varicoceles.

MEDICAL POLICY CRITERIA

Note: This policy does not address surgical ligation of the spermatic vein(s) or uterine artery embolization.

Embolization, ablation, and sclerotherapy of ovarian veins, internal iliac veins, or gonadal veins is considered **investigational** for the treatment of pelvic congestion syndrome and varicoceles.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

1. Varicose Vein Treatment, Surgery, Policy No. 104

BACKGROUND

Enlarged ovarian and internal iliac veins can lead to pelvic congestion syndrome in women, and enlarged gonadal and internal iliac veins can lead to a varicoceles in men. Each are discussed separately below.

PELVIC CONGESTION SYNDROME

Pelvic congestion syndrome (PCS), also called pelvic venous incompetence, is a rare condition characterized by chronic pelvic pain. Although this condition is primarily found in women it can also be found in men. PCS is often aggravated by standing for long periods of time, and often manifests during or after pregnancy. The syndrome is thought to be associated with dilated and refluxing incompetent pelvic veins, similar to what happens in varicose veins of the legs. However, the cause of PCS is unclear. Furthermore, there are no definitive diagnostic criteria for PCS. Instead the diagnosis is generally based on a combination of symptoms, tenderness on physical exam, and documentation of pelvic vein dilation or incompetence after excluding all other causes for the nonspecific findings. Although imaging may show vein dilation or incompetence, these findings are common nonspecific findings and therefore no diagnostic.

There is no standard treatment approach for PCS, and the optimum treatment is unknown. Instead, therapy is individualized and based on symptoms. Medical therapy is generally the first line of treatment, as it is low risk and non-invasive. Other methods, such as embolization has been proposed as an alternative to surgical treatment for patients who fail medical therapy with analgesics. Embolization therapy involves the occlusion of blood flow through the ovarian and internal iliac veins with coils, glue, or chemical sclerosants. The internal iliac veins may be treated at the same time or a later date to prevent recurrence.

VARICOCELES

A varicocele is the dilation of the pampiniform plexus of the gonadal veins. Varicocele's are present in 15 to 20% of post-pubertal males, and generally get larger over time. Most varicoceles occur in the left hemiscrotum because the left gonadal vein is one of the longest veins in the body and it enters the left renal vein at a perpendicular angle increasing pressure which can dilate the veins and cause incompetence of the valves, similar to what happens in varicose veins of the legs. Although varicoceles on the left are more common, bilateral varicoceles can occur; however, this could be caused by a possible underlying pathology warranting more investigation. Symptoms of a varicocele include dull, aching, left scrotal pain, which is often aggravated by standing for long periods of time, testicular atrophy, and decreased fertility. Although there are no clear guidelines regarding the established treatment for varicoceles, surgical ligation is the preferred first-line treatment.

EVIDENCE SUMMARY

The primary beneficial outcomes of interest for treatments of pelvic pain in both men and woman are symptom reduction and improvement in the ability to function. These are subjective outcomes that are typically associated with a placebo effect. Therefore, data from adequately powered, randomized controlled trials (RCTs) with sufficient long-term follow-up are required to control for the placebo effect, determine its magnitude, and to determine whether any treatment effect from provides a significant advantage over placebo or other treatment options.

TREATMENT FOR PELVIC CONGESTION SYNDROME

Health Technology Assessments

In 2016, Champaneria published a health technology assessment from the National Institute for Health Research that examined the diagnosis and treatment of pelvic vein incompetence and chronic pelvic pain in women.[1] Forty studies were included in the review; six association studies, ten studies involving ultrasound, two studies involving magnetic resonance venography, 21 case series, and one poor-quality randomized trial of embolization. The authors found that there were no consistent diagnostic criteria for pelvic congestion syndrome (PCS). Although the studies have showed associations between chronic pelvic pain (CPP) and pelvic vein incompetence (PVI), the prevalence of PVI ranged widely. The authors identified that transvaginal ultrasound with doppler and magnetic resonance venography are both useful screening methods; however, there is limited data on the accuracy of these methods for PCS. Finally, although the research showed embolization provides symptomatic relief in the majority of women, these studies were small case series. The authors concluded that more research is needed to determine what the diagnostic criteria for PCS are, and the efficacy of embolization as a treatment for PCS.

Systematic Reviews

Sutanto (2022) published a systematic review to study the efficacy and safety of the use of percutaneous coil embolization (CE) in isolation for pelvic venous reflux (PVR).[2] A total of 970 patients (range, 3-218, 100% female) undergoing isolated ovarian vein or mixed veins embolization from 20 studies were included. Pooled analysis revealed mean improvements of 5.47 points (95% CI, 4.77-6.16) on the visual analogue scale. Common symptoms such as urinary urgency and dyspareunia reported significant improvements of 78-100% and 60-89.5% respectively. Two randomized controlled trials revealed improved clinical outcomes with CE as compared with vascular plugs and hysterectomy. While this data suggests that isolated CE is technically effective and can result in clinical improvement among patients with PVR, further trials are required to ascertain the long-term effects.

A 2016 systematic review by Mahmoud identified 20 case series (total N=1081 patients) who underwent vein embolization for pelvic congestion syndrome.[3] The authors did not require any particular diagnostic criteria for pelvic congestion syndrome. The length of follow-up in the studies ranged from one month to six years. Seventeen studies (n=648 patients) reported the proportion of patients who reported symptom relief. Overall, 571 (88.1%) patients reported short-term symptom relief and 77 (11.9%) reported little or no relief. Seventeen studies (n=721 patients) reported symptom relief at 12 months. A total of 88.6% had symptom improvement and 13.4% reported little or no relief. Only one study used a comparison group, but patients in it received conservative treatment because they were ineligible for vein embolization therapy, so outcomes after the two interventions cannot be compared.

A systematic review by Daniels (2016) assessed the effectiveness of sclerotherapy or embolization for the treatment of chronic pelvic pain.[4] The review included 21 case series and one poor-quality randomized trial. Due to the overall low quality and heterogeneity of the studies, a meta-analysis was not performed. However, the authors reported that approximately 75% of women who underwent embolization experienced early pain relief. Adverse events noted included, transient pain following foam embolization and a small (<2%) risk of coil migration.

In 2015 Hansrani published a systematic review that evaluated the effectiveness of trans-venous occlusion as a treatment of chronic pelvic pain.[5] Thirteen studies were included comprising 866 women. The authors noted that all 13 studies were of poor methodological quality, and most studies did not use objective outcome measures or have consistent follow-up of outcomes. Studies on embolization for treatment of PCS were rated as poor due to lack of randomization and control groups, unclear patient selection criteria, and heterogeneous outcome measures that did not permit between-study comparison or estimates of overall treatment effects. There was one RCT included in the review, in which embolization resulted in significantly better pain reduction than hysterectomy, but the study also had significant limitations, including but not limited to, the randomization protocol was not described, and the hysterectomy patients (bilateral compared to unilateral salpingo-oophorectomy) were not blinded to their treatment allocation, small sample size limits the ability to rule out the role of chance as an explanation of study findings, and a discrepancy between reported outcomes in text and data tables. The authors recommended that more high quality studies are needed that compare embolization, with other treatments, including surgical treatments, hormonal therapy, and other noninvasive treatments.

Randomized Controlled Trials

A randomized, prospective trial by Guirola (2018) compared the safety and efficacy of embolization with vascular plugs (VP) or fibered platinum coils (FPC) in women with pelvic congestion syndrome.[6] Patients were enrolled (N=100) and randomly assigned to each treatment group via block randomization (N=50). Diagnosis of pelvic congestion syndrome was accomplished through a symptom screening questionnaire followed by an ultrasound study. Patients with 3 or more positive symptom responses advanced to the ultrasound screening, and patients with pelvic veins >6 mm in diameter and/or venous reflux or dilated midline communicating veins were advanced to randomization. Follow-up screening occurred at 1, 3, 6, and 12 months. The primary outcome was clinical success assessed subjectively through patient responses regarding relief of symptoms and pain scores assessed with the visual analog scale. Clinical success was achieved in 89.7% of the FPC group and 90.6% of the VP group. Improvement in visual analog scale pain scores at the end of 12 months was 90.2% overall and improvement was seen in 95.9% of the FPC group and 96% of the VP group. A total of 11 (22%) complications were seen in the FPC group and 5 (10%) in the VP group. Minor adverse events included access site hematoma and ovarian vein extravasation. Device migrations were considered major complications. A major limitation in the study is the significant difference in age and pre-treatment visual analog scale pain score between groups, both of which were higher in the VP group despite randomization.

Nonrandomized Studies

The remainder of the published literature regarding the clinical outcomes of embolization therapy consists of nonrandomized studies, case series, and retrospective reviews.[7-29] Collectively, conclusions concerning safety and effectiveness cannot be reached from these studies due to significant limitations in the data, including but not limited to:

- Lack of established diagnostic criteria for pelvic congestion syndrome. Without consistent criteria for patient selection it is unknown which patients are most likely to benefit, or not benefit, from treatment. Furthermore, it is unknown how results from the various case series can be applied to the overall population of patients with this condition.

- Lack of randomization and comparison groups. Failure to randomize patients to different treatment groups may introduce bias on the part of both the study participant and researchers in favor of the new technology. As noted above, for pain treatments, a comparator (preferably sham treatment) is necessary, in order to guard against this bias and to distinguish treatment from placebo effects.
- Retrospective design and failure to control for other treatments. Retrospective study designs do not allow for control of co-treatments or confounding factors that may influence results. This design may also introduce bias to interpretation of results. Control for additional factors, such as other medical therapies, is necessary to isolate treatment response to embolization therapy.
- Failure to define relevant study endpoints. Bias may also be introduced by failure to define study endpoints and treatment success prior to commencement of the study.

Adverse Effects

The following adverse effects associated with embolization of the uterine and internal iliac veins, though uncommon, have been reported in the literature.[7, 15]

- Embolization of coils to the pulmonary circulation
- Embolization of coils to the renal circulation
- Accidental embolization of glue fragments
- Perforations of the ovarian vein with extravasation of contrast
- Transient cardiac arrhythmia

Treatment of Varicoceles

Systematic Reviews

Belczak (2021) published a systematic review regarding semen parameter improvement after varicocele coil embolization.[30] There were six retrospective studies and two observational studies included involving 701 patients where semen concentration and motility were the primary outcomes. The authors concluded that semen concentration was improved significantly in all five studies using that outcome and semen motility was significantly improved in seven studies. This review is limited by a small number of studies and no randomized or comparative studies being included.

In 2012 Kroese published results from a systematic review and meta-analysis that examined the effect of treatment, surgery or embolization, for varicoceles in subfertile men.[31] Ten studies were included in the review, which comprised 894 men. The authors concluded that there is evidence to suggest treatment improves a couple’s chance of pregnancy; however, findings are inconclusive. Furthermore, the available evidence is of low quality and limited to men from couples with subfertility problems. Therefore further research is needed to determine the efficacy of treatment, surgery or embolization, for the treatment of varicoceles.

Randomized-Controlled Trials

No randomized controlled trials have been published comparing embolization therapy for the treatment of varicoceles to an alternative or sham/placebo treatment. Randomized controlled trials are especially needed in situations such as this where the primary symptom is pain, a subjective outcome for which a placebo response to treatment is likely.

Nonrandomized studies

The remainder of the published literature regarding the clinical outcomes of embolization therapy consists of case series and retrospective reviews.[32-49] Collectively, conclusions concerning safety and effectiveness cannot be reached from these studies due to significant limitations in the data.

PRACTICE GUIDELINE SUMMARY

PELVIC CONGESTION SYNDROME

American Congress of Obstetricians and Gynecologists

No relevant policy positions on embolization for treating pelvic congestion syndrome were identified on the American Congress of Obstetricians and Gynecologists (ACOG) website.[50]

Society for Vascular Surgery (SVS) and the American Venous Forum

The 2011 Society for Vascular Surgery (SVS) and the American Venous Forum (AVF) guidelines for the care of patients with varicose veins and associated chronic venous diseases provided a Grade 2B recommendation in favor of coil embolization, plugs, or transcatheter sclerotherapy for treatment of PCS. A Grade 2B recommendation is defined as a weak recommendation based on medium quality evidence.[51]

SUMMARY

There is not enough research to show that embolization, ablation, or sclerotherapy improves long term health outcomes for people with pelvic congestion syndrome or varicoceles, compared to other forms of therapy. Therefore, embolization, ablation, or sclerotherapy of ovarian veins, internal iliac veins, or gonadal veins are considered investigational for the treatment of pelvic congestion syndrome or varicoceles.

Balloon Ostial Dilation for Treatment of Sinusitis

Effective: November 1, 2023

Next Review: August 2024
Last Review: September 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Balloon ostial dilation is proposed as a less invasive alternative to traditional endoscopic sinus surgery. In this procedure, a balloon catheter is placed in the opening of the sinus and inflated to widen the opening, allowing for better drainage of secretions.

MEDICAL POLICY CRITERIA

I. The use of a catheter-based inflatable device for the treatment of chronic sinusitis may be considered **medically necessary** when all of the following Criteria are met:

   A. Patient has chronic sinusitis that interferes with lifestyle and has persisted for at least 12 weeks; and

   B. Documentation of abnormal findings from diagnostic evaluation including at least one of the following:

      1. CT findings suggestive of obstruction or infection of the sinus including but not limited to air fluid levels, air bubbles, significant mucosal thickening of greater than 3 mm, pansinusitis, or diffuse opacification documented by a formal CT scan report from an independent radiologist; or

      2. Nasal endoscopy findings suggestive of significant sinus ostial obstruction disease; and

C. Inadequate response to maximal medical therapy that included all of the following:

1. Saline nasal irrigations or saline nasal spray; and
2. Two or more antibiotic courses or one prolonged course of at least 21 days; and
3. A trial of nasal steroids.

II. The use of a catheter-based inflatable device for the treatment of chronic sinusitis is considered **investigational** when Criterion I. is not met.

III. The use of a catheter-based inflatable device for the treatment of recurrent acute rhinosinusitis may be considered **medically necessary** when all of the following Criteria are met:

A. Four or more documented and treated episodes of acute rhinosinusitis over a period of 12 months; and

B. CT findings performed during the fourth episode should demonstrate obstruction or infection of the sinus including but not limited to air fluid levels, air bubbles, significant mucosal thickening of greater than 3 mm, pansinusitis, or diffuse opacification documented by a formal CT scan report from an independent radiologist.

IV. The use of a catheter-based inflatable device for the treatment of recurrent acute rhinosinusitis is considered **investigational** when Criterion III. is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Indication for the requested service
- If indication is chronic rhinosinusitis:
  - Documentation of chronic rhinosinusitis including length of time present and interference with lifestyle;
  - CT and/or nasal endoscopy report;
  - Failure of maximum medical therapy including saline nasal irrigations/nasal spray, two or more antibiotic courses or one minimum 21 day course, and nasal steroid trial.
- If indication is recurrent acute rhinosinusitis:
  - Documentation of four or more documented and treated episodes of acute rhinosinusitis over 12 months;
  - CT report.

BACKGROUND

Balloon ostial dilation (BOD, also known as balloon sinuplasty, balloon catheter dilation, or sinus ostial dilation) for the treatment of sinusitis involves placement and inflation of a balloon catheter within an obstructed frontal, sphenoid, or maxillary sinus ostium. The balloon catheter is placed using transnasal endoscopy, or a transantral approach may be used for direct access to the maxillary sinus. Inflation of the balloon is intended to enlarge the sinus ostium by compressing mucosa and displacing local bony structures. This technique has been used as an alternative or adjunct to functional endoscopic sinus surgery (FESS) which involves surgical excision of the mucosa and bone. When performed in combination with FESS, it is sometimes referred to as a hybrid procedure.

REGULATORY STATUS

In March 2008, the “Relieva Sinus Balloon Catheter” (Acclarent, Menlo Park, CA) device was cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process. The FDA determined that this device was substantially equivalent to existing devices for use in dilating the sinus ostia and paranasal spaces in adults and maxillary sinus spaces in children. Subsequent devices developed by Acclarent have also been granted 510(k) approval. These include the Relieva Spin Sinus Dilation System®, approved in August 2011, and the Relieva Seeker Balloon Sinuplasty System®, approved in November 2012.

In June 2008, the FinESS™ Sinus Treatment (Entellus Medical, Inc, Maple Grove, MN) device was cleared for marketing by the FDA through the 510(k) process. The indication noted is to access and treat the maxillary ostia/ethmoid infundibulum in adults using a transantral approach. The bony sinus outflow tracts are remodeled by balloon displacement of adjacent bone and paranasal sinus structures. Two other balloon sinuplasty devices by Entellus Medical, Inc. also received 510(k) approval in August, 2012. These are the ENTrigue® Sinus Dilation System, and the XprESS® Multi-Sinus Dilation Tool.

In 2013, a sinus dilation system (Medtronic Xomed, Jacksonville, FL), later named the NuVent™ EM Balloon Sinus Dilation System, was cleared for marketing by the FDA through the 510(k) process for use in conjunction with a Medtronic computer-assisted surgery system when surgical navigation or image-guided surgery may be necessary to locate and move tissue, bone, or cartilaginous tissue surrounding the drainage pathways of the frontal, maxillary, or sphenoid sinuses.

Also in 2013, a sinus dilation system (ArthroCare, San Antonio, TX), later named the Ventera™ Sinus Dilation System, was cleared for marketing through the 510(k) process to access and treat the frontal recesses, sphenoid sinus ostia, and maxillary ostia/ethmoid infundibula in adults using a transnasal approach.

EVIDENCE SUMMARY

To determine the benefits and harms of BOD as a stand-alone procedure for the treatment of

sinusitis, it must be compared with standard functional endoscopic sinus surgery (FESS) which involves excision of ostial tissues. Well-designed prospective comparative studies, preferably randomized controlled trials (RCTs), are needed to compare health outcomes between the two procedures and determine whether balloon dilation is as effective and durable as excision.

The most important clinical outcomes to compare for treatment of sinusitis are:

- Symptom relief
- Durability of any beneficial effects
- Adverse event rate and severity
- Rate and type of reoperations including repeat dilation procedures

The focus of this evidence review is on systematic reviews, randomized controlled trials, and nonrandomized comparative trials.

ADULT PATIENTS

Systematic Reviews

Sinha (2023) published a systematic review comparing BOD to FESS which included 18 studies and a subset of seven studies were used to conduct a meta-analysis.[1] The primary outcome was post-operative Sinonasal Outcome Test-20 scores and the pooled difference in means between BOD and FESS was 0.44, which was below the clinically meaningful difference of 0.8 set out in the study. The authors conclude that BOD is an appropriate choice and shows positive outcomes in patients with chronic rhinosinusitis while calling for additional high-quality studies comparing BOD to other treatment options.

Levy (2016) reported on a systematic review and meta-analysis of studies of paranasal BOD for chronic rhinosinusitis.[2] The review included 17 studies, only three of which were RCTs. Two of the RCTs reported on differences in the change in 20-Item Sinonasal Outcome Test (SNOT-20) scores between patients treated with BOD or FESS (n = 110; standard mean difference [SMD] -0.42, 95% CI -1.39 to 0.55, I^2=76%).[3, 4] However, the reviewers found no significant differences in outcome in patients treated with BOD compared to those treated with conventional FESS (p=0.07). The reviewers did report improvements in SNOT-20 score and sinus opacification after BOD, but these conclusions were not drawn from comparative studies, but from five cohort studies.

A BlueCross BlueShield Association Technology Evaluation Center (TEC) Assessment was completed in 2012 titled “Balloon Ostial Dilation for Treatment of Chronic Rhinosinusitis”.[5] This Assessment reviewed evidence from one RCT, three non-randomized comparative studies, and nine case series. The following conclusions were made concerning the adequacy of this evidence for determining the effect of balloon sinuplasty on health outcomes:

> “The evidence is insufficient to determine the effect of the technology on health outcomes. One randomized clinical trial comparing balloon sinuplasty to FESS was inadequately powered and did not evaluate differences in outcomes between the two treatments. While most nonrandomized comparative studies of balloon sinuplasty and FESS show no difference in health outcomes between the two treatments, confounding factors may bias the comparison of the two treatments. Several case series show improvement in symptoms of rhinosinusitis over baseline measures, and such improvement appears durable up to 2 years. Case series do not allow conclusions

regarding the comparative efficacy of balloon sinuplasty to FESS."

A 2011 Cochrane systematic review on balloon sinuplasty for chronic rhinosinusitis concentrated on RCTs.[6] One small RCT[7] met the inclusion criteria. Patients were randomized to a "hybrid approach" that included balloon sinuplasty of the affected frontal recess along with traditional FESS of other paranasal sinuses (n = 16), or to traditional FESS (n = 16). At 12-months follow-up, both groups reported improvements in symptoms, but there were no significant differences between the two groups. The authors of the Cochrane review rated this study as having a low risk for bias for most parameters, but a high risk for bias in reporting of the outcomes. Specifically, symptom scores were not presented systematically and details of statistical testing were not reported. The overall conclusion of this review was that there is no convincing evidence supporting the use of balloon sinuplasty in chronic rhinosinusitis (CRS).

Batra (2011) performed a comprehensive review of the literature regarding balloon catheter technology (BCT) in rhinology.[8] The authors noted significant study design flaws in the studies, including lack of comparator group in most, lack of randomization in the single comparative study, unclear selection criteria, and use of patient-reported symptom improvement.

The authors reached the following conclusions:

> "The accrued data attests to its safety, whereas the largest published observational cohort studies have demonstrated the ability to achieve ostia patency for up to 2 years. However, because the selection criteria for these studies were not clearly defined, it is unclear if this data can be extrapolated to the general population with chronic rhinosinusitis (CRS). Is BCT superior or equivalent to the existing devices employed in FESS for the management of CRS? Will the use of BCT translate into improvements in patient outcomes, overall health, and/or quality of life? The many unsettled questions "will be best answered by prospective randomized trials that directly compare FESS to BCT, or directly compare medical to surgical treatment."

Randomized Controlled Trials (RCTs)

The REMODEL Study

The REMODEL (Randomized Evaluation of Maxillary antrostomy versus Ostial Dilation Efficacy through Long-term follow-up) study was an industry-sponsored RCT that compared BOD as a stand-alone procedure with FESS.[4] A total of 105 patients with recurrent acute sinusitis or chronic sinusitis and failure of medical therapy were randomized to BOD or FESS. BOD was performed with the Entellus device, which is labeled for a transantral approach. FESS consisted of maxillary antrostomy and uncinectomy with or without anterior ethmoidectomy. Thirteen patients withdrew consent prior to treatment, 11 in the FESS group (21%) and two in the BOD group (4%). The primary outcomes were the change in the SNOT-20 score at six-month follow-up, and the mean number of debridements performed postoperatively. Secondary outcomes included recovery time, complication rates, and rates of revision surgery. Both superiority and noninferiority analyses were performed on these outcomes.

A total of 91 patients were available at six-month follow-up. The improvement in the SNOT-20 score was 1.67 ± 1.10 in the balloon dilation group and 1.60 ± 0.96 in the FESS arm (p=0.001

for noninferiority). Postoperative debridements were more common in the FESS group compared with balloon dilation (1.2 ± 1.0 vs. 0.1 ± 0.6 in the FESS arm, p<0.001 for superiority). Patients in the balloon dilation arm returned to normal daily activities earlier (1.6 days vs. 4.8 days, p=0.002 for superiority), and required fewer days of prescription pain medications (0.9 days vs. 2.8 days, p=0.002 for superiority). There were no major complications in either group, and one patient in each group required revision surgery. This study was likely to have adequate power to detect group differences; however, there were some methodologic limitations. The study was unblinded and did not have blinded outcome assessment for the symptom-based outcomes or the secondary clinical outcomes. There was also evidence of differential dropout, with larger numbers of patients withdrawing from the FESS group following randomization (21% vs 4%).

Bikhazi (2014) reported one-year outcomes in the REMODEL study. A total of 92 patients (balloon dilation n = 50, FESS n = 42) were treated and 89 (96.7%) completed one-year follow-up.[9] Both groups showed clinically meaningful and statistically significant (p<0.0001) improvement in mean overall SNOT-20 scores and in all four SNOT-20 subscales. Ostial patency was 96.7 and 98.7% after balloon dilation and FESS, respectively, and each group reported significant reductions (p<0.0001) in rhinosinusitis episodes (mean decrease 4.2 for balloon dilation and 3.5 for FESS) during the follow-up period of one year. Overall work productivity and daily activity impairment due to chronic sinusitis were significantly improved (p<0.001) in both groups. There were no complications, and the revision surgery rate was 2% in each arm through one year. The authors concluded that stand-alone balloon dilation was as effective as FESS in the treatment of CRS in patients with maxillary sinus disease, with or without anterior ethmoid disease, who failed medical therapy, and met the criteria for medically necessary FESS. The study included the use of self-reported quality of life questionnaires, which are subject to recall bias.

Chandra (2015) published final results of the REMODEL study[10], which indicated that patients in the balloon sinus dilation groups experienced significantly faster recovery (1.7 vs. 5.0 days, p<0.0001), less nasal bleeding (32% vs. 56%; p=0.009), and less need for prescription pain medication (1.0 vs. 2.8 days, p<0.0001). Study authors also reported results of a meta-analyses of several stand-alone balloon sinus dilation studies. The meta-analysis was based on five studies that included non-randomized studies and two studies were reportedly unpublished. Based on results of the meta-analyses, FESS and balloon dilation were not significantly different for mean SNOT-20 symptom scores and revisions rates assessed at 12 months.

Other Randomized Controlled Trials

Sikand (2019) published results from a trial where the primary outcome was the difference between arms in change in Chronic Sinusitis Survey (CSS) score from baseline to 24 weeks.[11] The change in CSS was significantly greater in the BOD group compared to the control group (mean change 37.3 vs 21.8). Patients in the BOD group had a lower mean number of sinus infections through the 24-week followup period (0.2 vs 0.95). Durability of the outcome measure differences was demonstrated up to 48 weeks. After the 24-week followup period, 18 of 30 patients who were randomized to the control arm elected to receive BOD. Of those who crossed over at 24 weeks, none reported no change or worsening of symptoms, three reported improved symptoms but still used nasal sprays at high rates, four had improved symptoms to varying degrees but were not eliminated, and one reported a sinus infection just before their 24-week visit. There was one procedure-related serious adverse event in the BOD

group, two possibly procedure-related nonserious adverse events, and no device-related adverse events.

Bizaki (2014) reported results from an RCT that compared BOD to FESS among patients with symptomatic chronic or recurrent rhinosinusitis.[12] The trial enrolled 46 subjects, four of whom withdrew; the analysis included 42 patients (n = 21 in each group; statistical power calculations reported). Both groups demonstrated significant improvements in SNOT-22 scores from baseline to postprocedure. There were no differences in change in total SNOT-22 scores between groups at three months postprocedure. As a 2016 follow-up publication, trialists reported on nasal airway resistance and sinus symptoms between FESS- and BOD-treated groups.[13] For this analysis, 62 patients were included (32 from the FESS group, 30 from the balloon dilation group). Patients in the BOD group had significant improvements in nasal volume from pre- to postoperative measurements, but there were no significant differences between groups pre- or postoperatively in nasal volume.

Another RCT by Bizaki (2016) compared BOD to FESS, with a focus on mucociliary clearance.[14] It was conducted at the same institution as the previously reported Bizaki RCT; however, it was not specified whether it included the same patients. This trial enrolled 36 patients who were randomized to BOD (n=17) or FESS (n=19); seven patients dropped out (three in the FESS group, four in the balloon dilation group) and were not included in analyses. SNOT-22 scores improved in both groups from pre- to postoperative analyses. However, changes in total SNOT-22 scores did not differ significantly between groups. There was no significant change in mucociliary clearance before and after either treatment, nor was there a significant between-group difference in mucociliary clearance.

Marzetti (2014) reported results of a small RCT that compared BOD with an unspecified device (or devices) with FESS in the treatment of sinus headache.[15] The study included 83 patients with sinus headache, based on the American Academy of Otolaryngology-Head and Neck Surgery criteria, 44 of whom were randomized to conventional FESS and 35 to BOD. In the balloon dilation group, 23 patients were “only frontal sinus balloon” patients, in which balloon catheters were the only tools used for frontal sinus sinusotomy, and 12 were “hybrid,” in which balloon catheters and traditional endoscopic sinus surgery were used concurrently. It was not specified how patients were selected for these groups. FESS treatment was administered on participants in both groups, but specific data was not reported by study authors. At six months of follow up, scores on the SNOT-22 improved from 28.6 at baseline to 7.8 in the FESS group and 27.3 at baseline to 5.3 in the BOD group, with a statistically significant reduction in both groups ($p<0.001$). At six months of follow up, headache scores based on the visual analog score (VAS) improved from 6.5 to 5.4 in the FESS group and from 7.1 at baseline to 1.2 in the BOD group ($p<0.001$). Study authors did not report other patient-relevant outcomes, such as the number of headache days or use of pain medications following treatment. Limitations of this study included the small number of patients who received BOD, which limits the generalizability of study results, and the lack of blinding of both patients and clinical assessors. In addition, there were various concurrent surgical procedures conducted in both treatment and control groups, which made it difficult to properly assess the treatment effects of BOD.

Another small RCT published by Achar (2012) enrolled 24 patients with chronic sinusitis who had failed medical therapy and were scheduled for surgery.[3] Patients were randomized to balloon dilation or FESS and followed for a total of 24 weeks. The primary outcome measures were changes in the SNOT-20 score and the saccharine clearance time test. Both groups improved significantly on both outcome measures. The degree of improvement was greater for

the functional endoscopic dilatation sinus surgery group compared to the FESS group on both the SNOT-20 score (43.8 ± 15.2 vs. 29.7 ± 12.3, p<0.03) and on the saccharine clearance score (7.5 ± 5.1 vs. 3.5 ± 4.3, p=0.03). Adverse events were not reported.

A small RCT was published in 2011 that reported on physiologic outcomes.[16] Twenty patients were randomly assigned to removal of the uncinate process via FESS or balloon sinus ostial dilation as a stand-alone procedure. The main outcome measures were CO_2 concentration in the sinuses and maximum sinus pressure, both intended to be surrogate measures for sinus ventilation. The CO_2 concentration decreased in both study arms to a similar degree. The mean maxillary sinus pressure on inspiration decreased in the FESS group but did not change in the balloon sinus ostial dilation group.

Bozdemir (2011) published a small study of 10 patients with nasal polyposis, in which one side was treated with FESS and the other with balloon sinus ostial dilation.[17] All procedures were performed by the same surgeon, and polypectomy was performed prior to FESS or balloon sinus ostial dilation in all patients. Outcome measures included sinus patency, as measured by computed tomography (CT) scan (Lund-McKay classification) or repeat endoscopy (McKay grading). At 10 days following the procedure, there were improvements in both groups on measures of patency, but there were no differences between groups.

Nonrandomized Studies

Gould (2014) assessed the one-year changes in sinonasal symptoms and health care use after office-based, multi-sinus balloon dilation in an industry-sponsored prospective, multicenter study.[18] A total of 313 ostial dilations were attempted and 307 were successfully completed (98.1%) in 81 subjects. Seventy-six of the 81 patients completed the one-year follow-up. Mean procedure tolerance was 2.8 ± 2.2 (0 = no pain, 10 = severe pain). SNOT-20 symptom improvement was observed at one and six months and sustained through one year. The RSI questionnaire that rates five major and seven minor rhinosinusitis symptoms measured a treatment effect for all major rhinosinusitis symptoms. Compared with the previous one-year period, patients reported an average of 2.3 fewer acute sinus infections (p<0.0001), 2.4 fewer antibiotic courses taken (p<0.0001), and 3.0 fewer sinus-related physician visits (p<0.0001) after balloon dilation. No serious device or procedure-related adverse events occurred. One subject underwent revision surgery. The authors reported that patients reported significant reductions in both sinonasal symptoms and health care use after balloon dilation. Methodological limitations included the implementation of self-reported SNOT-20 and RSI questionnaires, which may lead to recall bias; lack of a comparison group, which precludes the ability to isolate any reported treatment effects; and the uncertain timing between the preoperative CT scan and failure of medical management.

Brodner (2013) reported a prospective, multi-center study to evaluate outcomes for the XprESS device for the treatment of the frontal recesses, maxillary ostia, and/or sphenoid sinus ostia in 175 adults who had previously been scheduled for conventional FESS.[19] The criteria for previously-scheduled conventional FESS are not specified. There were a mean 2.7 sinuses per patient treated; of the targeted sinuses, 479/497 (96.4%) were successfully accessed and treated. One-year follow up was planned in the first 50 subjects, who only underwent dilation of frontal recesses and sphenoid ostia; at one year, in the 41 subjects with one-year follow-up available, 76/83 (91.6%) of the ostia dilated with the study device were patent. At one year, in 44 subjects who completed follow-up, the average overall SNOT-20 score was 0.8 (vs 1.9 at baseline; p<0.0001 for change), which was considered a clinically meaningful improvement

(change ≥ 0.8).

Albritton (2012) reported results of a prospective, nonrandomized evaluation of the feasibility of in-office balloon sinus dilation with the Relieva device who were enrolled in the ORIOS trial.[20] The study included 37 subjects (59 sinuses) who had a diagnosis of chronic rhinosinusitis (>12 weeks of symptoms including but not restricted to nasal obstruction, sinus/facial pressure, nasal discharge, and congestion) that was unresponsive to maximal medical management. Successful access and dilation of all targeted sinuses occurred in 33/37 subjects (89%). Follow up was available for 32 (86.5%), 31 (83.8%), 26 (70.2%), and 21 (56.8%) at 1-, 4-, 24-, and 52-weeks post-procedure, respectively. Symptoms were assessed based on the change in SNOT-20 score from baseline to follow up, with a mean reduction from baseline of -0.98 (95% CI -1.27 to -0.70), -1.32 (95% CI -1.65 to -1.00), -1.25 (95% CI -1.65 to -0.85), and -1.42 (95% CI -1.87 to -0.90) at 1-, 4-, 24-, and 52-weeks post-procedure, respectively. For the 29 subjects who had CT scans available at baseline and 24 weeks of follow up, Lund-Mackay score improved from 6.62 preprocedure to 2.79 postprocedure (p<0.0001).

In the ORIOS2 study, Karanfilov (2013) reported results of a prospective, nonrandomized, multicenter evaluation of office-based balloon sinus dilation with the Relieva device in 203 patients who required FESS for medically refractory chronic sinusitis.[21] Three cohorts were enrolled, a lead-in cohort which consisted of each investigator's first cases where all targeted sinuses were successfully dilated (n = 36), a standard enrollment cohort which consisted of up to approximately 15 cases (n = 84), and an extended enrollment cohort which included subjects after the first 15 cases (n = 83). Dilation technically successful in 552 of 592 attempted sinuses (93.2%). Matched baseline and twenty-four week follow up was available for 112 patients, who demonstrated a mean improvement in SNOT-20 scores of -1.1 (p<0.0001). In the 110 patients with 24 week CT scans available, Lund-Mackay score improved by -4.3 compared with baseline (p<0.0001 for change).

Levine (2013) reported results of a prospective, nonrandomized, multicenter evaluation of office-based balloon sinus dilation with the FinESS device in 74 patients with chronic rhinosinusitis (n = 52) or recurrent acute sinusitis (n = 17).[22] Balloon dilation was successful in 69 patients, and analyses are reported per protocol. The overall technical success rate in patients was 91.9% (124 of 135 ostia) but it was not specified if this was in overall sample of 74 patients or in analysis sample of 69 patients. Mean SNOT-20 scores improved from a mean 2.3 at baseline to 1.1 at six months and 12 months in the 66 patients with follow up data available (mean change -1.2, p<0.0001). There were no significant differences in improvements reported between the chronic rhinosinusitis and recurrent acute sinusitis patients.

A number of additional nonrandomized studies have been identified, which do not allow conclusions concerning the impact of BSD on primary health outcomes compared with FESS. These studies have methodological limitations such as a limited number of patients,[20, 23] a heterogenous study population,[24] no primary health outcomes reported,[25] limited follow-up,[20, 23, 24, 26] retrospective study design[26, 27 , 28, 29], or implementation of self-reported questionnaires.[18, 25, 27] The exception is a single-arm study by Tomazic (2013), in which the authors planned to evaluate a cohort of 200 patients with BOD or a hybrid procedure, but ended the study early after 45 patients after a high technical failure rate was noted, with 44/68 sinuses in a planned BOD group and 29/44 sinuses in a planned hybrid procedure group failing.[30]

Retrospective studies are limited by the accuracy of the medical records reviewed or the recall ability of patients when filling out a study questionnaire. In addition, there is no randomization or blinding in a retrospective study design and therefore it is difficult to control for bias and confounders.

PEDIATRIC PATIENTS

Nonrandomized Studies

Wang (2015) reported on a perspective nonrandomized controlled study of 79 pediatric patients (age 7-12) with chronic sinusitis resistant to medical therapy, including 42 patients treated with sinus balloon catheter dilation balloon (SBCD) and 37 control patients treated conservatively (including oral antibiotics, local nasal steroid spray, and nasal saline irrigation).[31] At one-year posttreatment, the SN-5 scores were significantly better in the SBCD group (22 patients [52%] had marked improvement, 11 [26%] had moderate improvement, and six [14%] had mild improvement) than in the control group (five [14%], seven [19%], and four [11%], respectively) ($p < 0.05$ for all comparisons).

In a retrospective comparative study, Thottam (2012) evaluated the incremental value of Relieva balloon catheter sinuplasty when combined with FESS in 31 children (mean age 9.3 years) who had persistent chronic sinusitis despite standard maximal medical therapy.[32] The authors performed a blinded chart review of 15 children who underwent balloon catheter sinuplasty with ethmoidectomy and 16 children who underwent FESS. Thirteen children had prior adenoidectomy. A total symptom score was constructed for the number of complaints presurgery, postsurgery, and at the final postsurgical examination (> four months) including facial pain, sinus congestion, postnasal drip, rhinorrhea, headache, and low-grade fever. Success and improvement were defined as a decrease in the total complaint score of ≥ 1 point at the last visit, while total improvement was defined as total resolution of all complaints (i.e., symptom score of 0). Compared with baseline values, significant posttreatment reductions in overall sinusitis symptoms and needed interventions were observed in both treatment groups. In the Relieva balloon catheter sinuplasty group, 80% of the patients reported improvements in their overall sinus symptoms at an average of 37 weeks, versus 62.5% of the FESS patients. This difference between groups was not significant. No serious complications occurred.

In a prospective, nonrandomized controlled study, Ramadan (2010) compared the efficacy and safety of Relieva balloon sinuplasty combined with adenoidectomy (n=30) with that of adenoidectomy alone (n = 19) in 49 children (mean age 6.6 years, range 2-11) with chronic sinusitis that was refractory to medical therapy for at least six months.[33] The patients were followed at regular intervals for up to one year. Twenty-four of the 30 (80%) patients in the Relieva plus adenoidectomy group showed symptom improvement at one year compared with 10 of 19 (52.6%) children in the adenoidectomy alone group. Two (6%) patients with hypoplastic sinuses failed balloon sinuplasty and required revision FESS. One patient was lost to follow-up, and another had no improvement in SN-5 scores. Three (15%) children who did not improve after adenoidectomy had balloon sinuplasty. Overall, the mean SN-5 score for all participants decreased from a baseline value of 4.1 to 2.9 after surgery. In the Relieva plus adenoidectomy group, the mean SN-5 score decreased from 4.2 to 3.0, while in the adenoidectomy alone group, the score decreased from 3.8 to 2.9. No major complications occurred in either treatment group.

Prospective, multicenter single-arm studies have reported outcomes in pediatric patients with chronic sinusitis. In one study of 32 children, 24 had one-year follow-up data.[34] Of the 32

children enrolled, 24 were studied at one-year follow-up. Significant improvements in quality of life outcomes were reported using the SN-5 score ($p<0.0001$). Twelve (50%) children had a significant improvement of their SN-5 score, seven children (29%) had moderate improvement, two (8%) had mild improvement, one (4%) remained the same, and two children (8%) had worsening scores. A similar study with 50 participants and 157 total attempted dilations also reported significant improvement in SN-5 scores at six months ($p<0.0001$).[35] No adverse procedure-related events were reported in either study However, these studies lacked a comparison group, limiting conclusions regarding the efficacy of the procedure.

PRACTICE GUIDELINE SUMMARY

AMERICAN ACADEMY OF OTOLARYNGOLOGY-HEAD AND NECK SURGERY (AAO-HNS)

In 2018, the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) published a clinical consensus statement on balloon dilation of the sinuses.[36] Participating subgroups included the Triologic Society, the American Rhinologic Society, the American Academy of Otolaryngic Allergy, and the American Academy of Allergy, Asthma & Immunology. The following statements met consensus:

Patient Criteria:

- Balloon dilation is not appropriate for patients who are without both sinonasal symptoms and positive findings on CT. (Strong consensus)
- Balloon dilation is not appropriate for the management of headache in patients who do not otherwise meet the criteria for chronic sinusitis or recurrent acute sinusitis. (Strong consensus)
- Balloon dilation is not appropriate for the management of sleep apnea in patients who do not otherwise meet the criteria for chronic sinusitis or recurrent acute sinusitis. (Strong consensus)
- CT scanning of the sinuses is a requirement before balloon dilation can be performed. (Strong consensus)
- Balloon dilation is not appropriate for patients with sinonasal symptoms and a CT that does not show evidence of sinonasal disease.
- Balloon dilation can be appropriate as an adjunct procedure to FESS in patients with chronic sinusitis without nasal polyps.
- There can be a role for balloon dilation in patients with persistent sinus disease who have had previous sinus surgery.
- There is a role for balloon sinus dilation in managing patients with recurrent acute sinusitis as defined in the AAO-HNSF guideline based on symptoms and CT evidence of ostial occlusion and mucosal thickening.

Perioperative Considerations:

- Surgeons who consider reusing devices intended for dilation of the sinuses should understand the regulations set forth by the FDA for reprocessing such devices and ensure that they are followed. (Strong consensus)
- Balloon dilation can be performed under any setting as long as proper precautions are taken and appropriate monitoring is performed.
- Balloon dilation can be performed under local anesthesia with or without sedation.

Outcome:

- Balloon dilation can improve short-term quality-of-life outcomes in patients with limited CRS without polyposis.
- Balloon dilation can be effective in frontal sinusitis

SUMMARY

There is enough research to show that balloon ostial dilation improves health outcomes for patients with sinusitis compared to functional endoscopic sinus surgery (FESS). In addition, there are clinical practice guidelines that address balloon ostial dilation for the treatment of sinusitis. Therefore, balloon ostial dilation as a treatment for sinusitis, either as a stand-alone procedure or in conjunction with FESS, may be considered medically necessary when policy criteria are met.

There is not enough research to show that balloon ostial dilation improves health outcomes for patients with chronic or acute sinusitis when policy criteria are not met. Therefore, balloon ostial dilation as a treatment for sinusitis, either as a stand-alone procedure or in conjunction with FESS, is considered investigational when policy criteria are not met.

Surgical Treatments for Hyperhidrosis

Effective: May 1, 2023

Next Review: March 2024
Last Review: March 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

This policy addresses surgical treatments for hyperhidrosis, excessive sweating beyond a level required to maintain normal body temperature.

MEDICAL POLICY CRITERIA

Note: This policy only addresses the surgical treatment of hyperhidrosis.

I. Surgical treatment of hyperhidrosis, including craniofacial hyperhidrosis, via endoscopic transthoracic sympathectomy or excision of axillary sweat glands may be considered **medically necessary** when there is clinical documentation that all of the following Criteria (A. – C.) are met:

   A. Primary medical conditions causing hyperhidrosis have been identified and treated where possible; and

   B. The hyperhidrosis is persistent and severe, and has resulted in one or more of the significant medical complications below (see Policy Guidelines):

      1. Acrocyanosis of the hands; or

      2. Recurrent skin maceration with secondary bacterial or fungal infection; or

3. Recurrent secondary infections; or
4. Persistent eczematous dermatitis; or
5. Documentation of inability to perform critical activities of daily living or demands of employment (such as impaired grip and writing ability for employment, or impaired walking) due to symptoms of hyperhidrosis; and

C. A trial of all of the following nonsurgical treatments has been ineffective, not tolerated, or are contraindicated:

1. Prescription antiperspirants (e.g. aluminum chloride hexahydrate 20%) and/or anticholinergics (e.g. glycopyrrolate or oxybutynin); and
2. If the treatment is for axillary or palmar hyperhidrosis and the patient is age 18 years or older, a trial of botulinum toxin type A [Botox] injection is completed OR the patient does not have axillary or palmar hyperhidrosis.

II. Tympanic neurectomy may be considered **medically necessary** for the treatment of severe gustatory hyperhidrosis if a trial of nonsurgical treatments failed or is contraindicated.

III. Surgical treatment of hyperhidrosis via endoscopic transthoracic sympathectomy, excision of axillary sweat glands, or tympanic neurectomy is considered **not medically necessary** when the Criteria in I. or II. above are not met (see Policy Guidelines).

IV. All other surgical treatments of hyperhidrosis are considered **investigational**, including but not limited to lumbar sympathectomy; axillary liposuction or curettage performed alone or in combination with any other procedure; subdermal laser-assisted axillary hyperhidrosis treatment; percutaneous radiofrequency sympathicolysis or sympathectomy; and radiofrequency ablation for palmar hyperhidrosis.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Medical treatment of persistent hyperhidrosis is considered not medically necessary in the absence of significant medical complications associated with the condition. Skin irritation, skin maceration without secondary infection, need for frequent changing of clothing, or psychosocial distress alone are not considered to be significant medical complications.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes including the following:
  - Type of hyperhidrosis
  - Documentation primary medical conditions causing hyperhidrosis have been identified and treated where possible

- Documentation hyperhidrosis is persistent and severe and has resulted in significant medical complications including inability to perform critical activities of daily living or demands of employment, if relevant
- Documentation of specific nonsurgical treatments trialed and documented response including use of prescription antiperspirants and/or anticholinergics, and botulinum toxin type A [Botox] injection trial when appropriate per policy.

BACKGROUND

HYPERHIDROSIS

Hyperhidrosis may be defined as excessive sweating, beyond a level required to maintain normal body temperature in response to heat exposure or exercise. Hyperhidrosis can be classified as either primary or secondary.

Primary Hyperhidrosis

Primary focal hyperhidrosis is defined as idiopathic bilateral, relatively symmetric, excessive sweating of at least six months' duration induced by sympathetic hyperactivity in selected areas that is not associated with an underlying disease process. The most common locations are underarms (axillary hyperhidrosis), palms (palmar hyperhidrosis), soles of the feet (plantar hyperhidrosis) or face and scalp (craniofacial hyperhidrosis). The second (T2) and third (T3) thoracic ganglia are responsible for palmar hyperhidrosis, the fourth (T4) thoracic ganglia controls axillary hyperhidrosis, and the first (T1) thoracic ganglia controls facial hyperhidrosis.

Secondary Hyperhidrosis

Secondary generalized hyperhidrosis is a type of excessive sweating that is caused by another medical condition or is a side effect of a medication. Secondary hyperhidrosis can result from a variety of drugs, [e.g., tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs)], olfactory stimuli, or underlying diseases/conditions, such as febrile diseases, diabetes mellitus, anxiety, menopause, neurologic lesions, intrathoracic neoplasms, and Raynaud's disease.

Secondary gustatory hyperhidrosis is excessive sweating related to ingesting or thinking about the ingesting food. This trigeminovascular reflex typically occurs symmetrically on scalp or face and predominately over forehead, lips and nose and can include flushing, redness, and general discomfort felt at the cheek level. This phenomenon is associated with conditions including encephalitis, syringomyelia, diabetic neuropathies, and, most commonly, conditions resulting from damage to the parotid gland (sometimes referred to as Frey's syndrome) including herpes zoster parotitis and parotid abscess. Other conditions and diseases also can cause hyperhidrosis, including those listed at sweathelp.org.[1]

Frey's syndrome is an uncommon type of secondary gustatory hyperhidrosis that arises from injury to, or surgery near, the parotid gland resulting in damage to the secretory parasympathetic fibers of the facial nerve. After injury, these fibers regenerate and miscommunication occurs between them and the severed postganglionic sympathetic fibers that supply the cutaneous sweat glands and blood vessels. The aberrant connection results in

gustatory sweating and facial flushing with mastication. Aberrant secondary gustatory sweating follows up to 73% of surgical sympathectomies and is particularly common after bilateral procedures.

The consequences of hyperhidrosis are primarily psychosocial in nature. Excessive sweating may be socially embarrassing or may interfere with certain professions. Symptoms such as fever, night sweats, or weight loss require further investigation to rule out secondary causes. Sweat production can be assessed with the minor starch iodine test, which is a simple qualitative measure to identify specific sites of involvement.

A variety of medical therapies have been investigated for treating primary hyperhidrosis, including topical therapy with aluminum chloride or tanning agents, oral anticholinergic medications, iontophoresis, intradermal injections of botulinum toxin, and microwave treatment. Treatment of secondary hyperhidrosis naturally focuses on treatment of the underlying cause.

SURGICAL TREATMENT

This medical policy addresses only surgical treatment of hyperhidrosis. Surgical treatments for axillary hyperhidrosis include transthoracic sympathectomy and surgical excision of axillary sweat glands. Transthoracic sympathectomy may also be used for palmar hyperhidrosis. Surgical removal of axillary sweat glands has been performed in patients with severe isolated axillary hyperhidrosis. Removal may involve removal of the subcutaneous sweat glands without removal of any skin, limited excision of skin and removal of surrounding subcutaneous sweat glands, or a more radical excision of skin and subcutaneous tissue en bloc.

A variety of approaches have been reported for sympathectomy. For transthoracic sympathectomy, transthoracic endoscopic techniques have emerged as minimally invasive alternatives to transaxillary, supraclavicular, or anterior thoracic approaches. Percutaneous radiofrequency (RF) sympathicolysis has also been proposed as a sympathectomy technique in which RF lesions are made in the thoracic sympathetic chain under fluoroscopic guidance without the need for general anesthesia, intubation, or risk of lung collapse. Lumbar sympathectomy may be performed as a surgical treatment of plantar hyperhidrosis and may also be done endoscopically.

While accepted as an effective treatment, sympathectomy is not without complications. In addition to the immediate surgical complications of pneumothorax or temporary Horner's syndrome, compensatory sweating on the trunk can occur in up to 55% of patients, reducing patient satisfaction with the procedure. Gustatory sweating may also occur. Sympathectomy also results in cardiac sympathetic denervation, which in turn can lead to a 10% reduction in the heart rate. In addition to the complications associated with transthoracic sympathectomy, lumbar sympathectomy for plantar hyperhidrosis may have the additional risk of permanent sexual dysfunction in men and women. Medical researchers have investigated whether certain approaches, e.g., T3 versus T4 sympathectomy, result in less compensatory sweating, but there remains a lack of consensus about which approach best minimizes the risk of this side effect.

Tympanic neurectomy is a surgical technique that may be used for treatment of severe gustatory hyperhidrosis. The nerves are transected in the middle ear through a flap created in the ear drum. Possible risks from this surgery include rupture of the tympanic membrane, infection, hearing loss, and loss of taste in certain parts of the tongue.

EVIDENCE SUMMARY

In order to determine whether surgical treatment of hyperhidrosis results in sustained improvements in clinically meaningful health outcomes, comparisons to conventional therapies in well-designed comparative studies (ideally randomized controlled trials) are needed using standardized functional measurement tools.

For individuals who have primary axillary or palmar hyperhidrosis, a high rate of clinical efficacy after endoscopic transthoracic sympathectomy has been demonstrated,[2-10] although the rate of postoperative compensatory sweating was substantial.[11] Surgical excision of axillary sweat glands in individuals who have primary axillary hyperhidrosis has been shown to be highly effective. The evidence is sufficient to determine that endoscopic transthoracic sympathectomy and surgical excision of axillary sweat glands results in a meaningful improvement in the net health outcome for individuals who have primary axillary or palmar hyperhidrosis. These procedures are considered standard of care for these indications when a trial of non-surgical treatment has failed.

For individuals who have severe secondary gustatory hyperhidrosis who receive tympanic neurectomy, this treatment has been shown to have high success rates, without the need for repeated interventions. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome and this treatment is considered standard of care for this indication when a trial of non-surgical treatment has failed.

The focus of the following evidence summary is on systematic reviews (SRs), technology assessments (TAs), randomized controlled trials (RCT), and comparative nonrandomized studies for the investigational indications listed in the policy criteria.

LUMBAR SYMPATHECTOMY

Systematic Review

Chudry (2022) published a systematic review (SR) evaluating the effectiveness of interventions for primary palmar hyperhidrosis (PH).[12] Six studies were included in the review. Two of these studies addressed the use of endoscopic thoracic sympathectomy (ETS) in PH, and both reported over 95% patient symptom improvement. The authors conclude that ETS was reported as successful as other interventions in the reduction of PH, however, ETS carries significant adverse effects such as compensatory sweating and the potential of complications associated with surgery.

Lima (2020) conducted a SR and meta-analysis of lumbar sympathectomy for plantar hyperhidrosis.[13] Eight studies were identified, including a total of 517 patients. One RCT met inclusion criteria; the other studies were case series. In all of the studies, lumbar sympathectomy was conducted following transthoracic sympathectomy. Resolution of symptoms occurred in 92% of patients when mechanical sympathectomy was used with clipping or resection of the lymph nodes between L2 and L5, with similar results regardless of resection level, Overall, 44% of patients had mild to severe compensatory sweating after a mean of six months of follow-up. The RCT was conducted in 30 women at a single hospital in Brazil. The primary outcome measure was a quality-of-life questionnaire that was developed for use in patients undergoing thoracic sympathectomy. After six months, patients in the intervention group had a greater improvement in quality of life relative to the control group patients; 53% reported worsening compensatory sweating. This study was limited by its small

sample size, use of an unvalidated outcome measure, and lack of blinded outcome assessment.

Lima (2017) published a SR evaluating the efficacy of lumbar sympathectomy in plantar hyperhidrosis. Among the nine studies included, eight were retrospective studies, and one was a RCT.[14] None of the eight retrospective studies were considered to be of high quality, assessed by the Newcastle Ottawa Scale. The protocol was highly variable across trials, with respect to intervention site (ranging from L2/L3 to L5) and surgical technique (seven studies used mechanical clipping or resection sympathectomy, two used chemical sympathectomy). Across all studies, the percent of patients with resolution of symptoms ranged from 5 to 98%. There was a high variation in the incidence of complications across studies, including neuralgia (range, 3% to 42.2%), compensatory sweating, (1.5% to 90%), and sexual dysfunction (not reported by all studies). There is not enough evidence of the safety or long-term clinical outcomes of lumbar sympathectomy in the treatment of plantar hyperhidrosis. Additional RCTs with standardized protocols are needed.

Randomized Controlled Trials

No RCTs beyond those summarized in the SR above were identified.

Nonrandomized Studies

In addition to the nonrandomized studies summarized in the SR above, there have been case series published, however, these observations are not generalizable due to lack of randomization, lack of a control group for comparison, heterogeneous patient characteristics, lack of long-term follow-up, subjective outcomes, and the use of different surgical techniques.[15-17] In addition to low success rates, concerns have been reported for side effects in sexual functioning in both males and females.

REMOVAL OF AXILLARY SWEAT GLANDS BY LIPOSUCTION OR CURETTAGE

There is insufficient evidence to determine whether liposuction or curettage of sweat glands is safe or effective as a treatment of axillary hyperhidrosis. In a SR of treatments available in secondary care for the management of primary hyperhidrosis, Wade (2018) evaluated studies on curettage for axillary hyperhidrosis.[18] Nine studies were identified including four RCTs and five nonrandomized studies. All were considered to be at high risk for bias. Meta-analysis was not possible due to methodological differences. In four studies, curettage was compared to botulinum treatment and only one small RCT found a statistically significant improvement in symptoms, favoring botulinum.[19] No differences were found in sweating, quality-of-life or satisfaction outcomes, although, where reported, the incidence of adverse events was higher with curettage than with botulinum. Although this procedure has been performed for several decades, only scattered reports regarding its effectiveness were identified in a PubMed literature search.[20-25]

AXILLARY SUBDERMAL LASER TREATMENT

Systematic Reviews and Technology Assessments

In 2015, the Canadian Agency for Drugs and Technologies in Health (CADTH) published a rapid response review on the clinical effectiveness of laser therapy in axillary hyperhidrosis.[26] Five publications were included in the review, three RCTs and two nonrandomized studies. No relevant evidence-based guidelines were identified for inclusion. The authors reported that

although the evidence suggests laser therapy may reduce sweating in cases of axillary hyperhidrosis, these results should be interpreted with caution due to the methodological limitations of the studies, which include but are not limited to, small sample sizes, a lack of reporting on efficacy and safety outcomes, potential selection bias, and a lack of long term follow-up data.

Randomized Controlled Trials

No RCTs beyond those summarized in the review above were identified.

Nonrandomized Studies

No studies beyond those summarized in the review above were identified.

PERCUTANEOUS RADIOFREQUENCY TREATMENTS

Systematic Reviews

Hasimoto (2020) published a SR with meta-analysis of nine studies (N=378) evaluating the effectiveness of radiofrequency (RF) treatment of primary hyperhidrosis, including radiofrequency ablation (RFA) sympathectomy (N=238) and fractionated microneedle radiofrequency (FMRF) of the axillary (N=75) compared to video-assisted thoracic sympathectomy (VATS) (N=65).[27] In seven of the nine studies, patients were subjected to RF only, and in two of nine studies RF was compared to VATS. Across the three studies evaluating FMRF, there was a reduction in the severity of hyperhidrosis (mean difference -1.24, 95% CI -1.44 to -1.03) and minor improvement in reported quality of life (QoL) (-9.0, 95% CI -9.15 to -8.85). There was improvement in QoL found after RFA (two studies, mean difference -15.92, 95% CI -17.61 to -14.24), although the one study comparing QoL improvement after RFA or VATS found that VATS showed superior results. In the one study that evaluated symptom recurrence between VATS and RF found higher recurrence rates in RF (5% vs. 25%, respectively, $p<0.01$). There were no RCTs identified for inclusion, and of the two studies comparing RFA to VATS, one was a non-randomized controlled study and the other was a retrospective observational study. The authors concluded that there is a need for high-quality prospective studies comparing RF to current standard practice, particularly VATS.

Randomized Controlled Trials

Mostafa (2019) conducted a randomized controlled trial (RCT) of radiofrequency ablation compared to botulinum toxin type A in 80 patients with primary palmar hyperhidrosis.[28] Both groups showed improvements from baseline in HDSS scores at one week, one month, and two months after treatment, but scores in the radiofrequency ablation group were significantly lower (indicating more improvement with RFA) than in the botulinum toxin group at one week, one month, and two, six, and 12 months after treatment.

Rummaneethorn (2019) compared RFA to botulinum toxin A in 20 patients with primary axillary hyperhidrosis.[29] At the endpoint visit (week 12), the botulinum toxin A group had significantly greater reduction of mean HDSS score than the RFA group with 1.60 (0.59) versus 2.05 (0.68), respectively (p=0.0332). At week 12, the botulinum toxin A group also had significantly higher satisfaction score by quartile rating scale than the microneedle RF group (2.55 + 0.69 versus 1.70 + 1.03, respectively, p=0.004).

Nonrandomized Studies

No studies beyond those summarized in the SR above were identified.

PRACTICE GUIDELINE SUMMARY

In 2011, an expert consensus statement on the surgical treatment of hyperhidrosis was published by a task force of the Society of Thoracic Surgeons.[30] The document stated that endoscopic thoracic sympathectomy is the treatment of choice for patients with primary hyperhidrosis. They further recommend the following treatment strategies (with R referring to rib and the number to the specific rib):

- R3 interruption for palmar hyperhidrosis; an R4 interruption is also reasonable. The authors note a slightly higher rate of compensatory sweating with an R3, but R3 is also more effective at treating hyperhidrosis.
- R4 or R5 interruption for palmar-axillary, palmar-axillary-plantar or axillary hyperhidrosis alone; R5 interruption is also an option for axillary hyperhidrosis alone.
- R3 interruption for craniofacial hyperhidrosis without blushing; an R2 and R3 procedure is an option but may lead to a higher rate of compensatory sweating, and also increases the risk of Horner's syndrome.

SUMMARY

There is enough evidence to determine that endoscopic transthoracic sympathectomy and surgical excision of axillary sweat glands results in a meaningful improvement in the net health outcome for individuals who have primary axillary, craniofacial, or palmar hyperhidrosis. These procedures are considered standard of care for these indications when a trial of non-surgical treatment has failed. Clinical guidelines based on research recommend surgical treatment for primary hyperhidrosis. Therefore, endoscopic transthoracic sympathectomy and surgical excision of axillary sweat glands is considered medically necessary when policy criteria are met.

For individuals who have severe secondary gustatory hyperhidrosis who receive tympanic neurectomy, this treatment has been shown to have high success rates without the need for repeated interventions. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome and this treatment is considered standard of care for this indication when a trial of non-surgical treatment has failed. Therefore, tympanic neurectomy is considered medically necessary for the treatment of secondary gustatory hyperhidrosis when policy criteria are met.

There is not enough research to show surgical treatment for hyperhidrosis improves health outcomes for all other conditions and/or complications. Therefore, surgical treatment for hyperhidrosis is considered not medically necessary when policy criteria are not met.

There is not enough research to show that surgical treatments of hyperhidrosis including, but not limited to lumbar sympathectomy, axillary liposuction or curettage performed alone or in combination with any other procedure, subdermal laser-assisted axillary hyperhidrosis treatment, percutaneous radiofrequency sympathicolysis or sympathectomy and radiofrequency ablation for palmar hyperhidrosis improves health outcomes for people with hyperhidrosis. There are no evidence-based clinical practice guidelines recommending these

procedures for the treatment of hyperhidrosis. Therefore, these techniques are considered investigational.

Surgeries for Snoring, Obstructive Sleep Apnea Syndrome, and Upper Airway Resistance Syndrome

Effective: January 1, 2024

Next Review: October 2024
Last Review: November 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

When conservative therapies for obstructive sleep apnea or upper airway resistance syndrome fail, established surgical interventions may be indicated.

MEDICAL POLICY CRITERIA

Note: Contract language takes precedent over medical policy. Some member contracts have specific benefit limitations for orthognathic and telegnathic surgery.

Pediatric Patients

I. In pediatric patients (age 17 years and younger), surgical treatment for obstructive sleep apnea (OSA) and upper airway resistance syndrome (UARS) may be considered **medically necessary** when the request is not for any of the investigational procedures listed in Criterion III. below.

II. In pediatric patients, surgical treatment of snoring in the absence of documented obstructive sleep apnea is considered **not medically necessary**.

III. In pediatric patients, surgical treatment of obstructive sleep apnea (OSA) and upper

airway resistance syndrome (UARS) using any one or more of the following procedures is considered **investigational**:

A. Laser-assisted uvulopalatoplasty (LAUP) or volumetric tissue reduction

B. Palatal stiffening procedures, including but not limited to the following: Cautery-assisted palatal stiffening operation (CAPSO), injection of sclerosing agent (also known as snoreplasty), and implantation of palatal implants (also known as the pillar procedure)

C. Radiofrequency volumetric tissue reduction of the tongue base or palatal tissues

D. Tongue base suspension procedures, including but not limited to the AIRvance™ and the Encore™ tongue suspension systems

E. Uvulectomy

Adult Patients

IV. Surgical procedures for the treatment of obstructive sleep apnea (OSA) and upper airway resistance syndrome (UARS) in adult patients (age 18 years and older) may be considered **medically necessary** when all of the criteria below (A. - E.) are met:

A. There is documentation of a sleep study performed within the last 3 years; and

B. One or more of the following procedures are requested:

a. Hyoid myotomy and suspension

b. Mandible osteotomy with or without genioglossus advancement

c. Maxillo-mandibular advancement (MMA)

d. Palatopharyngoplasty (e.g., uvulopalatopharyngoplasty [UPPP], uvulopharyngoplasty)

e. Partial Glossectomy

C. Evidence, documented in the medical records, of exam findings that demonstrate upper airway collapse or obstruction as a reasonable cause of obstructive sleep apnea (e.g., palatine tonsils, epiglottis collapse, arytenoid collapse, lateral pharyngeal, craniofacial deficits).

D. The patient meets criteria for clinically significant obstructive sleep apnea (OSA) or upper airway resistance syndrome (UARS) as defined by Criteria 1. or 2. below:

1. Clinically significant obstructive sleep apnea (OSA) defined as Criteria a. or b. below:

a. An AHI equal to or greater than 15 per hour; or

b. An AHI equal to or greater than 5 per hour with at least one of the following associated symptoms:

i. Excessive daytime sleepiness that is not better explained by other factors

ii. Documented unexplained hypertension

iii. Ischemic heart disease or congestive heart failure

iv. Atrial fibrillation

v. History of stroke

vi. Obesity

vii. Diabetes and glucose intolerance

viii. Two or more of the following that are not better explained by other factors:

a.) Choking or gasping during sleep

b.) Recurrent awakenings during sleep

c.) Unrefreshing sleep with daytime fatigue

d.) Impaired concentration or cognition

e.) Insomnia

2. Upper airway resistance syndrome (UARS) that is clinically significant is defined as greater than 10 alpha EEG arousals per hour.

E. All of the following conservative medical therapies have failed to improve apnea/hypopnea including associated conditions such as excess daytime sleepiness:

1. Adjustment in sleep position when the sleep study shows improvement of sleep apnea when non-supine; and

2. An adequate trial (at least 3 consecutive months [90 days] of continuous [at least 5 nights per week]) of a custom-made mandibular repositioning appliance has failed OR the patient is not an appropriate mandibular repositioning appliance candidate (see Policy Guidelines); and

3. An adequate positive airway pressure (PAP, continuous or bi-level) trial that is a minimum of 4 hours per night for 3 weeks of PAP usage has failed OR the patient is not an appropriate PAP candidate (see Policy Guidelines).

V. Surgical treatment of obstructive sleep apnea (OSA) and upper airway resistance syndrome (UARS) in adult patients is considered **not medically necessary** when Criterion IV. is not met, including PAP therapy refusal, or to treat snoring in the absence of documented obstructive sleep apnea in adult patients.

VI. Surgical treatments of obstructive sleep apnea (OSA) and upper airway resistance syndrome (UARS) in adult patients not listed in Criterion IV.B. are considered **investigational** including, but not limited to the following:

A. Laser-assisted uvulopalatoplasty (LAUP) or volumetric tissue reduction

B. Palatal stiffening procedures, including but not limited to cautery-assisted palatal stiffening operation (CAPSO), injection of sclerosing agent (also known as snoreplasty), or implantation of palatal implants (also known as the pillar procedure)

C. Radiofrequency volumetric tissue reduction of the tongue base or palatal tissues

D. Tongue base suspension procedures, including but not limited to the AIRvance™ and the Encore™ tongue suspension systems

E. Uvulectomy

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

MANDIBULAR REPOSITIONING DEVICE

Not all patients are candidates for a mandibular repositioning device. Patients with tonsil hypertrophy criteria grade 3 or 4 on the Friedman scale, severe psychiatric diseases or dementia, untreated caries or periodontal disease, few teeth for anchoring a device, temporomandibular joint disorder, inadequate mandibular protrusive capacity, and class III malocclusion are examples of conditions that are contraindications to mandibular repositioning appliances.

POSITIVE AIRWAY PRESSURE (PAP)

PAP failure: defined as AHI greater than 20 events per hour while using PAP.

Not an appropriate PAP candidate: defined as being unable to use PAP therapy for at least 4 hours per night for 5 nights or more per week, with reasonable attempts having been made to address any medical, mechanical, or psychological problems associated with PAP, e.g., adjustment of pressure settings, appropriate medication and humidification, refitting of the mask, trial of alternative pressure delivery systems such as auto-adjusting positive airway pressure or bi-level positive airway pressure.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Current Symptomology
- Conservative Medical Therapies failed
- PAP Trial results
- Sleep Study results
- Documentation of an adequate trial of a mandibular repositioning device or documentation that the patient is not an appropriate appliance candidate with clinical rationale
- Evidence of airway obstruction or narrowing consistent with the procedure requested

BACKGROUND

OBSTRUCTIVE SLEEP APNEA (OSA)

Obstructive sleep apnea (OSA) is characterized by repetitive episodes of upper airway obstruction due to the collapse and obstruction of the upper airway during sleep. The hallmark symptom of OSA is excessive daytime sleepiness, and the typical clinical sign of OSA is snoring, which can abruptly cease and be followed by gasping associated with a brief arousal from sleep. The snoring resumes when the patient falls back to sleep, and the cycle of snoring/apnea/arousal may be repeated as frequently as every minute throughout the night.

Sleep fragmentation associated with the repeated arousal during sleep can impair daytime activity. For example, adults with OSA-associated daytime somnolence are thought to be at higher risk for accidents involving motorized vehicles (i.e., cars, trucks, heavy equipment). OSA in children may result in neurocognitive impairment and behavioral problems. In addition, OSA affects the cardiovascular and pulmonary systems. For example, apnea leads to periods of hypoxia, alveolar hypoventilation, hypercapnia, and acidosis. This, in turn, can cause systemic hypertension, cardiac arrhythmias, and cor pulmonale. Systemic hypertension is common in patients with OSA. Severe OSA is associated with decreased survival, presumably related to severe hypoxemia, hypertension, or an increase in automobile accidents related to overwhelming sleepiness.

A polysomnogram performed in a sleep laboratory and, in adults, home sleep apnea testing with a technically adequate device (see Appendix 1), are considered the gold standard tests used to diagnose OSA in adults.[1] Objective measures of OSA are compiled using polysomnography monitors, which document the number of apneic and hypopneic events per hour and combine them into the apnea-hypopnea index (AHI). The respiratory disturbance index (RDI) may be defined as the number of apneas, hypopneas and respiratory effort-related arousals (RERAs) per hour of sleep. The final diagnosis of OSA rests on a combination of objective and subjective criteria (e.g. AHI or RDI and excessive daytime sleepiness) that seek to identify those levels of obstruction which are clinically significant. When sleep onset and offset are unknown (e.g., in home sleep studies) the AHI or RDI may be calculated based on the number of apneas, hypopneas, and/or RERAs per hour of recording time.

An increase in mortality is associated with an AHI greater than 15. More difficult to evaluate is the clinical significance of patients with mild sleep apnea. Mortality has not been shown to be increased in these patients, and frequently the most significant manifestations reported by the patient are snoring, excessive daytime sleepiness, witnessed breathing interruptions, awakenings due to gasping or choking, nocturia, morning headaches, memory loss, irritability, or hypertension.[2, 3] The hallmark clinical symptom of OSA is excessive snoring, although it is important to note that snoring can occur in the absence of OSA. Isolated snoring in the absence of medical complications, while troubling to the patient's bed partner, is not considered a medical problem requiring surgical intervention.

There are racial and ethnic health disparities seen for OSA, impacting the prevalence of disease and accessibility to treatment options, particularly affecting children. Black children are four to six times more likely to have OSA than white children.[4] Among young adults younger than 26 years, African American individuals are 88% more likely to have OSA compared to white individuals. Another study found that African American individuals 65 years of age and older were 2.1 times more likely to have severe OSA than white individuals of the same age group. These health disparities may affect accessibility of treatment for OSA and impact health

outcomes. One analysis of insurance claims data, including over 500,000 patients with a diagnosis of OSA, found that increased age above the 18- to 29- year range (p<0.001) and Black race (p=.020) were independently associated with decreased likelihood for receiving surgery for sleep apnea.[5] Lee (2022) found that Black men had a continuous mortality increase specifically related to OSA over the study period (1999 to 2019; annual percentage change 2.7%; 95% confidence interval, 1.2 to 4.2) compared to any other racial group.[6]

Table 1. Definitions of Terms for Obstructive Sleep Apnea

Terms	Definition
Apnea	The frequency of apneas and hypopneas is measured from channels assessing oxygen desaturation, respiratory airflow, and respiratory effort. In adults, apnea is defined as a drop in airflow by ≥90% of pre-event baseline for at least 10 seconds. Due to faster respiratory rates in children, pediatric scoring criteria define an apnea as ≥2 missed breaths, regardless of its duration in seconds.
Hypopnea	Hypopnea in adults is scored when the peak airflow drops by at least 30% of pre-event baseline for at least 10 seconds in association with either at least 3% arterial oxygen desaturation or an arousal or at least 4% arterial oxygen desaturation (depending on the scoring criteria). Hypopneas in children are scored by a ≥50% drop in nasal pressure and either a ≥3% decrease in oxygen saturation or an associated arousal.
Apnea/Hypopnea Index (AHI)	The average number of apneas or hypopneas per hour of sleep
Obstructive sleep apnea (OSA)	Repetitive episodes of upper airway obstruction due to the collapse and obstruction of the upper airway during sleep
Mild OSA	In adults: AHI of 5 to <15 In children: AHI ≥1 to <5
Moderate OSA	In adults: AHI of 15 to <30 In children: AHI ≥5 to <10
Severe OSA	Adults: AHI ≥30 Children: AHI ≥10
Continuous positive airway pressure (CPAP)	Positive airway pressure may be continuous (CPAP) or auto-adjusting (APAP) or Bi-level (Bi-PAP). CPAP is a more familiar abbreviation and will refer to all types of PAP devices.
PAP Failure	Usually defined as an AHI greater than 20 events per hour while using PAP (continuous or bi-level)
PAP Intolerance	PAP use for less than 4 h per night for 5 nights or more per week, or refusal to use PAP (continuous or bi-level). PAP intolerance may be observed in patients with mild, moderate, or severe OSA

UPPER AIRWAY RESISTANCE SYNDROME (UARS)

Upper airway resistance syndrome (UARS) was initially used to describe a variant of OSA which is characterized by a partial collapse of the airway resulting in increased resistance to airflow. This resistance does not result in apnea, but the increased respiratory effort required to move air into the lungs results in fragmented sleep. These sleep fragmentations (RERAs) can be measured using an electroencephalogram (EEG). Diagnosis of UARS rests on documentation of more than 10 EEG arousals per hour of sleep along with documented episodes of abnormally negative intrathoracic pressure (i.e., more negative than -10 cm) associated with the EEG arousals. The drop in intrathoracic pressure can be measured by a variety of tests including use of an esophageal manometer, if available, as part of a polysomnogram. RERAs can also be detected absent manometry during polysomnography. It

has been proposed that UARS is a distinct syndrome from OSA that may be considered a disease of arousal.

See Appendix 1 for additional information on diagnostic tests for OSA and UARS.

SURGICAL TREATMENTS FOR OSA AND UARS

Medical therapy is considered the first-line treatment for OSA and UARS. These therapies include weight loss, various continuous positive airway pressure (CPAP) devices, or orthodontic repositioning devices in appropriate patients. See Appendix 2 for a description of medical devices used in the treatment of OSA and UARS. Most guidelines consider surgical intervention only after all appropriate medical treatments for OSA or UARS have failed. Conventional surgeries for OSA include uvulopalatopharyngoplasty (UPPP) and a variety of maxillofacial surgeries such as maxillo-mandibular advancement (MMA).

Uvulopalatopharyngoplasty (UPPP)

UPPP involves surgical modification of the oropharynx and/or velopharynx by resection or reconstruction of the associated structures (soft palate, uvula, and associated muscles).[7, 8] The UPPP procedure enlarges the oropharynx but cannot correct obstructions in the hypopharynx. Therefore, if hypopharynx obstruction is identified, then alternate procedures are considered. In addition, patients who fail UPPP may be candidates for additional procedures, depending on the site of obstruction. Additional or alternate procedures include hyoid suspensions, maxillary and mandibular osteotomies, and mandibular and maxillary advancement surgery.

Mandibular and maxillary advancement (MMA) surgery

Mandibular and maxillary advancement (MMA) surgery (may also be referred to as telegnathic surgery) is more extensive and is proposed for patients who do not have an adequate response to UPPP or other procedures, or who have mandibular or maxillary deficiency. These surgeries may be used to correct obstruction of the hypopharynx, oropharynx, or velopharynx; the areas of the full length of the throat.

Laser assisted uvuloplasty (LAUP)

LAUP is an outpatient procedure that has been proposed as a treatment of snoring with or without associated OSA. In this procedure, the tissues of the soft palate (palatal tissues) are reshaped using a laser. The extent of the surgery is typically different than standard UPPP, since only part of the uvula and associated soft-palate tissues are reshaped. The procedure, as initially described, does not remove or alter tonsils or lateral pharyngeal wall tissues. The patient undergoes from 3 to 7 sessions at 3- to 4-week intervals. LAUP cannot be considered an equivalent procedure to the standard UPPP, with the laser simply representing a surgical tool that the physician may opt to use. LAUP is considered a unique procedure, raising unique issues of safety and effectiveness.

Palatal stiffening procedures and radiofrequency tissue reduction

<u>Radiofrequency ablation of the soft palate and radiofrequency volumetric reduction of the tongue base (RFTBR)</u>

Radiofrequency energy is used to produce thermal lesions within the tissues. Radiofrequency devices transmit low frequency energy that causes ionic friction, which leads to coagulation necrosis, inflammation, and fibrosis.[9] These procedures may reduce the volume of soft tissue and may stiffen the tissue due to the creation of a submucosal scar. Radiofrequency based treatments to modify tissues of the soft palate have historically been referred to as somnoplasty.

Cautery assisted palatal stiffening procedure (CAPSO)

This palatal stiffening procedure uses cautery (electrically heated probes) to induce a midline palatal scar designed to stiffen the soft palate to eliminate excessive snoring.

Other palatal stiffening procedures

Other palatal stiffening procedures in use include injection sclerotherapy (also known as injection snoreplasty) and the pillar procedure, which involves the permanent implantation of braided polyester filaments into the soft palate through a needle.

Suspension of the tongue base and hyoid bone

Tongue or hyoid bone suspension is performed through a small incision under the chin. A titanium screw is inserted under the chin in the posterior aspect of the lower jaw at the floor of the mouth. For tongue suspension, a loop of suture is passed through the tongue base and attached to the mandibular bone screw. For hyoid suspension a suspension loop is placed around the hyoid bone and anchored to the mandibular screw or to the thyroid cartilage. Once the suspension loop is attached to the screw it is pulled forward to advance the tongue base out of the airway, making it less likely for the base of the tongue to drop backward during sleep.

Uvulectomy

This procedure surgically removes the uvula, the small tissue hanging from the soft palate at the back of the throat above the tongue. The uvula, which helps stiffen and shape the back of the throat and prevents food from going down the airway, is believed to be associated with excessive snoring.

Partial Glossectomy

This procedure, also referred to as midline glossectomy, surgically removes a portion of the tongue in an effort to reduce tongue volume and open the oropharynx and/or hypopharynx.

REGULATORY STATUS

The Somnoplasty® device has been cleared for marketing by FDA for RFA of palatal tissues for simple snoring and for the base of the tongue for OSA. FDA product code: GEI.

AIRvance® (Medtronic; formerly the Repose™ Bone Screw System from Influence) was cleared for marketing through the FDA 510(k) process in 1999 with intended use for anterior tongue base suspension by fixation of the soft tissue of the tongue base to the mandible bone using a bone screw with prethreaded suture. It is indicated for the treatment of OSA and/or snoring.

The Encore™ Tongue Suspension System (Siesta Medical) received clearance for marketing by FDA in 2011, citing the PRELUDE III Tongue Suspension System (Siesta Medical) as a predicate device.

The Pillar® Palatal Implant System (originally Restore Medical, St. Paul, MN, acquired by Medtronic, Minneapolis, MN) is an implantable device that has been cleared for marketing through the FDA 510(k) process. The labeled indication of the device is as follows: “The Pillar™ Palatal Implant System is intended for the reduction of the incidence of airway obstructions in patients suffering from mild to moderate OSA (obstructive sleep apnea).” FDA product code: LRK.

EVIDENCE SUMMARY

Positive airway pressure (PAP, continuous or bi-level) is the most widely accepted medical therapy for treatment of obstructive sleep apnea (OSA) in adults and improvement of primary health outcomes such as cardiovascular disease, type 2 diabetes, and overall mortality associated with OSA.[8] Surgical interventions are being proposed as a second line treatment for patients who have experienced PAP failure or intolerance.

Appropriately controlled and adequately powered, long-term randomized controlled trials (RCTs) are needed to determine the safety and effectiveness of various surgical interventions for treatment of OSA.

The evidence suggests conventional uvulopalatopharyngoplasty (UPPP), hyoid suspension, mandible osteotomy, partial glossectomy, and maxillofacial surgeries such as maxillo-mandibular advancement (MMA), may improve health outcomes for some patients with OSA who have failed medical therapies for OSA.

- The available evidence does not currently support the widespread use of surgical interventions in the management of unselected patients with obstructive sleep apnea. Given the proven safety and efficacy of CPAP in patients with moderate and severe symptoms and significant sleep disordered breathing, surgery cannot be recommended as a first line therapy, ahead of positive airways pressure systems.[8, 10]
- While studies on UPPP and hyoid suspension procedures were not randomized, data from ten studies which included more than 750 patients consistently reported improved outcomes for patients with OSA as measured by postoperative polysomnographic assessment of sleep disturbance and compared with concurrent groups being treated with CPAP.[11]
- UPPP, hyoid suspension, mandible osteotomy, partial glossectomy and MMA procedures are widely practiced among surgeons in the United States. These procedures have been considered a standard of care in the medical community.[11]

Evidence is uncertain for use of other surgical interventions in the treatment of OSA, including but not limited to uvulectomy and minimally invasive surgical procedures such as laser-assisted uvuloplasty (LAUP), radiofrequency tongue base reduction (RFTBR), pillar stiffening procedures, and pillar implants. Therefore, the following evidence review will be focused on the investigational indications in this policy.

SURGICAL TREATMENTS FOR OSA

Technology Assessments and Systematic Reviews

Maniaci (2022) compared the efficacy and success rates of lateral pharyngoplasty techniques (LP) vs. uvulopalatopharyngoplasty (UPPP) among adult patients surgically treated for obstructive sleep apnea.[12] Nine articles for a total of 312 surgically treated patients with OSA were included in this systematic review. LP techniques for obstructive sleep apnea were used on 186 (60%) subjects, while 126 patients (40%) were treated with UPPP. Both surgical procedures resulted in significant improvements in apnea-hypopnea index (AHI), Epworth Sleepiness Scale (ESS) score, and lowest oxygen saturation (LOS) ($p<0.001$ in all cases). Although better outcomes were reported with lateral pharyngoplasty, the differences were not significant compared to UPPP post-operative results ($p>0.05$ in all cases). The authors further say, “Further evidence comparing the surgical effect on patients with OSA is needed to discriminate post-operative outcomes”.

A 2011 Agency for Healthcare Research and Quality (AHRQ) Comparative Effectiveness Review entitled “Diagnosis and Treatment of Obstructive Sleep Apnea in Adults” included studies conducted only in adults, defined as over 16 years of age. The authors state the following regarding the available evidence for surgical interventions for the treatment of OSA:[8]

- *The strength of evidence is insufficient to evaluate the relative efficacy of surgical interventions for the treatment of OSA.*
- *The strength of evidence is insufficient to determine the relative merits of surgical treatments versus CPAP.*
- *Due to the heterogeneity of interventions and outcomes examined, the variability of findings across studies, and the inherent bias of all but one study regarding which patients received surgery, it is not possible at this time to draw useful conclusions comparing surgical interventions with CPAP in the treatment of patients with OSA.*

The review cited the lack of comparative trials between CPAP and proposed surgical modalities and the lack of trial data providing long-term health outcomes associated with OSA treatment as limitations to available evidence.

Earlier evidence-based systematic reviews on the use of surgical therapies in OSA cited the lack of well-designed randomized controlled trials (RCTs) assessing different surgical techniques with inactive and active control treatments.[10, 13] These reviews were not able to make the highest-level recommendation supporting the use of any one surgical intervention. Limitations of studies include heterogeneous patient populations with mixed OSA severity, as measured by AHI; and lack of long-term followup. These reviews state that long-term follow-up of patients who undergo surgical correction of upper airway obstruction would help to determine whether surgery is curative, or whether the signs and symptoms of sleep apnea return, prompting patients to seek further treatment.

The 2009 systematic review by Franklin evaluated benefits and adverse effects of surgery for snoring and OSA.[14] The authors found only a small number of randomized controlled trials (RCTs) that assessed surgical procedures for snoring or sleep apnea. Key findings are as follows:

- Results from 45 studies reporting adverse events revealed persistent side effects after uvulopalatoplasty (UPP) and uvulopalatopharyngoplasty (UPPP) in about half the patients. Difficulty swallowing, globus sensation, and voice changes were especially common. The authors concluded that additional research with RCTs of surgery other

than UPP and UPPP is needed, as these surgical procedures are related to a high risk of adverse effects, especially difficulty swallowing.

- Four RCTs, rated as high quality, were identified for laser-assisted palatoplasty (LAUP) and radiofrequency ablation (RFA).[15-18] Study results were mixed and inconclusive for Apnea/Hypopnea Index (AHI), and showed no benefit on daytime sleepiness or quality of life. Interpretation of this result is limited by the inclusion of studies with one-stage procedures and subjects whose main symptom was disruptive snoring.[17] The relevant trials are described in greater detail below.

RADIOFREQUENCY VOLUMETRIC TISSUE REDUCTION OF THE TONGUE BASE OR PALATAL TISSUES

Systematic Reviews

Baba (2015) performed a systematic review and meta-analysis that addressed the efficacy of temperature controlled radiofrequency tissue ablation (TCRFTA) to alleviate symptoms of OSA.[19] The analyses included three small nonrandomized comparative trials comparing TCRFTA with three different nonsurgical or surgical interventions and seven prospective case series (of which all but one were small). TCRFTA was categorized based on location: base of tongue, soft palate and multilevel. Analysis showed significant reductions in respiratory disturbance index (RDI), Epworth Sleep Scale (ESS), lowest oxygen saturation (LSAT), and snoring for procedures performed at the base of the tongue. TCRFTA at the soft palate showed limited efficacy, although there was a paucity of studies in this area. Multilevel TCFFTA did show a significant reduction in RDI, in the short term. Analysis of AHI was not completed as this outcome was not consistently reported within the studies. The authors reported that the studies were generally of low quality and there was significant heterogeneity which did not allow for strong conclusions. Studies with longer-term outcomes would be useful in evaluating the benefits of this procedure.

In 2008, Farrar published a meta-analysis of RFA for the treatment of OSA in patients with a RDI of 5 or more.[9] Sixteen studies met the inclusion criteria; three were randomized and 13 were nonrandomized. Six studies treated both the base of the tongue and the soft palate, two treated the soft palate only, and eight ablated the base of the tongue only. The population was in the overweight, but not obese, category, with a mean BMI of 28.5. In half of the studies, the average baseline RDI was less than 30, and in six of the studies, the average baseline ESS was less than 10. The meta-analysis indicated a 31% reduction in both ESS and RDI. The lowest oxygen saturation level was not improved by RFA. The mean number of treatments required for patient satisfaction was 3.7 for the soft palate, 4.3 for the base of the tongue, and 4.8 for both sites (range, 3-7). Complications were noted in 4% of patients; two tongue abscesses progressed to airway obstruction requiring tracheotomy. Only two of the studies provided 2-year follow-up, with a 32% reduction in ESS and a 45% reduction in RDI. The number of patients who were successfully treated (e.g., 50% reduction in RDI) was not reported. This meta-analysis is limited by the inclusion of poor-quality uncontrolled studies.

Randomized Controlled Trials

McKay (2020) published the results of a randomized controlled trial (RCT, multicenter, parallel-group, open-label) that compared multilevel surgery (modified uvulopalatopharyngoplasty and radiofrequency tongue volume reduction; n=51) and ongoing medical management (e.g., advice on sleep positioning, weight loss; n=51) for the treatment of OSA.[20] There was a statistically significantly greater improvement from baseline to six months in AHI in the surgery

group (47.9 vs. 20.8) than in the ongoing medical management group (45.3 vs. 34.5, mean baseline-adjusted between-group difference,−17.6 events/h of sleep [95%CI, −26.8 to −8.4]; p<0.001) and in the ESS in the surgery group (12.4 vs 5.3) compared with the ongoing medical management group (11.1 vs 10.5, mean baseline adjusted between-group difference,−6.7 [95%CI,−8.2 to−5.2]; p<0.001). There were six serious adverse events in four participants in the surgery group and no serious adverse events in the ongoing medical management group. Although the results of this study did surpass the minimal clinically important difference for AHI, they did not meet the sufficiently important difference for AHI (the amount needed to account for the cost and potential morbidity of surgery), indicating that further studies are needed to establish the long-term effectiveness, safety, and cost-effectiveness of this surgical treatment for OSA. In addition, women were underrepresented in the trial and the study cohort was limited to a select population that excluded patients with severe obesity (BMI of 38 or greater), patients older than 70 years, and patients with retrognathia and significant comorbidities, limiting generalizability of the outcomes. No comparison of UPPP alone to RF tongue reduction alone or of these procedures alone compared to medical management was provided. Ultimately, the authors conclude “further research is needed to confirm these findings in additional populations and to understand clinical utility, long-term efficacy, and safety of multilevel upper airway surgery for treatment of patients with OSA.”

A single-blinded RCT of single-stage radiofrequency surgery of the soft palate was reported in 2009 by Back.[21] Thirty-two patients with mild OSA (AHI between 5 and 15), habitual snoring, and excessive daytime sleepiness according to subjective patient history, were randomized to a single session of RFA or sham ablation. There was no difference between the groups for baseline to posttreatment (4-6 months) changes in the Epworth Sleepiness Scale (ESS) (3-point improvement in ESS for both groups), reports of snoring (1-point improvement in both groups), AHI (no clinically significant change), or any other outcome measure. None of the patients reported any treatment-related symptoms or complications four months after treatment. Results of this small single-blinded RCT indicate that single-stage RFA of the soft palate is not effective for the treatment of mild OSA.

A RCT from 2009 by Fernandez-Julian compared efficacy and adverse effects of two tongue-based procedures (RFA or tongue-base suspension) when combined with UPPP in 57 patients with moderate-to-severe sleep apnea (AHI ≥15).[22] Patients with a BMI of 35 kg/m^2 or greater were excluded. Although interpretation of results is limited by the lack of a control group treated with UPPP alone, the success rate for combined RFA + UPPP (defined as a ≥50% reduction and final AHI <15) was 51%. BMI was the main predictor of success, with success rates of only 12.5% in patients with a BMI between 30 and less than 35 kg/m^2.

A 2003 two-site RCT study by Woodson compared the use of multilevel RFA with the current criterion standard of CPAP.[16] The study included patients with mild obesity levels (BMI ≥34 kg/m^2) who had mild to moderate sleep apnea with an AHI between 10 and 30. Statistically significant improvement was noted with RFA and CPAP over placebo in OSA-specific quality of life using the Functional Outcomes of Sleep Questionnaire. However, the small size of the trial resulted in most outcomes not being statistically significant. The same group of authors reported a further subgroup analysis from the same trial, focusing on the 26 patients randomized to the RFA arm of the trial to determine whether additional treatments improved outcomes.[23] Specifically, the authors focused on multilevel treatments on various combinations of palatal and tongue tissues. Greater improvements in quality of life were reported for those patients who had a total of five treatments compared with 3. Another subgroup analysis focused on multilevel treatments in 26 patients.[24] This subgroup likely

contains overlapping patients with the previous report, and the results were similar (i.e., greater improvements were reported in those patients who had a total of five treatments).

Nonrandomized Studies

Herman et al (2023) published a prospective, open-label, single-arm, nonrandomized trial that investigated multilevel RFA as an alternative therapy for patients with mild-to-moderate OSA (AHI 10 to 30) with intolerance or inadequate adherence to CPAP.[25] Patients were treated with three sessions of office-based RFA to the soft palate and tongue base. Of the 56 patients recruited for the study, 43 completed the protocol. Overall, 22/43 (51%) were considered complete responders with a ≥50% reduction in baseline AHI and an overall AHI <20 at study completion. A reduction in mean and median AHI was observed at six months follow-up (p=.001 for both); the mean AHI decreased from 19.7 to 9.86 and the median AHI decreased from 17.8 to 7.5. Likewise, ODI scores were significantly reduced at 6 months follow-up; the mean ODI score decreased from 12.79 to 8.36 (p=.006) and the median ODI score decreased from 11.65 to 6.23 (p=.008).

A 2008 retrospective cohort study assessed the incremental value of RFA of the tongue in combination with UPPP.[26] All patients with both palatal and retroglossal obstruction, an RDI between 5 and 50, and no previous OSA surgery were included in the study. Seventy-five patients meeting the inclusion criteria had been treated with UPPP during the three year period, 38 had UPPP alone, 37 had UPPP plus RFA. The groups were comparable for age, sex, BMI, AHI, and mean arterial oxygen saturation (Sa_{O_2}); however, no details were provided regarding the choice of procedure. With surgical success rate defined as more than 50% reduction of the AHI and AHI below 20, the success rate was 42% with UPPP alone and 49% with RFA (not significantly different). Two patients had an additional RFA treatment. No major complications were observed. The study concluded that the addition of RFA to UPPP resulted in only limited improvement, but there was no major downside to it.

Two earlier case series have been published by Steward (2005) and Stuck (2004) on the use of radiofrequency ablation of both tongue base and soft palate tissue, referred to as a combined or multi-level radiofrequency tissue ablation technique.[27, 28] Both case series reported significant improvements, including reductions in mean respiratory disturbance and apnea-hypopnea indexes, and in one case series these improvements persisted for a median of 23 months. However, both case series are limited by size, including 29 and 20 patients, respectively, and potential selection bias among the included participants. In addition, the ability to detect true long-term efficacy of this treatment is limited by the case series study design with lack of control group.

Radiofrequency Volumetric Tissue Reduction of the Tongue Base or Palatal Tissues Section Summary

The evidence for the use of radiofrequency volumetric tissue reduction of the tongue base or palatal tissues for the treatment of obstructive sleep apnea or upper airway resistance syndrome includes two systematic reviews, three randomized controlled trials, and four non-randomized studies. The considerable heterogeneity of outcomes tested across studies does not allow for conclusions about the potential benefit of these procedures. Additional appropriately controlled studies are needed to inform the clinical outcomes of these procedures alone or in addition to standard of care, as well as to evaluate the long-term benefits of these procedures.

TONGUE BASE SUSPENSION PROCEDURES

Systematic Reviews

In 2013, Handler reported a systematic review of tongue suspension versus hypopharyngeal surgery for the treatment of OSA.[29] The review included 27 studies reporting on four separate procedures; tongue suspension alone, tongue suspension + UPPP, genioglossus advancement (GA) + UPPP, and genioglossus advancement + hyoid suspension (GAHM) + UPPP. A successful treatment was defined as a 50% decrease in the RDI or AHI and a postoperative RDI or AHI less than 20. Tongue suspension alone (six studies, 82 patients) had a success rate of 36.6%, while the success rate of tongue suspension + UPPP (eight studies, 167 patients) was 62.3%. A success rate of 61.1% was found for GA + UPPP (seven studies, 151 patients) and for GAHM + UPPP (12 studies, 467 patients). The adverse effects of tongue suspension appear to be milder than GA or GAHM and are reversible. Most of the studies identified in this review were level IV evidence (case series).

Randomized Controlled Trial

One level II RCT by Fernandez-Julian (2009) included in the systematic review compared two tongue base surgeries (RFA or tongue-base suspension) combined with UPPP for moderate to severe sleep apnea (AHI ≥15).[22] In the tongue suspension plus UPPP group (n=28), the mean AHI decreased from 33.1 to 15.1 events per hour. The success rate for the combined procedure (defined as a ≥50% reduction, final AHI <15, and ESS <11) was 57.1%, compared with a success rate of 51.7% in the UPPP plus RFA group (p=0.79). BMI was the main predictor of success, with a success rate for tongue base suspension plus UPPP of only 10% in patients with a BMI between 30 and 35 kg/m^2. Morbidity and complications were higher with the tongue suspension procedure compared with RFA.

Nonrandomized Studies

In 2013, Li conducted a nonrandomized comparative study to evaluate the use of the Repose system in conjunction with UPPP to treat patients with obstructive sleep apnea hypopnea syndrome (OSAHS) caused by suspected glossoptosis.[30] Seventy-eight patients with OSAHS caused by suspected glossoptosis were non-randomly divided into two groups. The 45 patients in the first group received UPPP and tongue-base suspension (Repose). The 33 patients in the second group received UPPP alone. Follow-up was conducted over six months, and polysomnography was used to determine the effects of treatment. Follow-up results at six months revealed that the degree of improvement in patients treated with UPPP + Repose was significantly greater than that seen in patients treated with UPPP alone. In the UPPP + Repose group, 17 patients were cured, 23 showed marked improvement, and five did not improve. In the UPPP alone group, one patient was cured, 16 showed marked improvement, and 16 did not improve. The marked improvement rates of the two groups were 88.9 and 51.5 %, respectively, a significant difference.

In a 2010 multicenter, prospective case series, Woodson assessed the safety and effectiveness of an adjustable lingual suspension device (Advance System) for treating OSA.[31] Forty two surgically naive patients with moderate to severe OSA and tongue base obstruction underwent surgical insertion of a midline tissue anchor into the posterior tongue and connected to an adjustable mandibular bone anchor with a flexible tether. Outcomes included changes in AHI, sleepiness, sleep-related quality-of-life, snoring, swallowing, speech and pain. After six months, all patients noted improvement for AHI, sleepiness and sleep-

related quality of life. Post implant pain scores were mild to moderate at day one and resolved by day five. Device related adverse events included wound infection (7%) and edema or seroma (5%), which resolved. However, in 31 percent of patients, asymptomatic tissue anchor barb fractures were observed radiographically. The tissue anchor failure rate of the tested device precludes its clinical use. Further investigation is warranted.

In 2002, Miller conducted a retrospective analysis of the Repose System for the treatment of OSA to describe preliminary experience using the system in conjunction with UPPP in the multilevel surgical approach.[32] The authors evaluated 19 consecutive patients undergoing UPPP and the Repose System tongue base suspension for the management of OSA during a one-year period. Fifteen patients had complete preoperative and postoperative PSG data. A 46% reduction in RDI was demonstrated at a mean of 3.8 months after surgery. The apnea index demonstrated a 39% reduction. The authors concluded that the Repose System in conjunction with UPPP has been shown to produce significant reductions in the RDI and apnea index, as well as a significant increase in oxygen saturation. Despite the improvement in these objective parameters, the overall surgical cure rate was only 20% (three of 15 patients) in this retrospective series. Further research is warranted to define the role of the Repose System in the management of obstructive sleep apnea patients.

In 2000, DeRowe performed minimally invasive technique for tongue-base suspension with the Repose system in 16 patients with sleep-disordered breathing.[33] Fourteen patients reported an improvement in daytime sleepiness, and their bed partners reported an improvement in snoring. The mean respiratory distress index before surgery was 35. Two months after surgery, the mean respiratory distress index was 17, an improvement of 51.4%. These preliminary results show the initial efficacy and safety of this new surgical procedure. Similar improvements were reported in other small case series (n=8-14 patients with OSA) who underwent the same procedure.[34-36]

Tongue Base Suspension Procedures Section Summary

Evidence for the tongue base suspension procedures for the treatment of sleep apnea or upper airway resistance syndrome includes one systematic review, one randomized controlled trial, and four non-randomized studies. These studies report low success rates of the procedure, particularly in obese individuals, and adverse events including wound infection, edema, pain, and tissue anchor barb fractures are reported. Long-term outcomes of the procedure are not well characterized. Additional studies with longer end-points including those addressing safety and efficacy are needed.

LASER-ASSISTED PALATOPLASTY

Systematic Reviews

Wischhusen (2019) published a SR evaluating the complications and side effects of laser-assisted uvulopalatoplasty (LAUP) across 42 studies (N=3,093). Mean follow-up was 16.1 months (median six months, range of 0.5 – 134 months).[37] Across all 42 studies, the total number of LAUP complications based on a population of 1,000 patients with a 95% CI was reported as 255.71 ± 23.33. The authors also calculated relative risk of specific complications compared to published population studies and found significant effects for complications of globus sensation and velopharyngeal (VP) insufficiency with 95% CI of 1.07–2.06 and 1.29–3.94, respectively. In the four studies with the longest follow-up duration with a mean of 100.5 months, these complications were 12.2% and 10.8%, respectively, suggesting that these may

be long-term complications of the procedure. The authors conclude “based on the findings of this systematic review, we recommend that LAUP be performed with caution using the tissue-sparing approach or avoided altogether, given the potential for complications identified in the current literature.”

Randomized Controlled Trials

Ferguson (2003) reported a trial that randomized 45 subjects with mild-to-moderate sleep apnea (defined as an AHI ranging between 10-27 per hour) to either uvulopalatoplasty (LAUP) or no treatment.[15] The LAUP procedure was repeated at 1- to 2-month intervals until either the snoring was significantly reduced, no more tissue could safely be removed, or the patient refused further procedures. The primary outcome measurement was the reduction in AHI in the LAUP group versus the control group. An AHI of less than 10 was considered a successful treatment. In the treatment group, 24% were considered treatment successes and 76% were failures. In the control group (who received no therapy), 16.7% were considered treatment successes. The authors concluded that LAUP can be effective in some patients, but the reduction in AHI and the level of symptomatic improvement were minor overall.

Nonrandomized Studies

In 1995, Walker prospectively evaluated the outcomes of 65 patients who underwent LAUP for the treatment of OSA.[38] Of the 65 OSAS patients treated with LAUP, postoperative polysomnograms were obtained in 33 patients (51%). Surgical success was achieved in 16 (48%) of the 33 patients. However, seven patients (21%) had repeat polysomnograms that were worse than their preoperative polysomnograms, and five patients (15%) had no significant change.

CAUTERY-ASSISTED PALATAL STIFFENING OPERATION

Systematic Reviews

Iannella (2021) performed a systematic review that discusses the state of the art and evolution on the barbed reposition pharyngoplasty (BRP) in the velo-pharyngeal surgery.[39] Fifteen studies for a total of 1531 patients, out of which 1061 underwent barbed reposition pharyngoplasty. Five trials were uncontrolled prospective studies (215 patients, 14% of total), nine were retrospective studies (1266 patients, 82,6% of total), and one randomized prospective clinical trial (RCT) (50 patients, 3,32% of total). The authors commented that “Barbed reposition pharyngoplasty has proven to be an easy to learn, quick, safe and effective new palatopharyngeal procedure, that can be used in a single level surgery or as a part of multilevel procedures”.

Llewellyn (2018) published a SR with meta-analysis of outcomes for cautery-assisted palatal stiffening operation (CAPSO) as a treatment for adult OSA. This SR included eight studies (N=307) conducted in adult patients with sleep disordered breathing.[40] Additional inclusion criteria for the SR were: “outcomes for sleep study information, snoring and/or sleepiness; anterior palatoplasty *or* palatal stiffening operation *or* CAPSO *or* modified CAPSO with or without tonsillectomy/expansion pharyngoplasty (plication of palatopharyngeus);” and no other surgical procedures performed at the same time. Among these studies, four were considered to have high risk of bias in patient selection per QUADAS-2. The authors reported the following improvements (mean ± standard deviation [M ± SD] events per hour, percent change) in AHI: CAPSO alone (N=80 patients), (16.8 ± 11.9) to (9.9 ± 10.9), a 41.1% decrease; mixed CAPSO

with/without tonsillectomy (N=92), (24.8 ± 12.6) to (10.6 ± 9.5), a 61.7% decrease; CAPSO with expansion pharyngoplasty (N=78), (26.3 ± 17.7) to (12.6 ± 5.8), a 52.1% decrease. The authors also reported the following improvement in lowest oxygen saturation (LSAT): CAPSO alone (N=90), 5.4 point improvement; mixed CAPSO with/without tonsillectomy (N=77), 10.6 point improvement; and CAPSO with expansion pharyngoplasty (N=78), 5.2 point improvement. Although the authors reported effect sizes for pre- and post-surgery outcomes across all data, for none of the above analyses evaluating effects of CAPSO alone or in combination with other interventions were assessments of statistical significance (p values) reported. This SR included studies by Mair (2000) and Pang (2007), which focused on patients with simple snoring (AHI <5) or mild sleep apnea (AHI <15).[41, 42] A study with long-term follow-up reported in this SR found that 38% of patients with mild to moderate OSA had globus sensation and inability to clear phlegm 2 years after the operation.[43] Future RCTs evaluating the specific and long-term benefit of CAPSO in OSA are needed.

Randomized Controlled Trials

No additional RCTs beyond those addressed in the SR above on the use of cautery-assisted palatal stiffening operation in the treatment of OSA or UARS have been identified.

PALATAL IMPLANTS

Systematic Reviews

No SRs for the use of palatal implants for the treatment of OSA or UARS have been identified.

Randomized Controlled Trials

In 2012, Maurer reported a randomized double-blind, sham-controlled trial of the Pillar palatal implant in 20 patients with mild to moderate OSA because of palatal obstruction.[44] At 90 days, the AHI in the treatment group improved from 19.1 to 8.2 events per hour and lowest oxygen saturation improved from 82.8% to 88.3%. These measures did not improve significantly in the control group, and there was no significant difference in outcomes between the implant and control groups in this small trial. The ESS did not improve significantly in either group.

In a 2008 trial by Steward, 100 patients with mild to moderate OSA and suspected retropalatal obstruction were randomly assigned to palatal implants or sham placebo.[45] Patients with BMI greater than 32 kg/m^2 were excluded from the study. About 1000 patients were evaluated to identify the 100 study patients. At three-month follow-up, the average AHI increased in both groups from a baseline of about 17, although the increase was greater in the placebo group (8.9 vs 2.9, respectively). A reduction in AHI by at least 50% or to below 20 was more common in the implant group (26% vs 10%, respectively; p=0.05). Improvement in ESS did not differ from that of sham (p=0.62). Partial implant extrusion occurred in two patients (4%).

In 2008, Friedman reported an industry-sponsored randomized double-blind, sham-controlled trial of palatal implants in 62 patients with symptoms of OSA.[46] Other inclusion criteria included: Friedman tongue position I, II, or III; diagnosis of mild to moderate OSA (AHI ≥5 and <40) on baseline polysomnography (PSG); a soft palate of 2 cm or more but less than 3.5 cm; and BMI less than 32 kg/m^2. AHI at baseline was 23.8 events per hour in the implant group and 20.1 in controls. Seven patients did not return for repeat PSG and were considered treatment failures in the intention-to-treat analysis. At three-month follow-up, the AHI improved to 15.9 events per hour in the implant group but did not change significantly in the controls (21.0). The ESS improved from 12.7 to 10.2 in the implant group and did not change

significantly in the controls (11.7 to 11.1). With success defined as an AHI reduction of 50% or more and AHI less than 20, palatal implantation resulted in the successful treatment of 41.9% of implanted patients compared with 0% of controls. Two patients had partial implant extrusion.

Nonrandomized Studies

Neruntarat (2011) reported a case series with a minimum of 24-month follow-up.[47] This study included 92 patients with mild to moderate OSA (AHI ≤30 with daytime sleepiness or disturbed sleep) who had received palatal implants after failed medical management. At baseline, the mean AHI was 21.7 events per hour, and the lowest oxygen saturation was 87.4%. At mean 28.9-month follow-up, the AHI had decreased to 10.8, and the lowest oxygen saturation improved to 89.2%. Sleep efficiency improved from 80.6% to 87.2%, and the ESS score improved from a mean of 12.3 to 7.9. Implant extrusion occurred in seven patients (7.6%), and palatal abscess occurred in one patient (1.1%). Confounding factors, such as significantly lower BMI in “responders” may have affected the interpretation of the efficacy of this procedure in this patient population.

Walker published 90-day and 15-month follow-up from a multicenter study on palatal implants (Pillar System) in 63 subjects.[48, 49] The AHI decreased from a baseline of 25 to 22 in the 53 patients (84%) who were evaluated at 90 days. Twenty-two patients (35%) were available for the follow-up study; 13 had shown a decrease in AHI (from a baseline of 20 to 13) at 90 days. Of these, 10 (77% of the 13) maintained the decrease at 15 months. The nine patients whose AHI had not improved at 90 days had no subsequent improvement at the extended follow-up. Mean snoring was rated as eight at baseline (visual analog scale), and 4 at both 90 days and 15 months. Subjective daytime sleepiness measured by the ESS was reduced at 90 days (11 to 7) but returned to a score of 11 at the longer follow-up. In addition to the very large loss to follow-up, questions remain about the clinical significance of a three- to seven-point improvement in AHI.

In a prospective study, Nordgard (2007) assessed the long-term effectiveness of palatal implants for treatment of mild-to-moderate OSA.[50] A total of 26 referred patients with a pre-treatment AHI of 10 to 30 and a BMI of less than or equal to 30, representing an extended follow-up of a subset of 41 patients enrolled in previous short-term trials were included. Twenty-one of 26 patients (80.8 %) experienced a decrease in AHI. Fifteen of 26 patients (57.7 %) had a follow-up AHI less than 10 at one year, whereas 13 patients (50 %) had a 50 % or greater reduction to an AHI less than 10 at one year. Mean AHI was reduced from 16.5 +/- 4.5 at baseline to 12.5 +/- 10.5 at three months ($p < 0.014$) and to 12.3 +/- 12.7 at one year ($p < 0.019$). The authors concluded that patients initially responding to palatal implants with improved AHI maintained improvement through long-term follow-up at one year. The main limitation of this study was its small sample size. The authors noted that additional studies with longer follow-up would be appropriate.

Nordgard (2006) conducted a prospective nonrandomized study of 25 patients with untreated OSA with an AHI of 10–30, as determined by preoperative PSG, and BMI ≤ 30.[51] Three permanent implants were placed in the soft palate of each patient in an office setting under local anesthesia. A repeat PSG showed a mean decrease in AHI from 16.2 to 12.1 for the study group. Twenty of 25 patients demonstrated a reduced AHI, and 12 of 25 patients demonstrated an AHI of 10 or less 90 days post-implant. The mean ESS score decreased from 9.7 to 5.5. The authors concluded that palatal implants can significantly improve AHI and other sleep-related parameters in patients with mild to moderate OSA and BMI ≤ 30, with short-term

results comparable to those reported for UPPP. The authors acknowledged the lack of long-term outcomes in this study and the limited number of patients. As with other palatal procedures, reduction in effectiveness over time may be expected. The authors further concluded that while short-term durability and effectiveness have been established, longer-term research needs to be conducted.

In a retrospective, nonrandomized, controlled study, Friedman (2006) evaluated the Pillar implant system alone and in combination with other procedures for treatment of mild-to-moderate OSA/hypopnea syndrome (OSAHS).[52] A total of 125 patients who had mild-to-moderate OSAHS were assigned to palatal implantation alone (palatal group, n=29), or in combination with other procedures. Most of the procedures other than palatal implantation were not defined clearly. After a mean follow-up of eight months, mean AHI for the palatal group had decreased from 13.8 to 12.13; however, this difference was not statistically significant compared with baseline. Using the criteria of AHI < 20 and > 50% reduction of AHI as "cured," Friedman reported that seven (24%) palatal group patients and 43 (34%) of all patients were "cured." One of the study limitations was that many patients had an AHI < 20 at baseline, particularly in the Palatal Group, which had a baseline AHI of 13.8.

Three other small, uncontrolled studies have been performed to evaluate the Pillar Palatal Implant System for mild-to moderate OSA.[53, 54] These studies enrolled 16 to 26 patients who had an AHI score of 5 to 30. These studies reported that, compared with baseline, patients obtained small-to-moderate but statistically significant improvements in outcomes such as AHI and Epworth Sleepiness Scale (ESS) scores at up to one year of follow-up; however, these studies do not provide reliable evidence of efficacy since they did not involve any control or comparison groups.

Palatal Implants Section Summary

The literature on palatal implants consists of three moderately-sized RCTs and additional case series with medium-term follow-up. Evidence from sham-controlled trials shows a statistically significant but modest reduction in AHI and improvement in lowest oxygen saturation compared with placebo, with limited effects on daytime sleepiness. Additional studies are needed to determine whether there is a defined subset of patients who might benefit from this procedure. Studies with longer term follow-up are also needed to evaluate the potential for extrusion of the implants at longer time intervals.

THYROIDECTOMY

Masarwy (2022) performed an assessment of the impact of thyroidectomy on OSA to understand the intricate relationship between OSA and thyroid structure.[55] A systematic review of four electronic databases (PubMed (Medline), Embase, the Cochrane library, and ClinicalTrials.gov) was performed up to February 2022. The primary outcomes were preoperative and postoperative Apnea/Hypopnea Index (AHI), Epworth Sleepiness Scale (ESS), Berlin questionnaire scores, and continuous positive airway pressure (CPAP) use. Six cohort studies on 221 OSA patients who underwent thyroidectomies were included. The results showed that thyroidectomy was associated with significant reduction in postoperative AHI (Mean difference [MD], -6.39, 95% CI -12.46 to -0.32), however, no significant association was found with CPAP withdrawal (Odds ratio [OR], 0.38, 95% CI 0.12-1.18). The authors state that large-scale, well-designed prospective studies are necessary to validate these findings.

PRACTICE GUIDELINE SUMMARY

THE US DEPARTMENT OF VETERANS AFFAIRS AND THE DEPARTMENT OF DEFENSE

The 2019 US Department of Veterans Affairs and Department of Defense (VA/DoD) Guideline for the Management of Chronic Insomnia Disorder and Obstructive Sleep Apnea provide the following recommendations regarding surgical treatment of OSA:[56]

> *For patients with severe obstructive sleep apnea who cannot tolerate or are not appropriate candidates for other recommended therapies, we suggest evaluation for alternative treatment with maxillomandibular advancement surgery. (Strength of recommendation: weak for. Category: new recommendation following review of the evidence)*

AMERICAN ACADEMY OF OTOLARYNGOLOGY - HEAD AND NECK SURGERY

The American Academy of Otolaryngology - Head and Neck Surgery (AAO-HNS) has published a number of consensus-based policy statements on various techniques for surgical management of obstructive sleep apnea.[7, 57-61] AAO-HNS position statements, by definition are “based on an informal process of expert or committee consensus that draws upon best available evidence and quality products.” thus each of the position statements may be supported to varying degrees by evidence. Procedures the AAO-HNS supports as effective and not considered investigational when part of a comprehensive approach in the medical and surgical management of adults with OSA include palatal advancement, uvulopalatopharyngoplasty, uvulopalatoplasty (including laser assisted and other techniques), genioglossal advancement, hyoid myotomy, midline glossectomy, tongue suspension, and maxillary and mandibular advancement.

No evidence-based practice guidelines from the AAO-HNS were identified.

AMERICAN ACADEMY OF SLEEP MEDICINE

The American Academy of Sleep Medicine (AASM, 2021) published practice guidelines on when to refer patients for surgical modifications of the upper airway for OSA.[62] These guidelines replaced the 2010 practice parameters for surgical modifications.[63] The AASM guidelines note that positive airway pressure (PAP) is the most efficacious treatment for OSA, but effectiveness can be compromised when patients are unable to adhere to therapy or obtain adequate benefit, which is when surgical management may be indicated. The AASM guideline recommendations are based on a systematic review and meta-analysis of 274 studies of surgical interventions, including procedures such as uvulopalatopharyngoplasty (UPPP), modified UPPP, MMA, tongue base suspension, and hypoglossal nerve stimulation.[64] The systematic review deemed most included data of low quality, consisting of mostly observational data. The AASM strongly recommend that clinicians discuss referral to a sleep surgeon with adults with OSA and body mass index (BMI) <40 kg/m2 who are intolerant or unaccepting of PAP. Clinically meaningful and beneficial differences in nearly all critical outcomes, including decrease in excessive sleepiness, improved quality of life (QOL), improved Apnea/Hypopnea Index (AHI) or respiratory disturbance index (RDI), and sleep quality, were demonstrated with surgical management in patients who are intolerant or unaccepting of PAP. The AASM makes a conditional recommendation that clinicians discuss referral to a sleep surgeon with adults with OSA, BMI <40 kg/m2, and persistent inadequate PAP adherence due to pressure-related side effects, as available data (very low-quality) suggests that upper airway surgery has a moderate effect in reducing minimum therapeutic PAP level and increasing PAP adherence. In adults with OSA and obesity (class II/III, BMI

>35) who are intolerant or unaccepting of PAP, the AASM strongly recommends discussion of referral to a bariatric surgeon, along with other weight loss strategies.

SUMMARY

There is enough research to suggest that uvulopalatopharyngoplasty (UPPP) and its variants, hyoid suspension, mandible osteotomy, partial glossectomy, and maxillofacial surgeries such as maxillo-mandibular advancement (MMA) may improve health outcomes for some patients with obstructive sleep apnea (OSA) or airway resistance syndrome (UARS). These procedures have become a standard of care and may therefore be considered medically necessary when the policy criteria are met.

There is not enough research to support surgery as first-line treatment of obstructive sleep apnea (OSA) or upper airway resistance syndrome (UARS). Therefore, surgical treatments may be considered medically necessary only after failed medical therapy, including nasal continuous positive airway pressure (PAP) and a custom-made mandibular repositioning appliance. In addition, surgical treatments including uvulopalatopharyngoplasty (UPPP) and its variants, hyoid suspension, mandible osteotomy, partial glossectomy, and maxillofacial surgeries such as maxillo-mandibular advancement (MMA) are considered not medically necessary when criteria are not met.

There is not enough research to determine the safety and efficacy of surgical interventions including but not limited to uvulectomy, and minimally invasive surgical procedures such as laser-assisted uvuloplasty (LAUP), radiofrequency tongue base or tissue volume reduction, palatal stiffening procedures, and palatal implants. The use of these interventions is considered investigational for the treatment of obstructive sleep apnea (OSA) or airway resistance syndrome (UARS).

Snoring in the absence of clinically significant obstructive sleep apnea (OSA) is not considered a medical condition. Therefore, any surgical intervention, including but not limited to uvulopalatopharyngoplasty (UPPP), laser-assisted uvulopalatoplasty (LAUP), radiofrequency volumetric tissue reduction of the palate, or palatal stiffening procedures for snoring alone is considered not medically necessary.

CODES

Codes	Number	Description
CPT	21121	Genioplasty; sliding osteotomy, single piece

Codes	Number	Description
	21122	Genioplasty; sliding osteotomies, two or more osteotomies (eg, wedge excision or bone wedge reversal for asymmetrical chin)
	21141	Reconstruction midface, LeFort 1; single piece, segment movement in any direction (eg, for Long Face Syndrome), without bone graft
	21145	Reconstruction midface, LeFort 1; single piece, segment movement in any direction, requiring bone grafts (includes obtaining autografts)
	21196	Reconstruction of mandibular rami and /or body, sagittal split; with internal rigid fixation
	21198	Osteotomy, mandible, segmental
	21199	Osteotomy, mandible, segmental; with genioglossus advancement
	21685	Hyoid myotomy and suspension
	41120	Glossectomy; less than one-half tongue
	41512	Tongue base suspension, permanent suture technique
	41530	Submucosal ablation of the tongue base, radiofrequency, one or more sites, per session
	41599	Unlisted procedure, tongue, floor of mouth
	42140	Uvulectomy, excision of uvula
	42145	Palatopharyngoplasty (eg, Uvulopalatopharyngoplasty, Uvulopharyngoplasty)
	42160	Destruction of lesion, palate or uvula (thermal, cryo, or chemical)
	42299	Unlisted procedure, palate, uvula
HCPCS	S2080	Laser-assisted uvulopalatoplasty (LAUP)

Appendix 1: Procedures for the Diagnosis of Sleep Disordered Breathing	
Polysomnography (PSG)	Full night PSG consists of five to eight hours of monitoring, supervised by a sleep technician, while the patient sleeps. It is performed in a sleep lab and involves the following monitoring modalities: electroencephalogram (EEG) (to stage sleep and detect arousals), electro-oculogram (EOG) (to detect arousal and REM sleep) submental electromyogram, (EMG), electrocardiogram (EKG), two-leg EMG, respiratory airflow and effort (to detect apnea), snoring, oxygen saturation, time and position. In addition, a full night PSG may include additional monitoring modalities as indicated, such as esophageal pressure monitoring, blood pressure monitoring, carbon dioxide trends, and pulse transit time. The first three elements listed above (EEG, submental electromyogram, and electro-oculogram) are required for sleep staging. By definition, a polysomnogram always includes sleep staging, while a “sleep study” does not include sleep staging. The actual components of the study will be dictated by the clinical situation. Typically, the evaluation of obstructive sleep apnea would include respiratory airflow and effort, electro-oculogram, and oxygen desaturation. An EEG may not be considered necessary to evaluate OSA, although it is required to evaluate UARS, REM sleep behavior disorder (RBD), narcolepsy or other sleep disturbances.
Split Night Polysomnography	A split night study utilizes the first two or three hours for evaluating the presence of sleep apnea and the second half to titrate and adjust CPAP. The same monitoring modalities used in full night PSG are used in split night study. In patients with severe obstructive sleep apnea, a reliable assessment of the respiratory disturbance index is possible with a partial night study. Half night study for CPAP titration is reliable in selected cases of obstructive sleep apnea.

Appendix 1: Procedures for the Diagnosis of Sleep Disordered Breathing	
	Split night studies are appropriate in patients with severe sleep apnea syndrome. The decision to conduct a split night study depends on the technical skill and experience of the staff, the initial sleep latency period, the severity and frequency of respiratory events and patient compliance. Careful patient selection and education is required to conduct a successful split night study.
Home Sleep Apnea Testing Device (HSAT Device)	Per the 2017 American Academy of Sleep Medicine (AACM) Clinical Practice Guideline for diagnostic testing for adult obstructive sleep apnea, home sleep apnea testing with a technically adequate device may be used for the diagnosis of obstructive sleep apnea (OSA) in uncomplicated adult patients presenting with signs and symptoms that indicate an increased risk of moderate to severe OSA.[1] An uncomplicated patient is defined by the absence of: 1. Conditions that place the patient at increased risk of non-obstructive sleep-disordered breathing (e.g., central sleep apnea, hypoventilation and sleep related hypoxemia). Examples of these conditions include significant cardiopulmonary disease, potential respiratory muscle weakness due to neuromuscular conditions, history of stroke and chronic opiate medication use. 2. Concern for significant non-respiratory sleep disorder(s) that require evaluation (e.g., disorders of central hypersomnolence, parasomnias, sleep related movement disorders) or interfere with accuracy of HSAT (e.g., severe insomnia). 3. Environmental or personal factors that preclude the adequate acquisition and interpretation of data from HSAT. An increased risk of moderate to severe OSA is indicated by the presence of excessive daytime sleepiness and at least two of the following three criteria: habitual loud snoring, witnessed apnea or gasping or choking, or diagnosed hypertension. HSAT is to be administered by an accredited sleep center under the supervision of a board-certified sleep medicine physician, or a board-eligible sleep medicine provider. A single HSAT recording is conducted over at least one night. A technically adequate HSAT device incorporates a minimum of the following sensors: nasal pressure, chest and abdominal respiratory inductance plethysmography, and oximetry; or else peripheral arterial tone (PAT) with oximetry and actigraphy. A technically adequate diagnostic test includes a minimum of 4 hours of technically adequate oximetry and flow data, obtained during a recording attempt that encompasses the habitual sleep period. If a single HSAT is negative, inconclusive, or technically inadequate, polysomnography should be performed for the diagnosis of OSA.
SNAP™ Testing	The SNAP testing system is a reflective acoustic device marketed as a screening and analysis system to locate the source of snoring and detect sleep apnea conditions.

Appendix 1: Procedures for the Diagnosis of Sleep Disordered Breathing	
Multiple Sleep Latency Tests (MSLT)	The MSLT measures the speed of falling asleep under conditions that favor sleep, in a series of 20-minute trials during the patient's habitual periods of wakefulness. MSLT is the preferred method of establishing the presence of true physiological sleepiness but is accurate only if following strict protocols. MSLT is used in patients with complaints of irresistible daytime sleepiness suggestive of narcolepsy.
Maintenance of Wakefulness Test (MWT)	The patient is monitored during the usual periods of wakefulness but the patient is instructed not to fall asleep as a test of the patient's ability to stay awake. It may be used to evaluate the safety of drivers and their ability to stay alert.
Radiologic Studies	Radiologic images of the head and neck for anatomic abnormalities include MRI, CT scan, and cephalometry. Such studies are intended to assess for hypopharyngeal obstruction or other suspected pathology that might explain the symptoms associated with sleep disordered breathing.
Endoscopic Studies	Nasopharyngeal and laryngeal endoscopic measurements of structure and function of the upper airway are used in selected patients with suspected abnormal anatomy as an aid in the diagnosis of OSA or in the management of complications of treatment.
Epworth Sleepiness Scale	Excessive daytime sleepiness is predominantly a subjective symptom. The Epworth sleepiness scale is a self-administered questionnaire, performed as part of the clinical evaluation, that asks patients their likelihood of falling asleep in eight situations ranked from 0 (would never fall asleep) to 3 (high chance of dozing). The numbers are then added together to give a global score between 0 and 24. A value of 10 or below is considered normal. A decrease of 2 points is considered the minimum important difference (MID).[65]
Apnea-Hypopnea Index (AHI); Respiratory Disturbance Index (RDI)	Apnea is defined as the cessation of respiration for at least 10 seconds. Hypopnea is a reduction but not cessation of air exchange. Apneic and hypopneic events are combined into the apnea-hypopnea index (AHI). In turn the AHI is often referred to as the respiratory disturbance index (RDI), although more recently the RDI has been redefined by some physicians to include EEG arousals in addition to apneic and hypopneic events. An AHI of greater than or equal to 20 is typically considered moderate OSA, and AHI of greater than 50 is considered severe OSA. An increase in mortality is associated with an AHI of greater than 15.
Polysomnography (PSG)	Full night PSG consists of five to eight hours of monitoring, supervised by a sleep technician, while the patient sleeps. It is performed in a sleep lab and involves the following monitoring modalities: electroencephalogram (EEG) (to stage sleep and detect arousals), electro-oculogram (EOG) (to detect arousal and REM sleep) submental electromyogram, (EMG), electrocardiogram (EKG), two-leg EMG, respiratory airflow and effort (to detect apnea), snoring, oxygen saturation, time and position. In addition, a full night PSG may include additional monitoring modalities as indicated, such as esophageal pressure monitoring, blood pressure monitoring, carbon dioxide trends, and pulse transit time.

Appendix 1: Procedures for the Diagnosis of Sleep Disordered Breathing	
	The first three elements listed above (EEG, submental electromyogram, and electro-oculogram) are required for sleep staging. By definition, a polysomnogram always includes sleep staging, while a “sleep study” does not include sleep staging. The actual components of the study will be dictated by the clinical situation. Typically, the evaluation of obstructive sleep apnea would include respiratory airflow and effort, electro-oculogram, and oxygen desaturation. An EEG may not be considered necessary to evaluate OSA, although it is required to evaluate UARS, REM sleep behavior disorder (RBD), narcolepsy or other sleep disturbances.
Split Night Polysomnography	A split night study utilizes the first two or three hours for evaluating the presence of sleep apnea and the second half to titrate and adjust CPAP. The same monitoring modalities used in full night PSG are used in split night study. In patients with severe obstructive sleep apnea, a reliable assessment of the respiratory disturbance index is possible with a partial night study. Half night study for CPAP titration is reliable in selected cases of obstructive sleep apnea. Split night studies are appropriate in patients with severe sleep apnea syndrome. The decision to conduct a split night study depends on the technical skill and experience of the staff, the initial sleep latency period, the severity and frequency of respiratory events and patient compliance. Careful patient selection and education is required to conduct a successful split night study.

Appendix 2: Nonsurgical Devices for Treatment of OSA or UARS	
CPAP	Nasal or oral continuous positive airway pressure (CPAP) or auto-titrating continuous positive airway pressure (APAP) is continuous positive airway pressure applied through the nose or via oral appliance. It is delivered by a flow generator through a mask to supply a pressure level sufficient to keep the upper airway patent. The pressure used is determined individually with a range of three to 15 centimeters of water.
BiPAP ®	Bi-level respiratory assist device delivers alternating levels of positive airway pressure instead of the continuous pressure applied by CPAP. A bi-level positive airway pressure device with back-up rate feature is a ventilation support system. These devices are in the FDA category of non-continuous ventilator, and as such, are primarily intended to augment patient ventilation. The term BiPAP® is a registered trademark of *Respironics Inc*., but is widely used to describe any bi-level positive airway pressure device as described above.
APAP	Auto-adjusting CPAP (APAP) is a more recent technology which alternates airway pressure between exhalation and inhalation on a breath-by-breath basis. With the C-Flex™ (Respironics, Inc) airway pressure is reduced during early exhalation in proportion to the patient’s expiratory flow rate. Pressure is then increased again toward the end of exhalation when airway collapse is most likely. Unlike BiPAP which delivers a static lower expiratory pressure, the C-Flex varies the pressure within the expiratory phase.

Appendix 2: Nonsurgical Devices for Treatment of OSA or UARS	
Oral Appliances (OA)	OA for the treatment of sleep disordered breathing are devices worn in the mouth during sleep to maintain a patent airway by raising the uvula, depressing the tongue, and/or advancing the mandible (in which case they are also known as mandibular advancement devices [MAD]). Commercially available devices are usually custom-molded or custom-fitted for the individual patient by a qualified dental health professional trained and experienced in the overall care of oral health, the temporomandibular joint, dental occlusion and associated oral structures. According to the American Academy of Sleep Medicine, dental management of patients with oral appliances should be overseen by practitioners who trained in sleep medicine and sleep related breathing disorders.[66, 67] Oral appliances can range from simple retaining devices, to adjustable, hinged, or two-piece designs. Some designs can be used in conjunction with a CPAP device (e.g., OPAP®).

Occipital Nerve Stimulation

Effective: April 1, 2024

Next Review: February 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Occipital nerve stimulation (ONS) delivers a small electrical charge to the occipital nerve in an attempt to prevent migraines and other headaches in patients who have not responded to medications. The device consists of a subcutaneously implanted pulse generator (in the chest wall or abdomen) attached to extension leads that are tunneled to join electrodes placed across one or both occipital nerves at the base of the skull. Continuous or intermittent stimulation may be used.

MEDICAL POLICY CRITERIA

Occipital nerve stimulation is considered **investigational** for all indications, including but not limited to headaches.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

4. Implantable Peripheral Nerve Stimulation for Chronic Pain of Peripheral Nerve Origin, Surgery, Policy No. 205

BACKGROUND

Implanted peripheral nerve stimulators have been used for treatment of refractory pain for many years but only recently proposed for management of craniofacial pain. Occipital, supraorbital, and infraorbital stimulation have been reported in the literature.

There are four types of headache: vascular, muscle contraction (tension), traction, and inflammatory. Primary (not the result of another condition) chronic headache is defined as headache occurring more than 15 days of the month for at least three months. An estimated 45 million Americans experience chronic headaches. For at least half of these people, the problem is severe and sometimes disabling.

Migraine is the most common type of vascular headache. Migraine headaches are usually characterized by severe pain on one or both sides of the head, an upset stomach, and, at times, disturbed vision. One- year prevalence of migraine ranges from 6% to15% in adult men and from 14% to35% in adult women. Migraine headaches may last a day or more and can strike as often as several times a week or as rarely as once every few years. Drug therapy for migraine is often combined with biofeedback and relaxation training. Sumatriptan is commonly used for relief of symptoms. Drugs used to prevent migraine include methysergide maleate, propranolol hydrochloride, ergotamine tartrate; amitriptyline, valproic acid, and verapamil.

Hemicrania continua, also a vascular headache, causes moderate pain with occasional severe pain on only one side of the head. At least one of the following symptoms must also occur; conjunctival injection and/or lacrimation, nasal congestion and/or rhinorrhea, or ptosis and/or miosis. Headache occurs daily and is continuous with no pain-free periods. Hemicrania continua occurs mainly in women, and its true prevalence is not known. Indomethacin usually provides rapid relief of symptoms. Other nonsteroidal anti-inflammatories (NSAIDs), including ibuprofen, celecoxib, and naproxen, can provide some relief from symptoms. Amitriptyline and other tricyclic antidepressants are effective in some patients.

Cluster headache is a vascular headache that occurs in cyclical patterns or clusters of severe or very severe unilateral orbital or supraorbital and/or temporal pain. The headache is accompanied by at least one of the following autonomic symptoms: ptosis (drooping eyelid), conjunctival injection, lacrimation, rhinorrhea, and, less commonly, facial blushing, swelling, or sweating. Bouts of one headache every other day to eight attacks per day may last from weeks to months, usually followed by remission periods when the headache attacks stop completely. The pattern varies from one person to another, but most people have one or two cluster periods a year. During remission, no headaches occur for months, and sometimes even years. The intense pain is caused by the dilation of blood vessels, which creates pressure on the trigeminal nerve. While this process is the immediate cause of the pain, the etiology is not fully understood. It is more common in men than in woman. One-year prevalence is estimated to be 0.5 to 1.0/1,000. Management of cluster headache consists of abortive and preventive treatment. Abortive treatments include subcutaneous injection of sumatriptan, topical anesthetics sprayed into the nasal cavity, and strong coffee. Some patients respond to rapidly inhaled pure oxygen. A variety of other pharmacologic and behavioral methods of aborting and preventing attacks have been reported with wide variation in patient response.

REGULATORY STATUS

The U.S. Food and Drug Administration (FDA) has not yet cleared any occipital nerve stimulation device for treatment of headache.

The Synergy™ IPG (implantable pulse generator) device from Medtronic received marketing clearance in 1999 for management of chronic, intractable pain of the trunk or limbs, and off-label use for headache is described in the literature.

The Genesis™ neuromodulation system (St. Jude Medical) is approved by the FDA for spinal cord stimulation and has received CE mark approval in Europe for the treatment of chronic migraines.

EVIDENCE SUMMARY

The principal outcomes associated with treatment of headache are relief of pain, return to work, and improved functional level. Relief of pain can be a subjective outcome associated with a placebo effect. Therefore, data from adequately powered, blinded, randomized controlled trials (RCT) are required to control for the placebo effect and determine whether any treatment effect provides a significant advantage.

The technology must also be evaluated in general groups of patients against existing treatments. In patients with mild to moderate symptoms, occipital nerve stimulation may be compared to other forms of conservative therapy such as topical anesthetics, rest, or non-steroidal anti-inflammatory or migraine medications.

Therefore, the focus of the evidence summary is on RCTs comparing occipital nerve stimulation (ONS)-treated patients with those in a sham treatment or standard of care group.

SYSTEMATIC REVIEWS

Membrilla (2023) published a systematic review and meta-analysis to evaluate the effectiveness of pharmacologic and non-pharmacologic interventions in preventative treatment of chronic cluster headache (CCH) for people who do not respond to conventional therapy.[1] Studies were included if at least a portion of the participants met European Headache Federation diagnostic criteria for refractory CCH (rCCH), and if the reported outcome was reduced attack frequency. The review included a total of 45 studies, of which 12 were of ONS. Wilbrink (2021), as detailed below, was the only RCT on ONS. The meta-analysis also included the following studies that are cited below: Diaz-de-Teran (2021), Leplus (2021), and Magis (2011).[2-5] The pooled response rate from the 12 ONS studies was 57.3% (odds ratio [OR] 0.573, 95% confidence interval [CI] 0.481-0.665, I^2=68.45, p<0.001). Of the 45 studies included in the review only 7 were RCTs. While the authors concluded the available evidence supported the use of ONS, its harms were minimized (“these adverse events will likely be less prevalent because of technical advances”). The study noted that the overall analysis had high heterogeneity of interventions, study designs, and response measures, and most evidence was rated as having moderate to serious risk of bias.

As part of a consensus development process Barad (2022) published the results of a systematic review of studies on percutaneous strategies for migraine intervention.[6] This review included four randomized controlled trials (RCTs) on implantable ONS (Serra 2012, Slotty 2015, Silberstein 2012, and Saper 2011). An additional publication (Mekhail (2017) was excluded, as it was a subgroup analysis of the Silberstein cohort. The overall strength for the certainty of evidence for reduction of headache days was moderate with a moderate effect size. The strength of certainty of evidence for reduction in acute medication use was very low with a low, nonsignificant effect size. The strength of certainty of evidence for impairment as related to patient-related outcomes was moderate at 12 weeks with a moderate effect size.

Implantable ONS had significantly more adverse events that other interventional therapies examined. The recommendation was “weak” for the potential net benefit of implantable ONS for chronic migraine prevention.

Occipital nerve stimulation was addressed in the Comparative Effectiveness Review of Interventional Treatments for Acute and Chronic Pain that was prepared for the Agency for Healthcare Research and Quality (AHRQ) by the Pacific Northwest Evidence-Based Practice Center (2021).[7] The review assessed three studies, Saper (2011), Serra (2012), Silberstein (2012), and focused on the following outcomes: pain, function, number of days with headache, and mood state.[8-10] There was insufficient evidence to assess ONS compared to sham treatment for headache. While there was evidence of a reduction in headache pain, headache days, and disability at 3 months vs. usual care, the difference was not statistically significant ($p>0.05$). The review found evidence of harm from ONS, most often from lead migration that occurred in 14-24% of patients in the assessed studies, and one trial reported a 5.9% rate of device-related serious adverse events that required hospitalization.

Patel (2021) published a systematic review (SR) of data from RCTs on electrical nerve stimulation modalities, including occipital nerve stimulation (ONS), in the treatment of migraine.[11] Although 16 studies were included in the review, only three (Mekhail 2017, Dodick 2015, and Slotty 2015) were studies of ONS. Studies were rated low risk of bias in most domains, however, the authors note two of the ONS studies had “unknown” risk of bias due to open-label study design or high occurrence of adverse events. No pooled or quantitative comparisons for any outcomes were reported for any of the modalities.

A SR with meta-analysis of neuromodulation for acute and preventative migraine treatment was published by Moisset (2020).[12] This broad review included three studies of invasive ONS, all investigating its use for the treatment of chronic migraine. Only one of the identified studies was of high quality (Silbertstein 2012) which, as discussed below, did not identify a significant effect of the intervention on the primary outcome, although positive effects were found for secondary outcomes. The other two trials included in the review (Saper 2011 and Serra 2012) were low and moderate quality due to risk of biases in selective reporting, sample calculation, statistical methods, and/or blinding. Outcomes of the meta-analysis favored a positive effect of invasive ONS, with a large effect size (-1.090; 95%CI: -1.977 to -0.204) however high heterogeneity between studies ($I2 = 88\%$) was reported. Ultimately, the authors conclude that larger well-conducted studies are needed to confirm treatment efficacy and determine true effect sizes.

Cadalso (2017) published a systematic review (SR) evaluating the impact occipital nerve stimulation had on healthcare outcomes, for intractable primary headache disorders.[13] The SR included four RCTs, one follow-up study, and 19 case series. The authors stated that although the RCTs showed a decrease in headache frequency and improved migraine disability assessment scores, ONS did not improve pain intensity and there was heterogeneity of outcomes. In addition, the RCTs had small sample sizes and risk of bias.

Yang (2016) identified the same five RCTs as the 2015 SR by Chen, summarized below.[14] The Yang review only included studies conducted with patients with migraine of at least six months in duration who did not respond to oral medications. In addition to the RCTs, five case series met the inclusion criteria. Yang et al did not pool study findings. The definition of response rate varied across studies and could include frequency and/or severity of headaches. Response rates in three case series with self-reported efficacy were 100% each, and response

rates in the other two series were 50% and 89%, respectively. Complication rates in the series ranged from 40% to 100%. The authors noted that the case series were subject to biases (e.g., inability to control for the placebo effect), that RCT evidence was limited, and that complication rates were high.

Two SRs of the literature on occipital nerve stimulation (ONS) were published in 2015. Both included RCTs and observational studies. Chen identified five RCTs and seven case series with at least 10 patients.[15] Three of the RCTs were industry-sponsored, multicenter, parallel-group trials and two were single-center crossover trials. All five included a sham control group and one trial also included a medication management group. Risk of bias was judged to be high or unclear for all trials. Meta-analyses were performed on two outcomes. A pooled analysis of 2 studies did not find a significant difference in response rate between active and sham stimulation (risk ratio [RR], 2.07; 95% confidence interval [CI], 0.50 to 8.55; p=0.31) and a pooled analysis of three studies showed a significantly greater reduction in the number of days with prolonged moderate-to-severe headache (mean difference, 2.59; 95% CI, 0.91 to 4.27; p=0.003. Sweet (2015) published a SR that identified nine small case series (<15 patients each) assessing the efficacy of ONS for treating medically refractory occipital neuralgia.[16] The authors did not pool study findings. No conclusions can be drawn about the impact of ONS on occipital neuralgia due to the lack of RCTs or other controlled studies.

The National Institute for Health and Care Excellence (NICE, 2013) evaluated two RCTs and one case series to determine if ONS was effective in decreasing headache frequency, duration and severity.[17] Both RCTs compared ONS with sham stimulation at three months. Although the smaller RCT with 67 patients determined that the ONS group responded better than the sham group, the larger RCT with 157 patients showed no difference in responder rate. NICE concluded that ONS for intractable chronic migraines is efficacious in the short-term, but there is little evidence to indicate long-term outcome effects. NICE stated ONS should only be used for clinical governance, consent, and audit or research.

RANDOMIZED CONTROLLED TRIALS

Wilbrink (2021) published the safety and efficacy data from of a multicenter randomized controlled trial (RCT) of ONS for medically intractable chronic cluster headache (MICCH).[2] This trial is termed the ICON study (ClinicalTrials.gov NCT01151631). Patients were randomized (1:1) to 24 weeks of ONS at either 100% or 30% of the individually determined range between paraesthesia threshold and near-discomfort. Because ONS causes paraesthesia precluding masked comparison to placebo, high-intensity was compared to low-intensity stimulation, which is hypothesized to cause similar paraesthesia but with different efficacy. There were 150 patients enrolled and 131 were randomly assigned to treatment: 65 patients to 100% ONS and 66 to 30% ONS. In weeks 25-48, participants received individually optimized open-label ONS. The primary outcome was the weekly mean attack frequency in weeks 21-24 compared with baseline. In the 100% ONS stimulation group, attack frequency decreased from 17.58 (9.83 to 29.33) at baseline to 9.50 (3.00 to 21.25) at 21-24 weeks (median change from baseline -4.08, -11.92 to -0.25), and for the 30% ONS stimulation group, attack frequency decreased from 15.00 (9.25 to 22.33) to 6.75 (1.50 to 16.50; -6.50, -10.83 to -0.08). The difference in attack frequency between groups at the end of the masked phase in weeks 21-24 was -2.42 (95% CI -5.17 to 3.33). In the masked study phase, 129 adverse events occurred in the 100% ONS group and 95 occurred in the 30% ONS group. Of these, 17 and eight of the adverse events in the 100% and 30% groups, respectively, were considered serious, as they required hospital admission for minor hardware-related issues. The most

common adverse events were local pain, impaired wound healing, neck stiffness, and hardware damage.

Serra and Marchioretto (2012) conducted a crossover RCT in which 30 patients with chronic migraine (100% of patients) and medication overuse headache (85% of patients) were implanted with an ONS and randomized to “Stimulation On” or “Stimulation Off” arms.[9] After one month, or if headaches worsened during the off period, patients were crossed over to the other arm. The mean number of days when patients randomized to the off condition turned on the generators was 4.65 days (range, 1-12 days). Follow-up examinations were conducted at one, three, six, and 12 months after nerve stimulator implantation, during which time the stimulation parameters were adjusted in order to optimize the perception of paresthesia. In addition, the patients were provided with remote controls to modify the stimulation amplitude. At baseline, the average frequency of migraines was 5.8 days per week and the median headache severity was eight on an 11-point numerical rating scale. Headache intensity and/or frequency were significantly lower in the on arm compared to the off arm and decreased from baseline to each follow-up visit in all patients with Stimulation On. For example, the number of headaches decreased from a median of 6.3 days per week in the off phase to 2.1 days per week in the on phase. The median Migraine Disability Assessment (MIDAS) score decreased from 79 at baseline to 10 at 12-month follow-up. Quality of life measured by the SF-36 significantly improved from baseline throughout the follow-up period. Use of triptans decreased from a median of 20 to three doses/month and use of nonsteroidal anti-inflammatory drug (NSAIDs) use decreased from a median of 25.5 to two doses/month. There were two infections (6.7%) and three lead migrations (10%) during the study. This study is limited by the lack of a control group during follow-up and lack of blinding, although blinding of patients may be difficult due to paresthesia with this treatment.

Silberstein (2012) published a RCT of patients diagnosed with chronic migraine (CM), implanted with a neurostimulation device and randomized 2:1 to active (n=105) or sham (n=52) stimulation.[10] Authors defined the primary endpoint as the difference in the percentage of responders (defined as patients that achieved a ≥50% reduction in mean daily visual analog scale scores) in each group at 12 weeks. A significant difference was reported at a secondary endpoint of 30% reduction; however, no difference was reported between groups at the primary endpoint of 50% reduction. At a 30% reduction, significant difference in reduction of number of headaches, migraine-related disability, and direct reports of pain relief were reported compared to the sham group, but it is unknown if these results are clinically meaningful considering researchers did not meet their established primary endpoint of at least a 50% reduction in mean daily analog scores. In addition, the overall treatment effect was low, with only 17.1% of the active group and 13.5% of the control group classified as responders.

Results from the 52-week open-label extension of this study were published in 2014.[18] Results were reported for the intent-to-treat (ITT) population and for the 125 patients who met criteria for intractable chronic migraine. Twenty-four patients were excluded from analysis due to explantation of the system (n=18) or other loss to follow-up. Mean headache days at baseline were 21.6 for the ITT population and 24.2 for the intractable chronic migraine group. In the ITT population, headache days were reduced by 6.7 days, and a 50% or greater reduction in headache days and/or pain intensity was observed in 47.8% of patients. Sixty-eight percent of patients were satisfied with the headache relief provided by the device. Seventy percent experienced at least one of 183 device-related adverse events, of which 8.6% required hospitalization and 40.7% required surgical intervention. Eighteen percent of patients had persistent pain and/or numbness with the device.

A small industry-sponsored feasibility RCT reported preliminary safety and efficacy data on ONS for treatment of medically intractable chronic migraine (CM).[8] However, the findings from this small (n=110) and very short (follow-up=three months) study must be interpreted with caution due to the exploratory nature of the design:

- The sample size was chosen to gain experience with ONS and the study was not prospectively powered for efficacy evaluation.
- No primary end points were specified at the outset; at three months, a range of efficacy measures were evaluated in comparison to baseline.

Although the findings from this study may provide direction for future research, they do not provide reliable evidence on the clinical utility of ONS. Per the authors, “reliable conclusions regarding efficacy cannot be established on the basis of this study alone.”

NONRANDOMIZED STUDIES

Evidence from nonrandomized studies of occipital nerve stimulation (ONS) for treatment of headaches is considered insufficient due to methodological limitation such as nonrandom allocation of treatment, lack of adequate comparison groups, small sample size, and short-term follow-up, all of which limit conclusions regarding the safety and effectiveness of ONS treatment.[3, 19-21] Of note, several of these nonrandomized studies reported high rates of ONS revision (20-60%)[5, 22, 23] and/or complications (20-60%)[4, 5, 19, 24-26].

PRACTICE GUIDELINE SUMMARY

AMERICAN ACADEMY OF PAIN MEDICINE

A 2022 evidence-based practice guideline from the American Academy of Pain Medicine on percutaneous interventional strategies for the prevention of migraine provides a “weak” recommendation of implantable stimulation (based on studies of occipital nerve stimulation) for chronic migraine prevention.[6] Implantable stimulation was noted to have significantly more adverse events than other percutaneous interventions, contributing to this “weak” recommendation.

AMERICAN SOCIETY OF PAIN AND NEUROSCIENCE

A 2022 consensus-based guideline on the use of implantable peripheral nerve stimulation for treatment of chronic pain states multiple randomized trials have demonstrated benefit of ONS for chronic migraine.[27] The guideline cites Dodick (2014), Mekhail (2017), Saper (2011), and Serra (2012).[8-10, 18]

- Stimulation of occipital nerves may be offered to patients with chronic migraine headache when conservative treatments have failed. The average size for relief of migraine symptoms is modest to moderate (Level I, Grade B).

- There is presently insufficient evidence to recommend stimulation of supraorbital or infraorbital nerves for neuropathic craniofacial pain (Level II-3, Grade C).

CONGRESS OF NEUROLOGICAL SURGEONS

A 2023 evidence-based guideline from the Congress of Neurological Surgeons states: “the use of occipital nerve stimulation is a treatment option for patients with medically refractory

occipital neuralgia." The guideline was jointly funded by Congress of Neurological Surgeons and the Joint Section on Pain of the American Association of Neurological Surgeons/Congress of Neurological Surgeon. The statement had a level III recommendation based on a systematic review of the literature that only included case series with methodological limitations.

SUMMARY

There is not enough research to show that occipital nerve stimulation (ONS) improves net health outcomes for patients with any condition. Clinical guidelines based on research list ONS as a treatment option but consideration of evidence of benefits vs. harm of ONS is inconsistent in the guidelines. Therefore, ONS is considered investigational for all indications, including but not limited to as a treatment of headache.

CODES

Codes	Number	Description
CPT	61885	Insertion or replacement of cranial neurostimulator pulse generator or receiver, direct or inductive coupling; with connection to a single electrode array
	61886	Insertion or replacement of cranial neurostimulator pulse generator or receiver, direct or inductive coupling; with connection to 2 or more electrode arrays
	64553	Percutaneous implantation of neurostimulator electrode array; cranial nerve
	64555	Percutaneous implantation of neurostimulator electrode array; peripheral nerve (excludes sacral nerve)
	64568	Open implantation of cranial nerve (eg, vagus nerve) neurostimulator electrode array and pulse generator
	64569	Revision or replacement of cranial nerve (e.g., vagus nerve) neurostimulator electrode array, including connection to existing pulse generator
	64570	Removal of cranial nerve (e.g., vagus nerve) neurostimulator electrode array and pulse generator
	64575	Open implantation of neurostimulator electrode array; peripheral nerve (excludes sacral nerve)
	64585	Revision or removal of peripheral neurostimulator electrode array
	64590	Insertion or replacement of peripheral, sacral, or gastric neurostimulator pulse generator or receiver, requiring pocket creation and connection between electrode array and pulse generator or receiver
	64596	Insertion or replacement of percutaneous electrode array, peripheral nerve, with integrated neurostimulator, including imaging guidance, when performed; initial electrode array
	64597	Insertion or replacement of percutaneous electrode array, peripheral nerve, with integrated neurostimulator, including imaging guidance, when performed; each additional electrode array (List separately in addition to code for primary procedure)
	64598	
	64999	Unlisted procedure, nervous system
	95970	Electronic analysis of implanted neurostimulator pulse generator/transmitter (eg, contact group[s], interleaving, amplitude, pulsewidth, frequency [Hz], on/off cycling, burst, magnet mode, dose lockout, patient selectable parameters, responsive neurostimulation, detection algorithms, closed loop parameters, and passive parameters) by physician or other qualified health care professional; with brain, cranial nerve, spinal cord, peripheral nerve, or sacral nerve, neurostimulator pulse generator/transmitter, without programming
	95971	;with simple spinal cord, or peripheral nerve (eg, sacral nerve) neurostimulator pulse generator/transmitter, programming by physician or other qualified health care professional
	95972	;with complex spinal cord, or peripheral nerve (eg, sacral nerve) neurostimulator pulse generator/transmitter programming by physician or other qualified health care professional
HCPCS	C1820	Generator, neurostimulator (implantable), with rechargeable battery and charging system

Codes	Number	Description
	L8679	Implantable neurostimulator, pulse generator, any type
	L8680	Implantable neurostimulator electrode, each
	L8681	Patient programmer (external) for use with implantable programmable neurostimulator pulse generator, replacement only
	L8682	Implantable neurostimulator radiofrequency receiver
	L8683	Radiofrequency transmitter (external) for use with implantable neurostimulator radiofrequency receiver
	L8685	Implantable neurostimulator pulse generator, single array, rechargeable, includes extension
	L8686	Implantable neurostimulator pulse generator, single array, non- rechargeable, includes extension
	L8687	Implantable neurostimulator pulse generator, dual array, rechargeable, includes extension
	L8688	Implantable neurostimulator pulse generator, dual array, non-rechargeable, includes extension
	L8689	External recharging system for battery (internal) for use with implantable neurostimulator

Adipose-derived Stem Cell Enrichment in Autologous Fat Grafting to the Breast

Effective: January 1, 2024

Next Review: October 2024
Last Review: November 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Autologous fat grafting to the breast has been used as an adjunct to reconstructive breast surgery to address issues such as post-mastectomy pain and irradiated skin. Adipose-derived stem cells have been proposed as a supplement to the fat graft in an attempt to improve graft survival.

MEDICAL POLICY CRITERIA

Notes:

- This policy does not address the use of autologous fat grafting without adipose stem cell enrichment for breast reconstruction, which may be considered medically necessary.
- This policy does not address free flap autologous fat grafting with micro vascularization.
- This policy does not address the use of autologous fat tissue in aesthetic breast augmentation (i.e., cosmesis).

The use of autologous fat grafting to the breast with supplemented adipose-derived stem cells is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

AUTOLOGOUS FAT GRAFTING TO THE BREAST

Autologous fat grafting to the breast has been proposed for indications which include breast augmentation and following oncologic surgery. Proposed indications following oncologic surgery include as an adjunct to reconstruction post mastectomy or lumpectomy for contour deformities and improved shape and volume of the breast, for post mastectomy pain syndrome (neuropathic pain), and for irradiated skin to soften the skin and restore it to non-irradiated appearance and consistency.

ADIPOSE-DERIVED STEM CELLS (ADSCS)

Stem cell biology, and the related field of regenerative medicine, involves multipotent stem cells that exist within a variety of tissues, including bone marrow and adipose tissue. Studies have shown that 1 gram of adipose tissue yields approximately 5 x 10^3 stem cells, which is up to 500 times greater than the number of mesenchymal stem cells in 1 gram of bone marrow.[1] Stem cells, because of their pluripotentiality and unlimited capacity for self-renewal, offer promise for tissue engineering and advances in reconstructive procedures. Adipose tissue in particular represents an abundant and easily accessible source of adipose-derived stem cells (ADSCs), which can differentiate along multiple mesodermal lineages.[1] ADSCs may allow for improved graft survival and generation of new fat tissue after transfer from another site.

This identification of several potentially beneficial therapeutic properties of ADSC has led to proposed novel techniques of fat grafting in conjunction with ADSC therapy for breast fat grafting, including the differentiation of ADSC into adipocytes as a reservoir for adipose tissue turnover, the differentiation of ADSC into endothelial cells and the subsequent increase in blood supply to the grafted fat tissue, thereby decreasing the rate of graft resorption, the release of angiogenic growth factors by ADSC and the induction of angiogenesis, protection of the graft from ischemic reperfusion injury by ADSC, and acceleration of wound healing at the recipient site.[1]

Current methods for isolating ADSCs can involve various processes, which may include centrifugation and enzymatic techniques that rely on collagenase digestion followed by centrifugal separation to isolate the stem cells from primary adipocytes. Isolated ADSCs can be expanded in monolayer on standard tissue culture plastic with a basal medium containing 10% fetal bovine serum,[2] and newly developed culture conditions provide an environment

within which the study of ADSCs can be done without the interference of animal serum. They also allow rapid expansion of autologous ADSCs in culture for use in human clinical trials. A standard expansion method has not yet been established.

Yoshimura (2008), in an effort to address the problems of unpredictability and low rates of fat graft survival, developed a technique known as cell-assisted lipotransfer (CAL), which produces autogenous fat rich in ADSCs.[3] In CAL, half of the lipoaspirate is centrifuged to obtain a fraction of concentrated ADSCs, while the other half is washed, enzymatically digested, filtered, and spun down to an ADSC-rich pellet. The latter is then mixed with the former, converting a relatively ADSC-poor aspirated fat to ADSC-enriched fat.

REGULATORY STATUS

A point-of care system is available for concentrating ADSCs from mature fat. The Celution™ system (Cytori Therapeutics, Inc.) is designed to transfer a patient's own adipose tissue from one part of the body to another in the same surgical procedure. The system received 510(k) marketing clearance from the U.S. Food and Drug Administration as a cell saver device. The system is cleared for the collection, concentration, washing and re-infusion of a patient's own cells for applications that may include, but are not limited to, cardiovascular, plastic and reconstructive, orthopedic, vascular, and urological surgeries and procedures.

In 2017, the Revolve Envi 600 Advanced Adipose System (LifeCell Corporation, Branchburg, NJ) was cleared for marketing by the FDA through the 510(k) process. The system harvests, filters, and transfers autologous adipose tissue for fat grafting. Uses include reconstructive surgery. In May of 2020, the Revolve Envi 600 System underwent various design modifications (K163647). FDA product code: MUU.

EVIDENCE SUMMARY

The literature on the use of fat grafting to the breast with the use of adipose-derived stem cell (ADSC) enrichment consists of retrospective cohort studies, case series, and case reports. The following is a summary of the key literature to date, including all identified case series using fat grafting to the breast with the supportive use of ADSCs.

Systematic Reviews

A 2021 SR published by Li and Chen compared the efficacy of CAL and conventional lipotransfer in breast augmentation.[4] Six studies including 353 patients met inclusion criteria. Of these, one was a randomized trial, four were retrospective observational case-series, and one was a prospective controlled trial. No evaluation of study quality was reported. The fat survival rate was significantly higher in the CAL group than in the control group (standard mean difference [SMD]=1.79, 95% CI 0.28 to 3.31; p=0.02). No statistically significant differences in complication rates between groups (SMD=1.79, 95% CI 0.28 to 3.31; p=0.02). There were also no statistically significant differences identified in the subgroup analyses between the groups in fat survival rate (SMD=1.52, 95% CI -0.21 to 3.24; p=0.08).

In 2017, Lazole conducted a SR to evaluate the safety and efficacy of CAL. Twenty-five studies addressing fat grafting to the breast and face were included in the systematic review and 16 in the meta-analysis.[5] The fat survival rate was significantly higher with CAL than non-CAL fat graft, only for injection volumes < 100 mL. There was no significant difference between groups in frequency of multiple procedures after fat grafting. The incidence of complications

was significantly higher in the CAL group.

In 2016, Zhou conducted a SR with the same purpose as the above systematic review, and included seventeen articles (n=387) for all indications, including breast.[6] For all indications combined, the pooled fat survival rate was significantly higher in the CAL group than in the nonlipotransfer group (60% vs. 45%, p=0.0096). Complication incidence was similar in the two groups. In breast fat grafting fat survival was improved by only 9% in the CAL group, which was not statistically significant. In addition, lipotransfer in breast cases was associated with a higher complication incidence compared with other indications (p<0.001).

Randomized Control Trial

Vester-Glowinski (2022) published a randomized control trial (RCT) trial aimed to investigate whether ADSCs improve fat graft volume retention in patients undergoing breast augmentation with lipofilling.[7] This was a double-blind, randomized controlled trial of breast augmentation with ADSC-enriched fat grafting. Healthy women aged 30 to 45 years were enrolled. First, the participants underwent liposuction to obtain fat for culture expansion of ASCs. Then, the participants were randomly assigned to undergo a 300- to 350-mL breast augmentation with ADSC-enriched fat grafting (10 × 106 ASCs/mL fat graft) to 1 of their breasts and placebo-enriched fat grafting of identical volume to the contralateral breast. Fat graft volume retention after one year was 54.0% (95% CI, 30.4%-77.6%) in the breasts treated with ASC-enriched fat grafting (n = 10) and 55.9% (95% CI, 28.9%-82.9%) in the contralateral breasts treated with placebo-enriched fat grafting (n = 10) (p=0.566). The authors concluded that the findings of this trial do not support that ASC-enriched fat grafting is superior to standard fat grafting for breast augmentation.

Nonrandomized Studies

Jørgensen (2021) performed a phase I trial aimed to assess whether ADSCs can alleviate lymphedema in clinical reality with long-term follow-up in patients with breast cancer-related lymphedema (BCRL).[8] They treated 10 patients with BCRL using ADSCs and a scar-releasing lipotransfer to the axillary region, and all patients were followed one, three, six, twelve, and forty-eight months after treatment. There was no significant decrease in BCRL volume after treatment. However, self-reported upper extremity disability and arm heaviness and tension improved. The authors reported that in this phase I study with four years of follow-up, axillary delivered ADRCs and lipotransfer were safe and feasible and improved BCRL symptoms and upper extremity function. The authors also recommended more RCTs to confirm the results of this study.

Jeon et al (2020) evaluated the efficacy of CAL on the fat graft retention rate in patients with volume deficit after undergoing autologous breast reconstruction following total mastectomy.[9] This 12-month prospective study included 20 patients (20 breasts) between 2017 and 2019. Patients were divided into two groups: autologous fat graft without stromal-vascular fraction (i.e., without ADSC) or autologous fat graft with stromal-vascular fraction of ADSC. The retention rate of the fat graft was higher in the group with ADSC than in the group without at both postoperative 6 months (73.8% vs 62.2%; p=0.03) and 12 months (65.4% vs 48.4%; p=0.03). Based on a modified BREAST-Q questionnaire at 12 months, the group who received fat graft with ADSC reported higher patient satisfaction (49.4 points out of 55 compared to 44.2 points out of 55), although this was not statistically significant. Fat necrosis occurred in one patient each in both groups, however, locoregional recurrence was not observed in any patient during follow-up. The authors concluded that CAL with stromal-vascular fraction provided

better outcomes in terms of volume retention compared to CAL without ADSC.

Mazur (2018) evaluated the risk of cancer recurrence in 56 patients having the breast reconstructed with autologous ASC (transplanted as the subpopulation present in the stromal vascular fraction [SVF]).[10] Tumor recurrence in these patients was compared with tumor recurrence in 252 matched patients that did not receive breast reconstruction. Cancer recurrence in the ASC and control groups was 3.7% and 4.13%, respectively, which was not significantly different (p=1.0).

In 2016, Jung conducted a small single-arm, prospective study to evaluate the impact of ADSCs, using CAL, on graft survival, including five patients.[11] One year after CAL, breast volume had decreased to 47% of the initial postoperative volume. The ratio of ADSC cell count to grafted fat volume showed no correlation with graft survival. The addition of SVF cells did not appear to improve the retention of grafted fat in these patients. Skin tension may be an important factor influencing the absorption pattern of grafted fat.

In 2013, Peltoniemi conducted a prospective comparative study to evaluate if stem cell enrichment is important for success in lipofilling for cosmetic breast augmentation.[12] A total of 18 women underwent breast augmentation, with 10 of the cases including transferred lipoaspirate enriched with ADSCs using the Cytori Celution(®) system MRI-based volumetric analysis was done preoperatively and six months post-procedure. MRI analysis revealed mean graft survival was not significantly different between groups (54% in nonADSC group vs. 50% in the ADSC-enrichment patients). After centrifugation survival was not significantly different between groups (79% in nonADSC group vs. 74% in the ADSC-enrichment patients. The investigators concluded that they did not see any advantage in stem cell enrichment by the Celution(®) system in cosmetic fat transplantation to the breast.

In 2012, Pérez-Cano conducted a single-arm, prospective, multicenter clinical trial of 71 women who underwent breast conserving surgery for breast cancer and autologous adipose-derived regenerative cell (ADRC)-enriched fat grafting for reconstruction of defects ≤150 mL (the RESTORE-2 trial).[13] Trial endpoints included patient and investigator satisfaction with functional and cosmetic results and improvement in overall breast deformity at 12 months post-procedure. Female patients (18 to 75 years of age) presenting with partial mastectomy defects and without breast prosthesis were eligible. The RESTORE-2 protocol allowed for up to two treatment sessions and 24 patients elected to undergo a second procedure following the six-month follow-up visit. Of the 67 patients treated, 50 reported satisfaction with treatment results through 12 months. Sixty-one patients underwent radiation therapy as part of their treatment; two patients did not receive radiation and the status of radiation treatment was not known for the other four patients. Using the same metric, investigators reported satisfaction with 57 out of 67 patients. There were no serious adverse events associated with the ADRC-enriched fat graft injection procedure. There were no reported local cancer recurrences. The LENT-SOMA scale included investigator and patient assessment of post-radiation signs and symptoms. The investigators of the trial found that LENT-SOMA was insufficiently sensitive to adequately reflect the clinical improvements seen in the trial population. Patients with LENT-SOMA III and IV scores (most severe symptoms) were excluded during screening, which may have contributed to the subtle LENT-SOMA score changes observed in the trial. The investigators reported improvement from baseline through 12 months in the degree of retraction or atrophy in 29 out of 67 patients, while 34 patients had no change and four patients reported worse symptoms. Post-radiation fibrosis at 12 months was reported as improved in 29 patients, while 35 patients had no change and three patients had worse symptoms. Management of atrophy

was reported as improved in 17 patients, with 48 patients having no change and two patients reporting worse symptoms. Improvement in these measures reached statistical significance. The authors concluded that future comparative studies are needed to determine the incremental benefit of ADRC-enriched fat grafting as compared to traditional fat grafting in various clinical circumstances.

In 2011, Kamakura and Ito reported on the use of ADSC enriched fat grafting for breast augmentation in a prospective, nonrandomized open-label study of 20 Japanese women.[14] After the adipose tissue was harvested by liposuction, it was processed in the Celution 800 System® to wash and isolate the adipose-derived regenerative cells and produce a fat graft enriched with the regenerative cells. Clinical outcomes measured included improvement in circumferential breast measurement from baseline state. There was improvement in circumferential breast measurement in all patients, and breast measurements were stable by three months after grafting. At nine months, the mean breast measurement had increased 3.3 cm from preoperative measurements. The procedure was well-tolerated without any serious adverse events. Postoperative cyst formation was seen in two patients.

In 2008, Yoshimura and colleagues reported on the development of CAL, in which autologous ADSCs are used in combination with lipoinjection.[3] From 2003 to 2007, the group performed CAL in 70 patients: in the breast in 60 patients (including eight who had breast reconstruction after mastectomy). They reported outcomes for 40 patients with healthy thoraxes and breasts who underwent CAL for purely cosmetic breast augmentation; patients undergoing breast reconstruction for an inborn anomaly or after mastectomy were not included. Nineteen of the 40 patients had been followed for more than six months, with a maximum follow-up of 42 months. The authors observed that the transplanted adipose tissue was gradually absorbed during the first two postoperative months, and the breast volume showed a minimal change thereafter. Final breast volume showed augmentation by 100 to 200 mL after a mean fat amount of 270 mL was injected. The difference in breast circumference (defined as the chest circumference at the nipple minus the chest circumference at the inframammary fold) had increased in all cases by 4 to 8 cm at six months. Cyst formation or microcalcification was detected in four patients. The authors concluded that their preliminary results suggest that CAL is effective and safe for soft tissue augmentation and superior to conventional lipoinjection but that additional study is necessary to further evaluate the efficacy of this technique.

In 2007, Rigotti reported the results of a pilot study on the presence and effectiveness of ADSCs in 20 consecutive patients undergoing therapy for adverse effects of radiation treatment to the breast, chest wall or supraclavicular region, with severe symptoms or irreversible function damage (LENT-SOMA scale grade 3 and 4). LENT-SOMA is one of the most common systems to assess the late effects of radiotherapy.[15] The mean patient age was 51 years (range, 37 to 71 years). The rationale behind the study was that the ADSCs, which have been shown to secrete angiogenic and antiapoptotic factors and to differentiate into endothelial cells, could promote neovascularization in ischemic tissue such as irradiated tissue. Targeted areas included the supraclavicular region, the anterior chest wall after mastectomy with or without breast prosthesis, and breast after quadrantectomy. A lipoaspirate purification procedure was performed by centrifugation to remove a large part of the triglyceride portion of the tissue and disrupt the cytoplasm of the mature adipocytes to favor their rapid clearance after injection. A stromal-vascular fraction was isolated by enzymatic digestion of extracellular matrix, centrifugation and filtration, and the fractions were cultured for two to three weeks to obtain a homogenous cell population. To assess the presence of mesenchymal stem cells, the stromal-vascular fraction derived from the adipose tissue was

cultured and characterized by flow cytometry. The number of procedures was one in five patients, two in eight patients, three in six patients, and six in one patient. Clinical follow-up varied between 18 and 33 months (mean, 30 months). Clinical results after treatment with lipoaspirates were assessed by LENT-SOMA scoring. The 11 patients initially classified as LENT-SOMA grade 4 (irreversible functional damage) progressed to grade 0 (no symptoms), grade 1 and grade 2 in four, five, and one cases, respectively. In one case, no improvements were observed. In the four patients who had undergone mastectomy and had breast prostheses and areas of skin necrosis, the necrosis showed complete remission. In the group of nine patients classified as LENT-SOMA grade 3, fibrosis, atrophy, and retraction progressed to grade 0 and 1 in five and four cases, respectively.

PRACTICE GUIDELINE SUMMARY

NATIONAL INSTITUTE FOR HEALTH AND CLINICAL EXCELLENCE (NICE)

In 2012 NICE published an evidence-based clinical practice guideline addressing breast reconstruction using lipomodelling after breast cancer treatment. Regarding the use of stem cell enrichment, it states, “Further information about the outcomes of this and other adaptations of the technique of lipomodelling is desirable for guiding their future use in clinical management.”[16]

AMERICAN SOCIETY OF AESTHETIC PLASTIC SURGERY AND AMERICAN SOCIETY OF PLASTIC SURGEONS[17]

A joint task force of the American Society for Aesthetic Plastic Surgery (ASAPS) and the American Society of Plastic Surgeons released a position statement on the use of stem cells in aesthetic surgery during the 2011 annual meeting of ASAPS.[17] Based on a systematic review of the peer-reviewed literature, the task force concluded that while there is potential for the future use of stem cells in aesthetic surgical procedures, the scientific evidence and other data are very limited in terms of assessing the safety or efficacy of stem cell therapies in aesthetic medicine.

SUMMARY

The current research on the use of supplemented adipose-derived stem cells in combination with fat grafting to the breast has many limitations. In addition, the research is starting to show that the use of these cells does not increase graft survival or decrease resorption rates. More research is needed on the long-term effectiveness and safety of enrichment of adipose-derived stem cells in fat grafting to the breast. In addition, no evidence-based clinical practice guidelines recommend the use of adipose-derived stem cell enrichment in fat grafting to the breast. Therefore, the use of adipose-derived stem cell enrichment in conjunction with fat grafting to the breast is considered investigational.

CODES

NOTE: There is no specific code to report the use of the additional adipose-derived stem cell enrichment in autologous fat grafting.

Codes	Number	Description
CPT	11950	Subcutaneous injection of filling material (eg, collagen); 1 cc or less
	11951	Subcutaneous injection of filling material (eg, collagen); 1.1 to 5.0 cc
	11952	Subcutaneous injection of filling material (eg, collagen); 5.1 to 10.0 cc
	11954	Subcutaneous injection of filling material (eg, collagen); over 10.0 cc
	15769	Grafting of autologous soft tissue, other, harvested by direct excision (eg, fat, dermis, fascia)
	15771	Grafting of autologous fat harvested by liposuction technique to trunk, breasts, scalp, arms, and/or legs; 50 cc or less injectate
	15772	Grafting of autologous fat harvested by liposuction technique to trunk, breasts, scalp, arms, and/or legs; each additional 50 cc injectate, or part thereof (List separately in addition to code for primary procedure)
	19380	Revision of reconstructed breast (eg, significant removal of tissue, re-advancement and/or re-inset of flaps in autologous reconstruction or significant capsular revision combined with soft tissue excision in implant-based reconstruction)
	19499	Unlisted procedure, breast
HCPCS	None

Bronchial Valves

Effective: July 1, 2023

Next Review: March 2024
Last Review: May 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Bronchial (endobronchial, intrabronchial) valves are synthetic devices that are deployed with bronchoscopy into ventilatory airways of the lung for the purpose of controlling airflow.

MEDICAL POLICY CRITERIA

I. The use of a bronchial valve may be considered **medically necessary** for the treatment of *severe emphysema* when all of the following Criteria (A.- O.) are met:

A. The valve has been approved by the FDA (Zephyr® Endobronchial Valve System or Spiration® Valve System); and

B. Patient is age 40 years or older; and

C. Body mass index (BMI) less than 35kg/m^2; and

D. Patient has completed a pulmonary rehabilitation program prior to valve placement; and

E. The patient is not a cigarette smoker OR there is clinical documentation that the patient has been abstinent from cigarette smoking for at least four consecutive months prior to and throughout evaluation for the procedure; and

F. Little or no collateral ventilation as determined using the Chartis (Zephyr) or

SeleCT (Spiration) systems (see Policy Guidelines) is present; and

G. Total lung capacity (TLC) is greater than 100% predicted; and

H. Six-minute walking distance (6MWD) ≥100m and <500m; and

I. Patient has not had any of the following: prior lung transplant, lung volume reduction surgery (LVRS), ipsilateral bullectomy, or lobectomy; and

J. Residual volume (RV) is greater than or equal to 175% predicted; and

K. High resolution computed tomography (HRCT) obtained within 90 days of screening demonstrates all of the following (1.- 3.):

1. *Absence* of large bullae encompassing greater than 30% of either lung; and
2. Target lobe has greater than or equal to 40% emphysema destruction; and
3. Greater than or equal to 10% disease severity difference (heterogenous emphysema) between the targeted lobe and the ipsilateral lobe; and

L. Post-bronchodilator forced expiratory volume (FEV1) is between 15% and 45% of predicted value; and

M. PaCO2 <60mmHg and PaO2 >45mm Hg on room air; and

N. Stable with less than 20 mg daily of prednisone (or equivalent); and

O. Patient has *no record of any of the following contraindications* as documented by an echocardiogram, right heart catheterization, and/or electrocardiogram completed within 90 days from screening:

1. Uncontrolled pulmonary hypertension (systolic pulmonary arterial pressure greater than 45 mm Hg); and
2. Left ventricular ejection fraction (LVEF) less than 45%; and
3. Evidence or history of cor pulmonale; and
4. Congestive heart failure; and
5. Resting bradycardia (less than 50 beats/min).

II. Removal, replacement, or revision of a U.S. Food and Drug Administration (FDA) approved bronchial valve (Zephyr® Endobronchial Valve System or Spiration® Valve System) may be considered **medically necessary** once the valve has been placed for the treatment of emphysema.

III. The use of a bronchial valve is considered **investigational** for all other indications, including but not limited to the following:

A. For the treatment of emphysema when Criterion I. is not met; or

B. For the treatment of air leaks.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

The goal of bronchial valve treatment is to achieve a lobar volume reduction or atelectasis

(collapse). In many patients, atelectasis cannot be achieved due to interlobar collateral ventilation (CV) generated through incomplete lobar fissures. There are several methods to assess the presence of CV, with endobronchial pulmonary assessment (e.g., the Chartis System) and CT-fissure analysis (e.g., SeleCT or StratX) being the most common.

CT-fissure analysis can be used to assess the completeness of the fissure. Typically, the analysis is done by experienced radiologists or pulmonologists. The target lobe and ipsilateral lobe must be separated with an intact fissure and an intact fissure is estimated visually to be ≥90% complete with no segmental vessels crossing from one lobe to the adjacent lobe after viewing the high-resolution CT in three dimensions (sagittal, axial, and coronal). Automated methods (SeleCT) to provide exact quantifications and support visual readings are recommended.

The Chartis system is used for bronchoscopic assessment of collateral ventilation and consists of a catheter with a balloon component at the distal tip. The Chartis system was originally validated in spontaneous breathing patients under conscious sedation, however the measurement has been performed under general anesthesia with positive pressure support or high frequency jet ventilation. The airway is blocked when the balloon is inflated and air from the targeted segment or lobe can flow only through the catheter. This air is directed to the Chartis console, which can assess both expiratory air flow, pressure, and resistance. Presence of collateral airflow is observed if expiratory airflow persists after occlusion of a lobe, and if there is no flow, this indicates no collateral airflow.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- Medical records, including history and physical/chart notes related to documenting that all of the requirements in Criteria I. are met, including but not limited to:
  - results of high-resolution CT obtained within 90 days of screening documenting the sub-criteria in Criterion I. are met
  - results of echocardiogram, right heart catheterization, and/or electrocardiogram documenting sub-criteria in Criterion I. are met
  - the type of valve system to be used.

BACKGROUND

Proper lung functioning is dependent upon a separation between the air-containing parts of the lung and the small vacuum-containing space around the lung called the pleural space. When air leaks into the pleural space, the lung is unable to inflate resulting in hypoventilation and hypoxemia; this condition is known as a pneumothorax. A pneumothorax can result from a variety of processes including trauma, high airway pressures induced during mechanical ventilation, lung surgery, and rupture of lung blebs or bullae, which may be congenital or a result of chronic obstructive pulmonary disease (COPD).

Bronchial valves are synthetic devices deployed with bronchoscopy into ventilatory airways of the lung to control airflow. They have been investigated for use in patients who have prolonged bronchopleural air leaks and as an alternative to lung volume reduction surgery in patients with hyperinflation from severe or advanced emphysema.

Emphysema, a form of COPD, is a progressive, debilitating disease characterized by irreversible destruction of alveolar tissue. This destruction results in reduced elastic recoil, progressive hyperinflation and gas trapping with patients experiencing chronic dyspnea, limited exercise tolerance and poor health related quality of life. In emphysematous COPD, diseased portions of the lung ventilate poorly, cause air trapping, and hyperinflate, compressing relatively normal lung tissue. The patterns and degree of emphysema heterogeneity (i.e., the extent and distribution of air space enlargements) can be measured using computed tomography (CT) density as an indicator for tissue destruction. The most diseased portions of lung can then potentially be targeted for lung volume reduction procedures. In homogeneous emphysema, there is minor or no regional difference in disease within or between lobes of the lung. Bronchial valves are synthetic devices deployed with bronchoscopy into ventilatory airways of the lung to control airflow. During inhalation, the valve is closed, preventing air flow into the diseased area of the lung. The valve can open during exhalation to allow air to escape from the diseased area of the lung. They have been investigated for use in patients who have prolonged bronchopleural air leaks and in patients with hyperinflation from severe or advanced emphysema.

When used to treat persistent air leaks from the lung into the pleural space, the bronchial valve theoretically permits less air flow across the diseased portion of the lung during inhalation, aiding in air leak closure. The valve may be placed, and subsequently removed by bronchoscopy. The use of bronchial valves to treat emphysema is based on the improvement observed in patients who have undergone lung volume reduction surgery. Lung volume reduction surgery involves excision of peripheral emphysematous lung tissue, generally from the upper lobes. The precise mechanism of clinical improvement for patients undergoing lung volume reduction has not been firmly established. However, it is believed that elastic recoil and diaphragmatic function are improved by reducing the volume of the diseased lung. Currently, and at the time the clinical trials were designed, very few lung volume reduction procedures were performed. The procedure is designed to relieve dyspnea and improve functional lung capacity and quality of life; it is not curative. Medical management remains the most common treatment for a majority of patients with severe emphysema.

In early trials of bronchial valves for treatment of emphysema, absence of collateral ventilation (pathways that bypass the normal bronchial airways) was associated with better outcomes, presumably because patients with collateral ventilation did not develop lobar volume reduction or atelectasis (collapse). In subsequent trials, patients were selected for absence of collateral ventilation, and it is current practice for patients to be assessed for the presence of collateral ventilation prior to undergoing the procedure. Collateral ventilation is measured by the Chartis system, which requires bronchoscopy, or as a surrogate, CT scanning to assess the completeness of fissures, SeleCT or StratX systems. After 45 days post-procedure, residual volume can provide information on whether lung volume reduction has been achieved successfully.

REGULATORY STATUS

Currently, two endobronchial valve systems are FDA-approved for treatment of patients with

severe emphysema (FDA product code: NJK). Both are one-way valves which work to prevent air flow to the diseased area of the lung during inhalation. The valves allow air to escape from the treated lobe(s) during exhalation. In June 2018, the FDA granted the Zephyr® Endobronchial Valve (formerly Emphasys, now Pulmonx) system breakthrough device status with expedited approval for the bronchoscopic treatment of adult patients with hyperinflation associated with severe emphysema in regions of the lung that have little to no collateral ventilation.[1] The Zephyr Endobronchial Valve (EBV) is a one-way, removable, silicone, duckbill valve mounted in a nitinol, self-expanding retainer that is covered with a thin silicone membrane. The valve is available in three sizes and implanted during bronchoscopy in bronchial lumens ranging from 4.0 to 8.5 mm in diameter. In December 2018, the FDA approved the Spiration® Valve System.[2] The Spiration® Valves are one-way endobronchial valves intended for adult patients with shortness of breath and hyperinflation associated with severe emphysema in regions of the lung that have low collateral ventilation. The Spiration® Valve System is deployed into the bronchial tree using the deployment catheter passed through the working channel of a flexible bronchoscope with working channel 2.6 mm or greater. The Spiration valves are provided in four sizes to accommodate airway diameters ranging from 4.75 to 8.75 mm. Both valves may require repeat procedures to reposition or restore functioning. Although more than one valve may be needed to achieve the desired clinical outcome, FDA safety testing assumed no more than 10 valves will be placed in a clinical procedure for the treatment of severe emphysema.

The intrabronchial IBV® Valve System (Spiration, Inc) was approved by the U.S. Food and Drug Administration (FDA) under the Humanitarian Device Exemption (HDE) number H060002. It is intended for use in controlling prolonged air leaks of the lung or significant air leaks that are likely to become prolonged air leaks following lobectomy, segmentectomy, or lung volume reduction surgery (LVRS), for a duration up to 6 weeks.[3]

EVIDENCE SUMMARY

PROLONGED OR SIGNIFICANT AIR LEAKS

The principal outcome associated with treatment of prolonged or significant air leaks include resolution of the leak. In order to understand the impact of bronchial valves for treatment of prolonged or significant air leaks, well-designed randomized controlled trials (RCTs) that compare this therapy to standard medical treatment, such as chest tube placement, performing a thoracotomy with mechanical or chemical pleurodesis, or additional operations, are needed.[3]

Systematic Review

No systematic reviews (SRs) were identified on the use of endobronchial or intrabronchial valves for prolonged or significant air leaks.

Randomized Controlled Trials

No randomized controlled trials (RCTs) were identified on the use of endobronchial or intrabronchial valves for prolonged or significant air leaks.

Nonrandomized studies

No comparative observational studies were identified. Nonrandomized studies have reported on the use of either intrabronchial[4], endobronchial valves[5, 6], or both types[7]. Conclusions

cannot be reached from of these studies, as the data are limited by a variety of factors, including but not limited to:

- Small study populations, less than 100 patients total, which limit the ability to rule out the role of chance as an explanation of study findings;[4, 5, 7] and
- Retrospectively abstracted records, leading to potential study bias in sample selection, including selection criteria.[5, 7]
- Follow-up of study subjects was over a short period of time, less than 6 months, so medium and long-term effects of endobronchial valves treatment are unknown.[4, 5, 7]

ADVANCED EMPHYSEMA

In patients with advanced emphysema, valves may be compared to other forms of medical treatment, such as bronchodilators, short courses of systemic corticosteroids, noninvasive positive pressure ventilation (NIPPV) and/or oxygen therapy. In patients who have exhausted conservative therapy, valves must be compared to more invasive treatment, such as lung volume reduction surgery. RCTs are needed in order to isolate the contribution of these implants from other components of therapy. Further, for treatment of chronic conditions, particularly those with a poor prognosis, an understanding of any adverse treatment effects must be carefully weighed against any benefits to understand the net treatment effect.

Systematic Reviews

Patel (2022) published a systematic review and meta-analysis of RCTs using EBVs to provide bronchoscopic lung volume reduction (BLVR) for emphysema. Nine studies that included 1383 randomized patients were analyzed. Of the 1383 patients, 888 received EBV and 495 received standard medications. The primary outcome measures were FEV_1, percent predicted FEV_1 ($\%FEV_1$), six-minute walk distance (6MWD), RV, and St. George's respiratory questionnaire (SGRQ) after EBV placement. Secondary outcomes were mortality and adverse event rates. All physiologic outcome measures showed significant improvement with EBV. FEV_1 (weighted mean difference [WMD] = 102.61 mL; 95% confidence interval [CI]: 82.80-122.43; p<0.05; I^2 = 42.61%, p=0.08) and %FEV1 (WMD=11.71; 95% CI: 9-14.42; p<0.05; I^2 = 71.13, p<0.05) were increased for the EBV group. EBV was associated with a reduction in RV (WMD= -533.48mL; 95% CI: -653.01 -- -413.94; p<0.05; I^2=26.90%, p=0.22). Quality of life and activity measures also showed significant improvement with EBV. SGRQ scores in the EBV arm compared with standard care were improved (WMD = -7.44; 95% CI: -9.01 -- -5.86; p<0.05; I^2 = 50.89%; p=0.03). 6MWD in patients who had EBV were also superior to those who were not treated with EBV (WMD = 37.45; 95% CI: 27.68-47.21, p<0.05; I^2 =72.98%; p<0.05). Other adverse events included pneumothorax, which was more likely in the EBV group (odds ratio [OR] = 10.50, 95% CI=5.31-20.79, p<0.05, I^2 = 32.55%, p=0.10). The difference in the incidence of respiratory failure was not significant between the two groups (OR = 0.93,95% CI = 0.49-1.76, p=0.82, I^2=0.00%, p=0.96). Pneumonia, acute exacerbation of COPD (AECOPD), and hemoptysis were increased in short-term (OR = 3.12, 95% CI=1.47-6.64, p<0.05; (OR-1.48, 95% CI = 1.02-2.13, p<0.05; OR = 3.56, 95% CI = 1.41-8.96 respectively), but not long-term follow-up (OR=1.66, 95% CI=0.90-3.06; OR=0.83, 95% CI: 0.57-1.19; OR=1.65, 95% CI=0.80-3.39). Patients without collateral ventilation (CV) who received EBV had more improvement in FEV_1 (p=0.01), %FEV1 (p<0.05) and RV (-619.87 vs. -370mL, p=0.18) than patients with unknown CV status. EBV was associated with improvement in most physiologic outcomes as well as quality of life measures; however, mortality rates were not significantly different between the EBV and control group (OR = 1.08, CU: 0.57-2.05, p=0.82; I^2=0.0%, p=0.95).

A 2020 systematic review (SR) with network meta-analysis by Iftikhar evaluated the effect of bronchial valves in patients with heterogeneous emphysema without lobar collateral ventilation (CV).[8] The review included 10 RCTs studying adult COPD patients with severe emphysema on optimal medical management and undergoing intervention with Zephyr or Spiration valves or coils for the intervention and standard of care as the comparator. A total of 912 total study participants (544 in intervention arms and 368 in control arms) were included in the meta-analysis. No statistical evidence of funnel plot asymmetry (or publication bias) was found. In patients with heterogeneous emphysema without CV, both Spiration and Zephyr valves showed significant increases in forced expiratory volume in 1 second (FEV1) (0.11 L [95% confidence interval (CI), 0.05 to 0.16] and 0.14 L [0.08 to 0.19], respectively) and in reducing St. Georges Respiratory Questionnaire (SGRQ) scores (-9.32 [-14.18 to -4.45] and -8.14 [-11.94 to -4.35], respectively) as compared with control, with no significant differences between interventions. Significant improvement (52.3 m [95% CI, 26.53 to 77.93]) in six-minute walk distance (6MWD) also was found for Zephyr valves, specifically. Both Spiration and Zephyr valves were associated with more frequent pneumothorax as compared with control (odds ratio, 10.32 [1.35 to 79.13] and 11.47 [2.91 to 45.27], respectively). No statistically significant association for COPD exacerbations was found for any of the interventions.

Majid (2020) published a systematic review (SR) with meta-analysis of four RCTs (N= 629) evaluating the Spiration® Valve System (SVS) in patients with severe emphysema and hyperinflation.[9] The RCTs included were published by Ninane (2012),[10] Wood (2014),[11] Li (2019),[12] and Criner (2019).[13] Outcomes evaluated were changes in: forced expiratory volume in 1s (FEV1), 6-min walking test (6MWT), residual volume, modified medical research council (mMRC) and Saint George respiratory questionnaire (SGRQ), as well as all-cause mortality, risk of pneumothorax, and risk of acute exacerbation of chronic obstructive pulmonary disease (AECOPD). An overall change of 0.03 L (-0.07 to 0.13, I^2 = 90%) in FEV1 and 2.03% (-2.50 to 6.57, I^2 = 96%) in the predicted FEV1 compared to baseline was found with SVS but no benefit in 6MWT (mean difference = 4.56 m [95% CI -21.88 to 31.00, I^2 = 73%]). Relative risk of mortality was 2.54 (95% CI 0.81-7.96, I^2 = 0%), for pneumothorax 3.3 (95% CI 0.61-18.12, I2 = 0%) and AECOPD 1.68 (95% CI 1.04-2.70, I^2 = 0%). In patients with severe heterogeneous emphysema and hyperinflation without collateral ventilation, treatment with SVS improved pulmonary function, quality of life, and dyspnea score. However, the significantly increased relative risk of adverse events, including mortality, warrants additional RCTs addressing the safety and long-term benefit of this treatment.

In a SR with network meta-analysis by Xu (2020), bronchoscopic lung volume reduction treatments for emphysema, including intrabronchial valve (IBV) and endobronchial valve (EBV) treatments, were evaluated.[14] Thirteen trials were included (N=1993), seven of which were on IBV or EBV, including some studies reported in previous SRs.[15-19] The quality of evidence was rated as moderate in most comparisons using the GRADE framework. Medical care (MC) was associated with the fewer adverse events than IBV (-2.5, [-4.70 to -0.29]) and EBV (-1.73, [-2.37 to -1.09]) treatments. Less of an improvement in FEV1 and 6MWT was found in MC compared with EBV (-0.45, [-0.69 to -0.20] and -0.39, [-0.71 to -0.07], respectively) and significantly more positive change in SGRQ was found in EBV compared with MC (0.44, [0.11 to 0.78]). This analysis provides important comparisons of bronchial valve treatments to medical care alone for emphysema. Although clinical and quality of life variables improved with valve treatment, more adverse events occurred with both IBV and EBV treatment compared to MC alone, which is consistent with other systematic reviews evaluating safety of these devices.

A SR with meta-analysis published by Low (2019) evaluated RCTs comparing EBV implantation versus standard medical treatment or sham bronchoscopy for advanced emphysema.[20] This SR included five RCTs (N= 703) published by Valipour (2016)[21], Sciruba (2010)[22], Klooster (2015),[23] Herth (2012),[19] and Davey (2015).[15] Across these studies, the percentage change of FEV1 was significantly improved in the EBV group compared with the control group [weighted mean difference (WMD)=11.43; 95% confidence interval (CI), 6.05-16.80; P<0.0001] as was the SGRQ score (WMD=-5.69; 95% CI, -8.67 to -2.70; P=0.0002). No group difference was found in the 6MWT (WMD=14.12; 95% CI, -4.71 to 32.95; P=0.14). There was an increased rate of pneumothorax [relative risk (RR)=8.16; 95% CI, 2.21-30.11; P=0.002), any hemoptysis (RR=5.01; 95% CI, 1.12-22.49; P=0.04)] and valve migration (RR=8.64; 95% CI, 2.01-37.13; P=0.004) in the EBV group. Although there were short-term improvements in lung function and quality of life observed with the EBV, the significant increases in complication rates demonstrate the need for additional studies to determine the long-term safety and effectiveness of the treatment.

La Barca (2019) published a SR with meta-analysis of RCTs evaluating the efficacy and safety of the Zephyr® valve.[24] Seven RCTs reported on Zephyr® valves and five RCTs included only patients without collateral ventilation. Outcomes evaluated were change in: FEV1, 6MWT, SGRQ, and in residual volume (RV). Safety analysis included relative risk (RR) of pneumothorax. Treatment with the Zephyr® valve improved FEV1 with a mean difference (MD) of 20.74% (CI, 15.68, 25.79, I^2 = 25%). Subgroup analysis showed significant FEV1 improvement following Zephyr® placement in patients with heterogeneous emphysema distribution: MD = 25.98%% (CI, 17.72, 34.24, I^2 = 58%) and 16.27% (CI, 8.78-23.76, I^2 = 0%) in patients with homogeneous emphysema. Follow-up of 6-12 months showed a consistent improvement of FEV1 MD = 17.90% (CI, 11.47-24.33, I2 = 0%). Despite these positive clinical outcomes, the relative risk of pneumothorax was 6.32 (CI, 3.74-10.67, I2 = 0%). While this SR found clinically meaningful improvements with Zephyr® valve, there also was a significant increase in adverse events with the device. These conclusions are consistent with a comprehensive review of lung volume reducing surgical and endoscopic interventions for emphysema published by van Geffen (2019) that also included seven RCTs of the Zephyr® valve.[25] Five of the studies are included in Table 1 under Endobronchial Valve Studies, and the additional two are LIBERATE[26, 27] and TRANSFORM[28]. Participants in the included studies were those with emphysema, older than 35 years, post-bronchodilator FEV1 < 60% of predicted, and residual volume >150% of predicted (N = 620 total, range per study varied 50-190). Studies lasted from 3-12 months in duration. Meta analyses found adverse events including mortality to be greater in those who received valves: OR 9.58 (5.56 to 16.50), p=<0.00001.

A 2017 SR with meta-analysis by Wang evaluated bronchoscopic lung volume reduction therapy in patients with severe emphysema which included six RCTs for EBVs and two RCTs for IBVs.[29] Better response in minimal clinically important difference (MCID) was found in EBV trials for FEV1 (RR = 2.96, 95% CI = 1.49 – 5.87, p = 0.002, I2 = 58%), for 6MWT (RR = 2.90, 95% CI = 1.24 – 6.79, p = 0.01, I2 = 80%), for SGRQ (RR = 1.53, 95% CI = 1.22 – 1.92, p = 0.0002, I2 = 0%), as well as for mMRC (RR = 2.53, 95% CI = 1.71 – 3.76, p <0.00001, I2 = 0%). Similarly, EBV therapy was associated with significant improvement in ΔFEV_1 (WMD = 11.44%, 95% CI = 6.11 – 16.77, p < 0.0001, I^2 = 57%), in Δ6WMT (WMD = 33.86m, 95% CI = 11.54 – 56.19, p = 0.003, I^2 = 76%), and in ΔSGRQ (WMD = -7.06 points, 95% CI = -10.71 – -3.41, p = 0.0001, I^2 = 63%), in ΔmMRC (WMD = -0.35 point, 95% CI = -0.56 – -0.14, p = 0.0008, I^2 = 30%). The IBV group was not found to be superior to the conventional group. No sub-analysis was provided for emphysema type (homogenous vs. heterogenous).

In 2017, a Cochrane Systematic Review evaluating bronchoscopic lung volume procedures for COPD was published by van Agteren.[30] Authors conducted in-depth analyses aimed at assessing the effects of bronchoscopic lung volume reduction procedures on the short- and long-term health outcomes in participants with moderate to severe COPD and determining the effectiveness of each technique. Endobronchial and intrabronchial valves were among the six techniques analyzed; only individually and cluster randomized controlled trials were included. See Table 1 for endobronchial and intrabronchial valve studies included for analyses. Studies including participants with giant or bullous emphysema were excluded. Primary outcomes included: lung capacity as measured by FEV1; survival as measured by perioperative and postoperative mortality; and health-related quality of life, measured by questionnaire (e.g., St Georges Respiratory Questionnaire [SGRQ]). Given the heterogeneity in treatment approaches, outcomes were meta-analyzed only per treatment type. Outcomes for continuous or dichotomous data were analyzed using a fixed-effect model up to the end of follow-up. Continuous outcomes were calculated using mean differences, and dichotomous outcomes with odds ratios, both with 95% confidence intervals. Heterogeneity was calculated using the I^2 statistic, and subgroup analysis was performed as appropriate. Studies were graded for bias as high, low, or unclear, with rationale reported. Quality of evidence was rated using the GRADE scale. EBV and IBV studies included both heterogenous and homogeneous disease status patients, though majority of the EBV studies included participants with only a heterogenous disease distribution. The average of participants ranged between 58 and 65 years of age; the STELVIO 2015 trial having the youngest average age (58 to 59 years of age); the IBV Valve Trial 2014 and the VENT US 2010 studies having the highest average age ranging between 64.7 and 64.8, and 64.9 and 65.3, respectively. Majority of the trials recruited more males than females.

Table 1. RCTs included in 2017 Cochrane Review

Endobronchial Valve Studies (Year)	Intrabronchial Valve Studies (Year)
BeLieVeR HIFi (2015)[15, 31]	Eberhardt (2012)[32]
IMPACT (2016)[21]	IBV Valve Trial (2014)[11]
STELVIO (2015)[23, 33]	Ninane (2012)[10]
VENT EU (2012)[19]	
VENT US (2010)[22, 34-39]	

Endobronchial Valves

The conclusions from the EBV studies were drawn from five studies totalling 703 participants, which used standard medical care as the comparator. The results from the Cochrane SR by van Agteren are consistent with the subsequent SRs noted above. The number of adverse events experienced by patients with endobronchial valves was higher than those who received standard medical treatment (OR [95% confidence interval], 5.85 [2.16, 15.84], high quality of evidence), though no significant difference in mortality was found. From baseline to follow-up, between-group differences in the EBV group compared to control, change in lung function (FEV1, standardized mean difference [SMD], of 0.48 [95% CI: 0.32 to 0.64], low-quality evidence), quality of life (mean difference [MD], -6.20 units [95% CI: -8.19 to -4.20]; low quality of evidence), and exercise capacity (38.40 meters [95% CI: 24.69 to 52.12]; low quality of evidence) were significantly improved. While positive results may have been found, due to high confidence intervals and standard deviations, the authors urged caution in interpreting the means reported for outcomes of their systematic review. Earlier trials found better outcomes in patients with intact fissures which affected selection criteria in future trails, and thus improvement in functional outcomes.

Intrabronchial Valves

Two RCTs comparing intrabronchial valves to standard medical treatment were included for review,[10, 11] as well as one trial comparing unilateral versus partial bilateral valve placement with intrabronchial valves[32]. Adverse events experienced by patients with intrabronchial valves was higher than those who received standard medical treatment (OR, 3.41 [1.48, 7.84]), and no significant risk in mortality. Between group difference in exercise capacity was found to favor controls (MD -19.54 meters; [95% CI -37.11 to -1.98], moderate-quality evidence), as did lung function. Lack of difference in the IBV Valve trials by Wood (2014) and Ninane (2012) may be explained by the Eberhardt (2012) trial, as the latter found those treated with unilateral valve placement as opposed to partial bilateral treatment showed significantly better results in lung function, quality of life, and exercise capacity. The other two trials did not specifically address collateral ventilation, nor did they aim to achieve lobar occlusion; this is supported by the EBV trials which all aimed to achieve lobar occlusion and found better functional results when achieved.

Overall, findings in the Cochrane meta-analyses are limited by the lack of long-term follow-up data, significant heterogeneity in results, presence of skew and high CIs, and the open-label character of a number of the studies.

Choi (2015) published a systematic review evaluating bronchoscopic lung volume reduction using a one-way endobronchial valve.[40] The systematic review included 15 studies and meta-analyzed RCTs. Forced expiratory volume in one second (FEV1) improved compared to control groups in favor of the valve group (mean difference of 6.71, 95% CI: 3.31-10.11). The six-minute walking distance and cycle workload were also improved. A subgroup analysis of patients with complete fissure, reported that the FEV1 change was higher in the valve group at six and 12-months compared to the control group. No deaths were reported for the bronchial valve group although the pneumothorax incidence and respiratory failure rates were higher in the EBV group.

Randomized Controlled Trials

RCTs not included in the above-described systematic reviews are summarized here.

Gompelmann (2019) published long-term follow-up data on patients with severe emphysema with no collateral ventilation treated with endobronchial or intrabronchial valves.[41] Of the 256 patients, 220, 200, 187, 100 and 66 patients completed the three-month, six-month, one-year, two-year and three-year follow-up visit, respectively. Lung function parameters [FEV1, vital capacity (VC), residual volume (RV), total lung capacity (TLC)] and exercise capacity [6-minute walk test (6-MWT)] were outcomes evaluated. Response rates were calculated as the number of patients who met the minimal important difference (MID) of >100 ml improvement in FEV1, >430 ml reduction in RV and >26 m improvement in 6-MWT. Patients who underwent further interventional strategies (LVRS, coil therapy, polymeric lung volume reduction, lung transplantation) within the observation timeframe were excluded after the additional therapeutic intervention. At six-month follow-up, 37% of the patients met the efficacy threshold of greater than 100 ml improvement in FEV1, 78% of the patients developed a greater than 430 ml reduction in RV and 58% of the patients experienced a greater than 26 m improvement on the 6-MWT. At one-year follow-up, significant improvement from baseline ($p<0.05$ in paired t-tests, uncontrolled for repeated observations) was found for lung function parameters including FEV1 and RV and exercise capacity (6-MWT). At three-year follow-up (n=66), the proportion of patients achieving the MID from baseline in RV and 6-MWT was 71% and 46%,

respectively. Radiological follow up was assessed in 251 of the patients, and of these, 22% (56/251) developed a pneumothorax. Management of pneumothorax was via chest tube insertion in 86% (48/56) of these patients, and in 41% (23/56), valve removal was necessary for pneumothorax management. Over the three-year observation, all valves were permanently removed in 24.6% (63/256) of the patients. Permanent valve removal was conducted due to the following reasons: missing clinical benefit in 55.6% (35/63), pneumothorax in 11.1% (7/63), definitive LVRS in 19% (12/63), poststenotic pneumonia in 6.3% (4/63), lung cancer in 3.2% (2/63), respiratory insufficiency in 3.2% (2/63) and recurrent pulmonary infections in 1.6% (1/63). No analyses specific to endobronchial versus intrabronchial valve use was provided. This trial is limited by the lack of a comparative group such as medical management alone and by the retrospective design, as well as considerable loss to follow-up. Despite these limitations, this study provides important data regarding longer-term outcomes for highly-selected patients undergoing endobronchial valve treatment for severe emphysema and indicate clinically meaningful improvement can be achieved in these selected patients.

In 2017, Klooster reported one-year follow-up data from the STELVIO study not included in the SRs above.[42] An intention-to-treat analysis showed greater improvements in all primary outcomes in the EBV group compared to the controls. However, of the 64 patients with follow-up data available, 47 serious adverse events were reported from 0-6 mos, and 11 from 6 mos to one year. Two patients in the valve group died.

Nonrandomized Studies

Everaerts (2023) published a retrospective review of 53 patients with emphysema due to alpha-1 antitrypsin deficiency (AATD) who were treated with EBV. AATD is a rare hereditary cause of COPD.[43] The authors note that people with AATD were largely excluded from clinical trials that led to the current clinical indications for EBV, but treatment for emphysema due to AATD is generally similar to treatment for COPD that is not AATD-induced. The study divided patients into two groups: 30 patients with serum alpha-1 antitrypsin levels (AAT) of less than 0.6g/L or a confirmed AATD diagnosis, and 23 patients with possible or mild AATD, and serum AAT levels of between 0.6 and 1g/L. The group with confirmed AATD was significantly younger ($p<0.01$) and had fewer pack-years of smoking ($p<0.001$). The AATD group also had less pronounced hyperinflation at baseline ($p<0.05$). The groups had similar baseline FEV_1, RV, diffuse capacity for carbon monoxide ($DL_{CO)}$, 6MWD, and SGRQ measures. Six weeks after EBV, more than 90% of patients in both groups experienced target lobe volume reduction (TLVR) at levels higher than 563ml, which was the minimally important clinical difference (MCID) cutoff. After EBV, both groups had significant improvement compared to baseline in FEV_1 increase, RV, 6MWD, and SGRQ ($p<0.01$ for all measures). Adverse events were similar in both groups, with 10% of the AATD group and 13% of the AAT group experiencing pneumothorax. Three patients (10%) in the AATD group and two (9%) in the AAT group required revision bronchoscopy. The authors concluded that while further study on larger groups is indicated, the evidence supports EBV as a therapy for people with AATD.

Hartman (2022) published a retrospective review of 1471 patients who had consultation and pulmonary function testing for BLVR treatment evaluation to compare survival rates between patients treated with BVLR and those that were not. The patients had evaluation at a centralized referral center in The Netherlands between June 2006 and July 2019.[44] Of the 1471 patients, 483 had BLVR treatment, 353 with EBV and 130 with coils; and 988 did not have BVLR treatment. At baseline, patients treated with BLVR had fewer COPD exacerbations in the previous year ($p<0.001$) but had worse pulmonary function (FEV_1 % of predicted; p

<0.001) lower body mass index (BMI) (p=0.10), and more cat scan (CT)-detected emphysema (p<0.001) and air-trapping (:<0.001). The BLVR treatment group was also more likely to be female (p=0.008), and more likely to have had either myocardial infarction, percutaneous coronary intervention, or stroke (p=0.007). Patients who were treated with BLVR had a significantly longer median survival time compared to patients who did not (3133 days; 95% CI 2777-3489 vs. 2503 days; 95% CI 2281-2725, p < 0.001), which equates to a difference between the groups of 630 days, or approximately 1.7 years. Multivariant analysis found that BLVR treatment was an independent predictor of survival when adjusted for age, gender, packyears, BMI, and multiple factors related to disease severity (p< 0.001). The authors note that the reason patients did not have BLVR treatment was largely due to ineligibility for the treatment, not personal preference. Therefore, even though BLVR was found to be an independent predictor of survival, it is not possible to know if the deaths in the non-BLVR group would have been altered with BLVR in people who do not meet criteria for the treatment.

Hartman (2021) conducted a prospective cohort study to investigate patient satisfaction and patient-specific treatment goals among individuals who received bronchial valves for treatment of severe emphysema at a single hospital in The Netherlands.[45] Patient satisfaction was measured by a questionnaire administered one year after valve placement. Patient-specific goals were measured using the Dutch patient-specific complaint (PSC) questionnaire. In this questionnaire, patients reported their three most personally desired post-treatment goals and used a numeric rating scale (0-10) to score the level of disability per goal before and one year after treatment. Lung function, exercise capacity, dyspnea severity, and quality of life were also measured before treatment and at one-year follow-up. Of 134 patients who underwent bronchial valve placement prior to January 1, 2019, 109 (81.3%) completed the patient-satisfaction questionnaire, 88 (65.7%) completed the PSC questionnaire at baseline and follow-up, and 94 (70.1%) returned to the hospital for a follow-up visit at one year. Reasons for loss to follow-up in 40 patients were bronchial valve removed (16 patients), died (n=5), comorbidity (n=5), revision at that time (n=3) lung volume reduction surgery (LVRS) or lung transplant (n=2), and other (n=9). The PSC-questionnaire score significantly improved one year after bronchial valve treatment, from 23.7 to 17.1 points (mean decrease of 6.5 points; p =0.001) and an improvement in the PSC-questionnaire sum score was significantly associated with a larger improvement in FEV1, residual volume, exercise capacity, dyspnea severity, and quality of life. Seventy-five percent of the patients who completed the questionnaire were satisfied or very satisfied with the treatment and 11% were unsatisfied or very unsatisfied. Just over half of the questionnaire respondents (52.6%) were satisfied or very satisfied with the reduction in their symptoms after treatment, and 24.9% were unsatisfied or very unsatisfied. For the question of whether the treatment satisfied their expectations (range 1 to 5), the mean score was 3.29 (standard deviation 1.43). Most of those who completed the questionnaire (91.4%) would recommend the treatment to other patients. This study was limited by its uncontrolled design and relatively high loss to follow-up (29.9%), but it provides information on outcomes important to patients.

A retrospective review of 1500 patients with severe COPD referred for bronchoscopic lung volume reduction (BLVR) treatment was conducted by Welling (2020) to investigate the differences between patients selected for BLVR and patients that were not.[46] Of those reviewed, 282 (19%) patients were selected for BLVR treatment, and of these, 175 patients (62%) were selected for EBV, 93 patients (33%) for lung volume reduction coil (LVRC), three patients (0.2%) for airway bypass stents, nine patients (3%) for polymeric lung volume reduction and two patients (0.1%) for a pneumostoma. Although the authors found that patients who were selected for any BLVR option lived significantly longer than those who were

not selected for BLVR (median 3060 versus 2079 days, p<0.001), these patients also were significantly younger (59 versus 63 years), had a lower FEV1 (28% versus 34% of predicted) and a higher residual volume (237% versus 215% of predicted) compared to the group of patients not selected for BLVR (all p<0.001). No significant survival difference was observed between patients who were selected for EBV treatment and those who were selected for LVRC (p=0.45).

Skowasch (2016) reported six month follow-up results from the VENT trial, a retrospective analysis of registry data for patients who have received endobronchial valves also described below.[47] Although lung function (FEV1 and residual volume), and COPD Assessment Test scores improved, 66 serious adverse events were reported in 55 patients. In the subsequent six months of follow-up, a total of 170 serious adverse events were reported in 125 patients.

Liberator (2016) published a retrospective analysis of the VENT trial.[37] The analysis evaluated outcomes and response based on lobe selection in patients receiving EBV therapy. The authors concluded that lobe selection does have a major role in EBV therapy. There was no difference in FEV1 outcomes between upper and lower lobe treatment groups. The authors further conclude that complete fissure status preprocedure has the greatest influence on FEV1 outcome improvement.

Several other small case series (n<100) have been published on the use of the Zephyr or IBV valves for severe emphysema.[18, 33, 48-52] The ability to draw conclusions based on these data is limited by a variety of factors, including small sample sizes, limited long-term follow-up data, and heterogeneity in study design including patient inclusion criteria and varying numbers of valves placed per patient. For example, a mean of four (SD: 1.6) and range of 1-8 in one study[53] and a mean of 6.7 and range of 3-11 in the other[48], and unreported mean and range in the third[50, 51], limiting comparisons of treatment effectiveness.

Section Summary: Advanced Emphysema

In patients with severe emphysema and low collateral ventilation, RCTs provide consistent evidence of clinically meaningful benefit for endobronchial valves compared to standard medical management on measures of lung function and quality of life. Systematic review of the available evidence also finds significant improvement in clinical and functional outcomes in select patients treated with endobronchial valves compared to standard medical management. Systematic review of the current evidence also indicates there is a greater risk of serious adverse events compared to usual care, including mortality and pneumothorax.

PRACTICE GUIDELINE SUMMARY

The 2023 Global Initiative for Chronic Obstructive Lung Disease (GOLD) report on the Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease makes the following statements on lung volume reduction interventions:[54]

- In selected patients with heterogeneous or homogeneous emphysema and significant hyperinflation refractory to optimized medical care, surgical or bronchoscopic modes of lung volume reduction (e.g., endobronchial one-way valves, lung coils, or thermal ablation) may be considered.
- In select patients with advanced emphysema, bronchoscopic interventions reduce end-expiratory lung volume and improve exercise tolerance, health status and lung function at 6-12 months following treatment (Evidence Level A for endobronchial valves: well-

designed RCTs with consistent findings in the intended population without any important limitations).

SUMMARY

There is enough research to show that bronchial valves improve net health outcomes (balance of benefit and harm) compared to current standard of care for highly selected patients with advanced emphysema. Clinical guidelines based on research recommend endobronchial valves in the treatment of advanced emphysema for select patients. Therefore, US Food and Drug Administration (FDA) – approved endobronchial valve placement may be considered medically necessary for the treatment of advanced emphysema when policy criteria are met.

Removal, replacement, or revision of bronchial valves placed for the treatment of severe emphysema may be required after the device has been placed. In these cases, revision may be medically appropriate to allow for the proper functioning of the device or removal may be appropriate when the condition of the patient has changed. Therefore, revision, replacement, or removal of an existing US Food and Drug Administration (FDA) – approved endobronchial valve may be considered medically necessary after the device has been placed.

There is not enough research to show that bronchial valves improve net health outcomes (balance of benefit and harm) compared to current standard of care for any indication other than for the treatment of severe emphysema when criteria are met. Clinical guidelines based on research recommend bronchial valves only in select patients. Therefore, bronchial valve placement is considered investigational for all indications other than for the treatment of severe emphysema when policy criteria are met, including for the treatment of air leaks and for the treatment of emphysema when policy criteria are not met.

Gastroesophageal Reflux Surgery

Effective: April 1, 2024

Next Review: December 2024
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Surgical fundoplication involves wrapping the fundus of the stomach around the lower esophagus in order to create a high-pressure zone that reduces gastroesophageal reflux.

MEDICAL POLICY CRITERIA

I. Esophagogastric fundoplication may be considered **medically necessary** for one or more of the following:

   A. In children and adolescents age 17 years and younger; or

   B. In patients with pulmonary fibrosis with symptomatic or asymptomatic gastroesophageal reflux disease; or

   C. When the procedure is performed with a paraesophageal hiatal hernia (Types II-IV as defined in List of Information Needed for Review), and the paraesophageal hiatal hernia is confirmed by imaging; or

   D. When the procedure is performed with esophageal myotomy in patients with achalasia; or

E. Initial esophagogastric fundoplication to treat symptomatic gastroesophageal reflux disease (e.g., heartburn, regurgitation) when all of the following criteria (1.-4.) are met:

1. A paraesophageal hiatal hernia repair (Types II-IV as defined in List of Information Needed for Review) is not requested or documented.
2. Symptoms are unresponsive to lifestyle modifications as appropriate to the individual patient (e.g., weight loss for overweight or obese patients, avoidance of late meals, elevation of the head of the bed); and
3. Medication therapy that meets one or more of the following:
    i. A 4-month total trial of proton pump inhibitors (PPIs) is ineffective, contraindicated, or not tolerated; or
    ii. PPIs are used for 12 or more consecutive months within the past 18 months, and surgery is considered an alternative to long-term medication use.
4. There is objective diagnostic confirmation by either of the following:
    i. Reflux and/or esophagitis is confirmed via endoscopy; or
    ii. If endoscopy is normal, objective evidence of reflux should include one or more of the following:
        a.) 24-hour ambulatory esophageal pH monitoring; or
        b.) Barium swallow.

F. Repeat esophagogastric fundoplication for a failed previous antireflux procedure when one or more of the following criteria are met:

1. Criteria I.E.1.-4. for initial esophagogastric fundoplication above are met; or
2. Repeat surgery is for a documented mechanical failure of previous antireflux procedure (e.g., obstruction).

II. Esophagogastric fundoplication is considered **not medically necessary** for the treatment of symptomatic gastroesophageal reflux disease (e.g., heartburn, regurgitation) when Criterion I. is not met.

III. The following surgical procedures are considered **investigational** for the treatment of gastroesophageal reflux:

A. Distal or partial gastrectomy performed with or without gastroduodenostomy, gastrojejunostomy, or Roux-en-Y reconstruction.

B. Hiatal hernia repair without current or prior fundoplication, including repair of sliding or paraesophageal hernia.

C. Hiatal hernia repair without fundoplication of greater than 180 degree wrap (e.g., Nissen, Toupet) due to prior bariatric surgery, including repair of sliding or paraesophageal hernia.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could our impact review and decision outcome.

- The specific surgical procedure and treatment plan;
- Medical records must document the following:
    - symptomatic gastroesophageal reflux disease (GERD; e.g., heartburn, regurgitation, etc);
    - any lifestyle modifications attempted and the outcomes (e.g., weight loss if appropriate, avoidance of late meals or foods that cause heartburn, avoidance of activities that cause heartburn, elevation of the head, etc.);
    - medication therapies, including PPIs, that have been attempted, and their outcomes;
    - diagnostic confirmation of reflux and/or esophagitis via endoscopy, 24-hour ambulatory esophageal pH monitoring, or barium swallow.
    - A paraesophageal hernia (**Types II-IV)** must be clearly documented by imaging for coverage of paraesophageal hernia repair. For example, esophagram, upper GI study, and CT scan are acceptable forms of documentation.
        - Hernia Classifications-

            - Type I – A hiatal hernia, commonly known as a sliding hernia, (type I), occurs when there is protrusion of the upper part of the stomach and esophagus (gastroesophageal junction) into the chest. This is the most common type (about 95%) of all hiatal hernias. This is also called a sliding hiatal hernia. A hiatal hernia of this type may also contain the upper segment of a sleeve gastrectomy or the pouch of a gastric band or gastric bypass. Additionally, if less than 50% of the stomach is located above the diaphragm, this is still considered a type I hiatal hernia and is not considered a paraesophageal hiatal hernia.
            - Type II - A paraesophageal hernia (type II) occurs when the esophagus and the gastroesophageal junction remain in their normal location but a part of the stomach, typically the fundus, protrudes through the hiatus next to the esophagus into the chest. These ‘pure' type II paraesophageal hiatal hernias seldom occur.
            - Type III – A paraesophageal hiatal hernia (type III) occurs when there is a combination of both type I and II hiatal hernias, when the stomach and esophagus protrude into the chest AND the fundus of the stomach lies above the gastroesophageal junction and rotates along its long axis in a rolling or twisting fashion, referred to as an organo-axial torsion. A "giant" hiatal hernia is a subset of type III hiatal hernias and defined when greater than 50% of the stomach has protruded into the chest. The majority of paraesophageal hernias are type III. However, all types of paraesophageal hiatal hernias make up about 5% of hiatal

hernias but account for most of the hiatal hernia complications. The complications are primarily due to interference with the blood flow from the left gastric artery to the twisted fundus.
    - Type IV – A paraesophageal hiatal hernia (type IV) occurs when a structure other than the stomach, such as the large intestine, small intestine, or omentum protrude through the hiatus into the chest.
  - Repair of the typical Type I hiatal hernia (e.g. sliding hernias) cannot be coded by a paraesophageal hernia (Types II-IV) repair code per CPT code definitions. The paraesophageal hiatal hernia repair codes cannot be reported unless a paraesophageal hiatal hernia is clearly documented.

- Indicate if request is for an initial treatment or a repeat esophagogastric fundoplication and reason for the need to repeat the procedure (e.g., continued symptoms, mechanical failure, etc.)
- Presence of other conditions, such as pulmonary fibrosis, hiatal hernia, achalasia, etc.

BACKGROUND

Gastroesophageal reflux disease (GERD) is a chronic medical condition, defined as “troublesome symptoms and/or complications” caused by reflux or regurgitation of stomach acid.[1] GERD is a common disorder; the proportion of North American adults with GERD (those who report experiencing symptoms such as heartburn or acid reflux at least once a week, or those with a physician diagnosis of GERD) is estimated to be around 19.8-20%.[2] GERD has also been associated with extraesophageal symptoms or conditions, such as cough, laryngitis, asthma and pulmonary fibrosis, although a direct causal relationship with GERD has not been established.

Standard treatment of GERD may address lifestyle modifications as appropriate to individual patients such as weight loss, smoking cessation, avoidance of specific foods that may precipitate reflux or heartburn, elevating the head of the bed, and avoiding recumbent positions until 2-3 hours after a meal.[1] When these actions are not successful, treatment generally consists of a daily regimen of proton pump inhibitors (PPIs). However, some patients with chronic GERD are unable or unwilling to continue ongoing medical treatment. For these patients, surgical treatment may be considered.

Surgical fundoplication involves wrapping the fundus of the stomach around the lower esophagus in order to create a high pressure zone that reduces gastroesophageal reflux. The fundal wrap can be either total (360 degrees) or partial (<360 degrees). Fundoplication may be performed as an open procedure but is more commonly performed laparoscopically.

ESOPHAGOGASTRIC FUNDOPLICATION WITH PARAESOPHAGEAL HIATAL HERNIA REPAIR

Paraesophageal hiatal hernias, also known as Type II or III hiatal hernias, occur when the stomach, and in some cases the gastroesophageal junction (GEJ), herniates through the diaphragmatic esophageal hiatus into the mediastinum. These cases are rare compared to the more common Type I or “sliding” type hiatal hernia. Diagnosis of a “true” paraesophageal hiatal hernia is confirmed through endoscopy or imaging studies. Prophylactic surgical treatment of paraesophageal hiatal hernias is usually required as they account for most of the complications associated with hiatal hernias, including but not limited to obstruction, perforation and strangulation.[3] In some cases, patients may exhibit a paraesophageal hiatal hernia with additional symptoms of GERD, requiring not only a hiatal hernia repair, but additionally a fundoplication.[4]

Hiatal hernia classification

The hiatus is an opening in the diaphragm where the distal esophagus passes through to enter the abdomen. A hiatal hernia occurs when intrabdominal contents, such as the stomach, bulge up into the chest through the hiatus. There are four types of hiatal hernias:[5]

- Type I – A hiatal hernia, commonly known as a sliding hernia, (type I), occurs when there is protrusion of the upper part of the stomach and esophagus (gastroesophageal junction) into the chest. This is the most common type (about 95%) of all hiatal hernias. This is also called a sliding hiatal hernia. A hiatal hernia of this type may also contain the upper segment of a sleeve gastrectomy or the pouch of a gastric band or gastric bypass. Additionally, if less than 50% of the stomach is located above the diaphragm, this is still considered a type I hiatal hernia and is not considered a paraesophageal hiatal hernia.

- Type II - A paraesophageal hernia (type II) occurs when the esophagus and the gastroesophageal junction remain in their normal location but a part of the stomach, typically the fundus, protrudes through the hiatus next to the esophagus into the chest. These ‘pure' type II paraesophageal hiatal hernias seldom occur.

- Type III – A paraesophageal hiatal hernia (type III) occurs when there is a combination of both type I and II hiatal hernias, when the stomach and esophagus protrude into the chest AND the fundus of the stomach lies above the gastroesophageal junction and rotates along its long axis in a rolling or twisting fashion, referred to as an organo-axial torsion. A "giant" hiatal hernia is a subset of type III hiatal hernias and defined when greater than 50% of the stomach has protruded into the chest. The majority of paraesophageal hernias are type III. However, all types of paraesophageal hiatal hernias make up about 5% of hiatal hernias but account for most of the hiatal hernia complications. The complications are primarily due to interference with the blood flow from the left gastric artery to the twisted fundus.

- Type IV – A paraesophageal hiatal hernia (type IV) occurs when a structure other than the stomach, such as the large intestine, small intestine, or omentum protrude through the hiatus into the chest.

ESOPHAGOGASTRIC FUNDOPLICATION IN PATIENTS WITH PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is a progressive lung disease which is often associated with additional comorbidities (e.g., pulmonary hypertension and gastroesophageal reflux) and symptoms (e.g., dyspnea, exercise limitation, fatigue, anxiety, mood disturbance, sleep disorders) that negatively affect patients' lives. GERD is highly prevalent in patients with IPF with up to 50% of patients with asymptomatic disease. Although the pathological significance of GERD in IPF remains uncertain, studies indicate that medical or surgical treatment of GERD may stabilize lung function and increase oxygenation.[6-9] It is hypothesized that fundoplication surgery may offer increased benefit over medication treatment by reducing acid as well as microaspirations of the gastric contents in to the lungs.[6]

Due to the complexities of IPF, treatment protocols are not rigid or standardized and often require a management approach which is tailored to the patients' specific conditions and symptoms. Nissen fundoplication surgery is one option which may be considered for treating patients with pulmonary fibrosis with symptomatic or asymptomatic GERD.

Note: This policy does not address transesophageal endoscopic therapies for GERD, which are addressed separately in Surgery Policy No. 110 (see Cross References).

EVIDENCE SUMMARY

In order to determine whether the benefits of surgical fundoplication in patients with chronic GERD outweigh the risks, well-designed randomized controlled trials (RCTs) are necessary, comparing medical therapy (proton pump inhibitors) with surgical fundoplication and reporting on relevant clinical outcomes.

The focus of the following literature review is on systematic reviews, randomized trials published after the systematic reviews, and clinical practice guidelines.

FUNDOPLICATION

Systematic Reviews

A systematic review published by Li (2023) compared laparascopic Nissen and Toupet fundoplications in patients with GERD from eight clinical trials.[10] Primary outcomes included postoperative reflux recurrence, postoperative heartburn, dysphagia and postoperative chest pain, patient satisfaction, and several other clinically important measures. The results of the review showed no significant difference between the Nissen and Toupet surgery types for the majority of outcomes. Those receiving the Toupet procedure had lower lower esophageal sphincter pressure, fewer postoperative dysphagia and inability to belch in the short and long term as well as less gas bloating in the short term when compared to the Nissen procedures. Both procedure types were shown to be effective in treating GERD.

In 2018, Richter reported results from a systematic review with network meta-analysis or randomized controlled trials comparing efficacy of laparoscopic Nissen fundoplication (LNF) to proton pump inhibitors in patients with GERD.[11] The authors also compared the Nissen procedure to transoral incisionless fundoplication, which is not within the scope of this policy, but is summarized elsewhere (see Cross References). Overall, 7 trials were included, totalling 1128 patients. Network meta-analysis using Bayesian methods under random-effects multiple treatment comparisons were implemented for analysis, as well as ranking probability by surface under the cumulative ranking curve. Patients who underwent LNF had a higher probability of persistent esophagitis (0.38) than those on PPI therapy (0.19). Out of all the

interventions studied, LNF had the highest probability of increasing percent time at pH <4 (0.99), followed by PPIs (0.64), and LNF also had a higher probability of increasing patients' health-related quality of life (0.66) than those on PPI therapy (0.05).

In 2010, The Cochrane Collaboration published a systematic review on medical versus surgical management for GERD in adults.[12] Included in the review were all randomized or quasi-randomized controlled trials comparing laparoscopic fundoplication with medical management; nonrandomized studies were excluded. Four trials with a total of 1232 patients were included.[13-16] All reported outcomes at one year, with only one reporting outcomes up to three years. There were no studies that followed patients longer than three years. Overall, the authors concluded that in the short- to medium-term there is evidence that laparoscopic fundoplication is more effective than medical management.

A 2015 update concluded that there is considerable uncertainty in the balance of benefits versus harms of laparoscopic fundoplication compared to long-term medical treatment with proton pump inhibitors.[17] Four randomized controlled trials were included for meta-analysis, consisting of three studies previously reported in the 2010 review, and longer term follow-up for the Anvari study.[18] The available evidence was rated low or very low, and further high-quality studies are needed.

Randomized Controlled Trials

In 2017, Emken reported results of a secondary analysis of an industry sponsored multicenter randomized controlled trial comparing anti-reflux surgery (open fundoplication) to proton pump inhibitor (omeprazole) therapy.[19] From the same study, 3-year trial results were described by Lundell in 2000,[20] followed by 12-year outcomes in 2009[21]. Several of the authors were former employees of the industry sponsor.

> Study design: Three hundred and ten patients across 16 centers in 4 Nordic countries were originally enrolled in the trial, randomized in a 1:1 design (N=155 in each arm). Overall study duration was 14 years, from 1991-2005. In a pre-entry study period, all patients were treated with omeprazole 20mg twice daily with the option of increasing to 40mg if needed to achieve healing of esophageal lesions and control of symptoms. Of the 155 patients randomized to open fundoplication, 144 went on to have surgery; 129 had data available at 3-years follow-up. Of the 154 patients in the omeprazole therapy group (one dropped out prior to starting therapy), 139 had 3-year data available. The secondary analysis report (2017) included 1- and 10-year outcomes from patients who underwent surgery (N=137) and long-term treatment with omeprazole 20–60mg daily (N=108).
>
> Outcomes from 1-, 3-, 10-, and 12-years are summarized here:
>
> - At 3-years follow-up, the authors concluded efficacy from both approaches when omeprazole dose was adjusted over time.
> - In 2009, 12-year results were available for 71 who were given omeprazole (46%) and 53 treated with surgery (37%).
>   - There was no difference in percent of patients in continuous remission between treatment groups (including those who had a dose adjustment and those who did not).

    - Of the patients who underwent surgery, 38% required a change in therapeutic strategy (e.g., to medical therapy or additional surgeries), compared to 15% of those on omeprazole.
    - Adverse events: Therapies were generally well-tolerated in both groups, though heartburn and regurgitation were significantly more common in patients given omeprazole; whereas dysphagia, rectal flatulence, and the inability to belch or vomit were significantly more common in surgical patients. Over the entire follow-up period, fatal outcomes and those of heart-related cause were more common in the omeprazole group than the surgery group. Mean hemoglobin values did not change over time in either group, though mean ferritin levels increased after ten years in the medication treated group. Procedural complications were listed as more common serious adverse events in the surgery group as compared to the omeprazole group, as expected. Authors reported no surgery-related deaths in the original study; two of the surgery patients died of heart-related causes, and two experienced non-fatal heart attacks. In the omeprazole treated group, 8 patients died of heart-related causes, and 9 experienced non-fatal heart attacks. The authors reported that an Food and Drug Administration analysis of these events concluded that baseline differences between groups may have biased the safety outcomes. For example, the median age was four years greater in the medication group, and more patients had experienced a previous heart attack in the medication group as compared to the surgery group (six and zero, respectively).
- At 1- and 10-years follow-up, data were available for 108 patients in the omeprazole group, and 137 patients in the surgery group. One hundred fourteen patients had complete data for both timepoints, and 79 had only 1-year data. There were no statistically significant differences in demographics, manometry measurements, or 24-hour pH-monitoring measurements between those with complete data versus those with only 1-year of data.
    - In those who underwent surgery, measurement of lower esophageal sphincter (LOS) function (via manometry) showed statistically significant increase in median resting pressure at 1-year, which was sustained at 10-years. There were no significant changes in resting pressure in the omeprazole group.
    - Those in the surgery group had statistically significant increases in median total and intra-abdominal length of LOS at 1- and 10-years. In the omeprazole group, the median total and intra-abdominal length of LOS did not change from baseline to the 1-year manometry, however, at 10-years the results were comparable to the surgery group.

Included in the publication of the 2015 Cochrane review, Anvari reported 3-year outcomes from a prospective RCT (one-year results were included in the 2010 Cochrane review).[18] Of note, *a priori*, a sample size of 216 was calculated for this study at a statistical significance level of $\alpha = 0.05$; however only 104 participants were ultimately randomized which may have impacted the ability of the study to detect significant changes.

Of the original 104 subjects, 93 were available for the 3-year follow-up assessment. The authors reported the following outcomes:

- Improvement from baseline in GERD symptoms was significant in both the medical treatment and surgical groups. Differences between the two groups were not significant. (Primary outcome)
- Surgical patients experienced a mean of 1.35 more heartburn-free days per week compared with the medical group, a significant difference. (Primary outcome)
- Both groups demonstrated improvements in acid reflux and did not differ significantly in change from baseline. (Secondary outcome)
- The surgical group had significantly better lower esophageal sphincter pressure than the medical group. (Secondary outcome)
- With respect to global symptom control compared with baseline measurements, medically treated patients maintained their control, but the surgical patients demonstrated a statistically significant improvement from baseline. (Secondary outcome)
- Significant improvements in quality of life scores were also seen in the surgical group compared with the medical group. (Secondary outcome)
- 6 (11.8%) patients in the surgical group and 8 (16%) patients in the medical group failed their primary treatment.
- No adverse events were reported in the medical treatment group. In the surgical group:
    - There were no intraoperative complications, major morbidities, or mortality
    - 7 patients experienced minor postoperative complications
    - 4 patients reported dysphagia; 7 reported postprandial bloating at 3 months
    - 2 patients required dilation of the wrap

SURGICAL TREATMENT OF GERD PATIENTS WITH PULMONARY FIBROSIS

Current evidence regarding fundoplication in patients with pulmonary fibrosis (PF) mainly consist of case series[22-24] and review articles, which indicated that silent reflux, or asymptomatic GERD, occurs in about one third of PF patients.[7, 9] Only a single case series was identified regarding the efficacy of reflux surgery in patients with idiopathic PF (IPF) and GERD symptoms who were awaiting lung transplant:

In 2006, Linden and colleagues evaluated Laparoscopic fundoplication in patients with GERD symptoms and end-stage lung disease awaiting transplantation.[8] Of 149 patients on the transplant wait list, 19 were identified as having a history of reflux and of those, 14 were diagnosed with IPF. All 14 IPF patients underwent a Nissen fundoplication and were compared to 31 patients with IPF on the transplant list who did not have fundoplication surgery. No perioperative complications or decreases in lung function were reported over a mean 15-month follow-up period. Authors reported that, "patients with idiopathic pulmonary fibrosis treated with fundoplication had stable oxygen requirements, whereas control patients with idiopathic pulmonary fibrosis on the waiting list had a statistically significant deterioration in oxygen requirement."

Overall, the evidence regarding Nissen fundoplication as a treatment of gastrointestinal reflux disease (GERD) in patients with pulmonary fibrosis (PF) is limited; however, treatment of PF is often tailored to treat a patients' specific condition and symptoms. Potential benefits of fundoplication surgery in PF patients include improved oxygenation and reduction of acid and microaspiration into the lungs. Considering no standardized treatment protocol for patients with PF if available, Nissen fundoplication surgery may be considered in patients with symptomatic or asymptomatic GERD to reduce acid reflux and microaspirations to the lungs.

GASTRECTOMY

Gastrectomy involves a partial or full surgical removal of the stomach and is most often performed to treat cancer, non-cancerous tumors, perforation, polyps, ulcers, or obesity. In order to determine whether the benefits of surgical gastrectomy in patients with chronic GERD outweigh the risks, well-designed RCTs are necessary, comparing gastrectomy to medical therapy and accepted surgical interventions (fundoplication).

Systematic Reviews and Randomized Controlled Trials

In 2016, Oor published results of a systematic review and meta-analysis of 33 studies examining the impact of laparoscopic sleeve gastrectomy on prevalence of GERD.[25] Pooled data from seven studies using validated symptom questionnaires for new-onset of GERD symptoms resulted in a 20% incidence following LSG (follow-up time ranging from one- to 60-months). There was heterogeneity amongst these studies (I^2=68%). For difference in prevalence of GERD before and after LSG, as reported by questionnaire, the pooled risk difference was found to be 4.3%; with heterogeneity present (I^2=89%). Of the 24 studies reviewed, the authors found new-onset GERD symptom incidence to range from zero to 34.9%. Data for new-onset esophagitis, changes in the use of antireflux medication, 24-hour pH monitoring, manometry, and combined pH-impedance results could not be pooled. The authors therefore concluded that LSG could induce serious GERD symptoms in patients with no preoperative GERD complaints. The heterogeneity found in analyses may be due to a lack of a standardized approach to LSG, as well has the variability in follow-up length. The authors also noted that range in prevalence of GERD symptoms may be in part due to the variability in reported preoperative BMI, as the LSG will be a more technically challenging procedure in those with a BMI of 60 kg/m^2 versus those with a BMI of 40 kg/m^2.

Nonrandomized Studies

Current evidence regarding the use of distal, partial or complete gastrectomy with or without gastroduodenostomy, gastrojejunostomy, or Roux-en-Y reconstruction as a treatment of gastric reflux disease consists of small case series.[26-28] These studies do not permit conclusions due to the small sample size, lack of a control group, differences in patient characteristics and surgical techniques, and other methodological limitations. In addition, several studies[28-32] were identified which reported on GERD reduction after sleeve gastrectomy in obese patients; however, the primary focus of these studies was on weight reduction and the reduction of GERD symptoms was a secondary outcome. In order to isolate the direct effects of gastrectomy upon chronic GERD symptoms, well-designed RCTs are required which compare health outcomes of patients treated with gastrectomy versus medication or fundoplication.

HIATAL HERNIA REPAIR WITHOUT FUNDOPLICATION

Several studies were identified which reported an improvement in GERD symptoms associated with sliding type hernia repair; however, no studies were identified which evaluated the use of hiatal hernia repair as an independent treatment of gastric reflux disease.

PRACTICE GUIDELINE SUMMARY

Three evidence-based clinical practice guidelines address surgical treatment of GERD. These guidelines offer differing recommendations concerning indications for surgery. No evidence-

based clinical practice guidelines were identified which recommend fundoplication surgery as a treatment of GERD in patients with pulmonary fibrosis. In addition, no evidence-based clinical practice guidelines were identified which address the use of gastrectomy or hiatal hernia repair as a treatment of GERD.

SOCIETY OF AMERICAN GASTROINTESTINAL AND ENDOSCOPIC SURGEONS

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guidelines recommend surgical therapy when the diagnosis of reflux is objectively confirmed, in individuals who:[33]

1) have failed medical management (inadequate symptom control, severe regurgitation not controlled with acid suppression, or medication side effects)
   OR
2) opt for surgery despite successful medical management (due to quality of life considerations, lifelong need for medication intake, expense of medications, etc.)
   OR
3) have complications of GERD (e.g., Barrett's esophagus, peptic stricture)
   OR
4) have extra-esophageal manifestations (asthma, hoarseness, cough, chest pain, aspiration)

"Surgical therapy for GERD is an equally effective alternative to medical therapy and should be offered to appropriately selected patients by appropriately skilled surgeons (Grade A*). Surgical therapy effectively addresses the mechanical issues associated with the disease and results in long-term patient satisfaction (Grade A). For surgery to compete with medical treatment, it has to be associated with minimal morbidity and cost."

**Definitions*

- Grade A: "Based on high level (Level I or II), well-performed studies with uniform interpretation and conclusions by the expert panels"
- Level I Evidence: "Evidence from properly conducted randomized, controlled trials
- Level II Evidence: "Evidence from controlled trials without randomization; cohort or case-control studies; multiple time series; dramatic uncontrolled experiments

AMERICAN GASTROENTEROLOGICAL ASSOCIATION

In 2008, the American Gastroenterological Association (AGA) published a guideline regarding the management of gastroesophageal reflux disease which made the following recommendations:[1]

- "When antireflux surgery and PPI therapy are judged to offer similar efficacy in a patient with an esophageal GERD syndrome, PPI therapy should be recommended as initial therapy because of superior safety." (Grade A**)
- "When a patient with an esophageal GERD syndrome is responsive to, but intolerant of, acid suppressive therapy, antireflux surgery should be recommended as an alternative." (Grade A)
- Antireflux surgery is recommended "for patients with an esophageal GERD syndrome with persistent troublesome symptoms, especially troublesome regurgitation, despite PPI therapy. The potential benefits of antireflux surgery should be weighed against the

deleterious effect of new symptoms consequent from surgery, particularly dysphagia, flatulence, an inability to belch, and postsurgery bowel symptoms." (Grade B**)
- "Patients with an extraesophageal GERD syndrome with persistent troublesome symptoms despite PPI therapy should be considered for antireflux surgery. The potential benefits of antireflux surgery should be weighed against the deleterious effect of new symptoms consequent from surgery, particularly dysphagia, flatulence, an inability to belch, and postsurgery bowel symptoms." (Grade C**)
- The AGA recommends against antireflux surgery (Grade D**):
    - "for patients with an esophageal syndrome with or without tissue damage who are symptomatically well controlled on medical therapy."
    - "as an antineoplastic measure in patients with Barrett's metaplasia."

***Definitions*

- Grade A: "strongly recommended based on good evidence that it improves important health outcomes."
- Grade B: "recommended with fair evidence that it improves important outcomes"
- Grade C: "balance of benefits and harms is too close to justify a general recommendation"
- Grade D: "recommend against, fair evidence that it is ineffective or harms outweigh benefits"

AMERICAN COLLEGE OF GASTROENTEROLOGY

In 2013, the American College of Gastroenterology (ACG) issued a guideline for the diagnosis and management of gastroesophageal reflux disease and made numerous recommendations regarding the management and surgical options for GERD.[34] The following are some of the major recommendations regarding PPI use and fundoplication:

- In patients with partial response to PPI therapy, increasing the dose to twice daily therapy or switching to a different PPI may provide additional symptom relief. (Conditional recommendation, low level evidence)
- Surgical therapy is a treatment option for long-term therapy in GERD patients. (Strong recommendation, high level of evidence)
- Surgical therapy is generally not recommended in patients who do not respond to PPI therapy. (Strong recommendation, high level of evidence)
- Surgical therapy is as effective as medical therapy for carefully selected patients with chronic GERD when performed by an experienced surgeon. (Strong recommendation, high level of evidence)

***Definitions*

- The strength of a recommendation was graded as "strong" when the desirable effects of an intervention clearly outweigh the undesirable effects and as "conditional" when there is uncertainty about the trade-offs.
- The level of evidence could range from "high" (implying that further research was unlikely to change the authors' confidence in the estimate of the effect) to "moderate" (further research would be likely to have an impact on the confidence in the estimate of effect) or "low" (further research would be expected to have an important impact on the confidence in the estimate of the effect and would be likely to change the estimate).

SUMMARY

ESOPHAGOGASTRIC FUNDOPLICATION

There is enough research to show that initial or repeat esophagogastric fundoplication improves symptomatic gastroesophageal reflux disease (GERD) for most patients with chronic GERD who have tried lifestyle changes and long-term use of proton pump inhibitors (PPIs), or in those with a documented mechanical failure from a previous antireflux procedure. It appears that initial or repeat esophagogastric fundoplication may also improve symptoms in patients with pulmonary fibrosis. When esophagogastric fundoplication is performed with a paraesophageal hiatal hernia repair, patients with a paraesophageal type of hiatal hernia may also benefit. Patients with achalasia may also have improved health outcomes when esophagogastric fundoplication is performed with an esophageal myotomy. Clinical guidelines based on research recommend fundoplication for select patients. Therefore, initial or repeat esophagogastric fundoplication may be considered medically necessary when policy criteria are met.

There is not enough research to show that initial or repeat esophagogastric fundoplication for GERD improves health outcomes when policy criteria are not met. Therefore, initial or repeat esophagogastric fundoplication for GERD when policy criteria are not met is considered not medically necessary.

GASTRECTOMY

There is not enough research to show that distal, partial or complete gastrectomy with or without gastroduodenostomy, gastrojejunostomy, or Roux-en-Y reconstruction improves health outcomes for people with gastrointestinal reflux disease (GERD). No clinical practice guidelines based on research recommend gastrectomy for people with GERD. Therefore, distal, partial or complete gastrectomy with or without gastroduodenostomy, gastrojejunostomy, or Roux-en-Y reconstruction is considered investigational as a treatment of GERD.

HIATAL HERNIA REPAIR WITHOUT FUNDOPLICATION

There is not enough research to show that hiatal hernia repair without fundoplication, including repair of sliding or paraesophageal hernia, improves health outcomes for people with gastrointestinal reflux disease (GERD). No clinical practice guidelines based on research recommend independent hiatal hernia repair as a treatment for GERD. Therefore hiatal hernia repair without fundoplication is considered investigational as an independent treatment of GERD.

There is not enough research to show that hiatal hernia repair without fundoplication of greater than 180 degree wrap (e.g., Nissen, Toupet) due to prior bariatric surgery, including repair of sliding or paraesophageal hernia, improves health outcomes for people with gastrointestinal reflux disease (GERD). No clinical practice guidelines based on research recommend hiatal hernia repair without fundoplication of greater than 180 degree wrap (e.g., Nissen, Toupet) due to prior bariatric surgery, including repair of sliding or paraesophageal hernia as a treatment for GERD. Therefore, hiatal hernia repair without fundoplication of greater than 180 degree wrap (e.g., Nissen, Toupet) due to prior bariatric surgery, including

repair of sliding or paraesophageal hernia is considered investigational as a treatment of GERD.

CODES

NOTES:

- Repair of the typical Type I hiatal hernia cannot be coded by a paraesophageal hernia repair code per CPT code definitions.
- The paraesophageal hiatal hernia repair codes (i.e., 43281) cannot be reported unless a paraesophageal hiatal hernia is clearly documented.
- CPT 43280 cannot be reported unless a fundoplication is performed.
- There are related procedures without specific CPT codes, including sliding (type I) hiatal hernia repair and the Hill procedure, and these are reported by unlisted codes.

Codes	Number	Description
CPT	43279	Laparoscopy, surgical, esophagomyotomy (Heller type), with fundoplasty, when performed
	43280	Laparoscopy, surgical, esophagogastric fundoplasty (eg, Nissen, Toupet procedures)
	43281	Laparoscopy, surgical, repair of paraesophageal hernia, includes fundoplasty, when performed; without implantation of mesh
	43282	; with implantation of mesh
	43325	Esophagogastric fundoplasty; with fundic patch (Thal-Nissen procedure)
	43327	Esophagogastric fundoplasty partial or complete; laparotomy
	43328	;thoracotomy
	43332	Repair, paraesophageal hiatal hernia (including fundoplication), via laparotomy, except neonatal; without implantation of mesh or other prosthesis
	43333	; with implantation of mesh or other prosthesis
	43334	Repair, paraesophageal hiatal hernia (including fundoplication), via thoracotomy, except neonatal; without implantation of mesh or other prosthesis
	43335	; with implantation of mesh or other prosthesis
	43336	Repair, paraesophageal hiatal hernia (including fundoplication), via thoracoabdominal incision, except neonatal; without implantation of mesh or other prosthesis
	43337	; with implantation of mesh or other prosthesis
	43338	Esophageal lengthening procedure (eg, Collis gastroplasty or wedge gastroplasty) (List separately in addition to code for primary procedure)

Medical Policy Manual Surgery, Policy No. 189

Microwave Tumor Ablation

Effective: January 1, 2024

Next Review: November 2024
Last Review: November 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Microwave ablation (MWA) uses microwave thermal energy to create thermal coagulation and localized tissue necrosis. MWA is proposed for treating tumors, controlling local tumor growth and palliating symptoms.

MEDICAL POLICY CRITERIA

Note: This policy does not address liver tumors (primary or metastatic). See Cross References.

I. Microwave ablation may be considered **medically necessary** to treat tumors when one or more of the following criteria are met:

A. Isolated peripheral non-small cell lung cancer (NSCLC) lesion that is no more than 3 cm in size when both of the following criteria are met:

1. Surgical resection or radiation treatment with curative intent is considered appropriate based on stage of disease, however, medical co-morbidity renders the individual unfit for those interventions; and

2. Tumor is located at least 1 cm from the trachea, main bronchi, esophagus, aorta, aortic arch branches, pulmonary artery and the heart.

B. Malignant non-pulmonary tumor(s) metastatic to the lung that are no more than 3 cm in size when all of the following criteria (1. – 3.) are met:

1. In order to preserve lung function when surgical resection or radiation treatment is likely to substantially worsen pulmonary status, or the patient is not considered a surgical candidate; and
2. There is no evidence of extrapulmonary metastases; and
3. The tumor is located at least 1 cm from the trachea, main bronchi, esophagus, aorta, aortic arch branches, pulmonary artery and the heart.

II. Microwave ablation is considered **investigational** as a technique for ablating all other benign or malignant tumors other than liver tumors that do not meet the policy criteria above.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

MICROWAVE ABLATION

MWA is a technique in which the use of microwave energy induces an ultra-high speed, 915 MHz or 2.450 MHz (2.45 GHz), alternating electric field which causes water molecule rotation and the creation of heat. This results in thermal coagulation and localized tissue necrosis. In MWA, a single microwave antenna or multiple antennas connected to a generator are inserted directly into the tumor or tissue to be ablated; energy from the antennas generates friction and heat. The local heat coagulates the tissue adjacent to the probe, resulting in a small, approximately 2 to 3 cm elliptical area (5 x 3 cm) of tissue ablation. In tumors greater than 2 cm in diameter, 2 to 3 antennas may be used simultaneously to increase the targeted area of MWA and shorten operative time. Multiple antennas may also be used simultaneously to ablate multiple tumors. Tissue ablation occurs quickly, within one minute after a pulse of energy, and multiple pulses may be delivered within a treatment session depending on the size of the tumor. The cells killed by MWA are typically not removed but are gradually replaced by fibrosis and scar tissue. If there is local recurrence, it occurs at the edges. Treatment may be repeated as needed. MWA may be used to: 1) control local tumor growth and prevent recurrence; 2) palliate symptoms; and 3) extend survival duration.

Complications from MWA are usually considered mild and may include pain and fever. Other potential complications associated with MWA include those caused by heat damage to normal tissue adjacent to the tumor (e.g., intestinal damage during MWA of the kidney or liver), structural damage along the probe track (e.g., pneumothorax as a consequence of

procedures on the lung), liver enzyme elevation, liver abscess, ascites, pleural effusion, diaphragm injury or secondary tumors if cells seed during probe removal. MWA should be avoided in pregnant patients since potential risks to the patient and/or fetus have not been established and in patients with implanted electronic devices such as implantable pacemakers that may be adversely affected by microwave power output.

MWA is an ablative technique similar to radiofrequency or cryosurgical ablation; however, MWA may have some advantages. In MWA, the heating process is active, which produces higher temperatures than the passive heating of radiofrequency ablation and should allow for more complete thermal ablation in a shorter period of time. The higher temperatures reached with MWA (over 100° C) can overcome the “heat sink” effect in which tissue cooling occurs from nearby blood flow in large vessels potentially resulting in incomplete tumor ablation. MWA does not rely on the conduction of electricity for heating, and therefore, does not have electrical current flow through patients and does not require grounding pads be used during the procedure to prevent skin burns. Unlike radiofrequency ablation, MWA does not produce electric noise, which allows ultrasound guidance to occur during the procedure without interference. Finally, MWA can be completed in less time than radiofrequency ablation since multiple antennas can be used simultaneously.

APPLICATIONS

MWA was first used percutaneously in 1986 as an adjunct to liver biopsy. Since then, MWA has been used to ablate tumors and tissue to treat many conditions including hepatocellular carcinoma, breast cancer, colorectal cancer metastatic to the liver, renal cell carcinoma, renal hamartoma, adrenal malignant carcinoma, non-small-cell lung cancer, intrahepatic primary cholangiocarcinoma, secondary splenomegaly and hypersplenism, abdominal tumors, and other tumors not amenable to resection. Well-established local or systemic treatment alternatives are available for each of these malignancies. The potential advantages of MWA for these cancers include improved local control and other advantages common to any minimally invasive procedure (eg, preserving normal organ tissue, decreasing morbidity, shortening length of hospitalization). MWA also has been investigated as a treatment for unresectable hepatic tumors (see Cross References).

REGULATORY STATUS

There are several devices cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process for MWA. Covidien’s (a subsidiary of Tyco Healthcare) Evident Microwave Ablation System has 510(k) clearance for soft tissue ablation, including partial or complete ablation of non-resectable liver tumors. The following are selected microwave ablation devices that have 510(k) clearance for MWA of (unspecified) soft tissue:

- BSD Medical Corporation’s MicroThermX® Microwave Ablation System (MTX-180);
- Microsulis Holdings Ltd’s Acculis Accu2i;
- MedWaves Microwave Coagulation/Ablation System;
- Covidien’s Emprint™ Ablation System and Emprint™ SX Ablation Platform with Thermosphere™ Technology;
- Angiodynamics’ Solero Microwave Tissue Ablation System;
- Surgnova Healthcare Technologies’ Microwave Ablation System; and
- Johnson & Johnson’s NEUWAVE Microwave Ablation System

FDA determined that these devices were substantially equivalent to existing radiofrequency and MWA devices. FDA product code: NEY.

EVIDENCE SUMMARY

The principal health outcomes associated with treatment of malignancies are typically measured in units of survival past treatment: disease-free survival (DFS), a period of time following treatment where the disease is undetectable; progression-free survival (PFS), the duration of time after treatment before the advancement or progression of disease; and overall survival (OS), the period of time the patient remains alive following treatment.

In order to understand the impact of microwave ablation (MWA) on these outcomes, well-designed randomized controlled trials (RCTs) are needed that compare this therapy with standard medical and/or surgical treatment of primary and metastatic tumors.

BREAST

SYSTEMATIC REVIEWS

A 2017 systematic review of imaging-guided breast cancer treatments by Mauri compared technical success, efficacy, and complications.[1] 1,156 patients and 1,168 lesions were included in the analysis. The results showed that the microwave technique had the lowest technical success (93%) amongst the techniques that were analyzed including laser (98%), HIFU (96%), radiofrequency (96%), and cryoablation (75%). Additionally, there were significant differences and heterogeneity in the technical efficacy of the methods used.

A 2010 review of ablation techniques by Zhao for breast cancer found only 0 to 8% of breast tumors were completely ablated with microwave ablation (MWA).[2] The authors noted that studies identified for the review were mostly feasibility and pilot studies conducted in research settings.

NONRANDOMIZED STUDIES

Yang (2020) published a prospective multicenter study of MWA for the treatment of benign breast lesions.[3] A total of 440 patients with clinicopathologically confirmed benign breast lesions were treated with MWA and evaluated for technical success, complications, volume reduction ratio (VRR), palpability, and cosmetic satisfaction. In the 755 treated lesions (mean maximum diameter 1.7 ± 0.6 cm), complete ablation was achieved in 100%. The median follow-up was 13.7 months. The 12-month VRR was 97.9% for all lesions, 98.6% for 1.0- to 2.0-cm lesions, and 96.9% for ≥ 2.0-cm lesions. The percent of palpable lesions went from 85.7% pre-treatment to 55.9% post-treatment. Patients rated the cosmetic and minimally invasive satisfaction rates as good or excellent in 98.4% and 94.5% of cases, respectively.

Yu (2020) reported a small cohort study comparing MWA with nipple-sparing mastectomy for invasive ductal carcinoma of the breast.[4] A total of 21 MWA-treated and 43 nipple sparing mastectomy-treated patients were retrospectively enrolled. The mean age of the MWA-treated patients was 24 years older than that of the nipple sparing mastectomy patients. Median follow-up was 26.7 months (range, 14.6 to 62.5 months). Technical effectiveness was 100%. No significant differences between groups in tumor progression were identified (p=0.16).

In 2012, Zhou reported on 41 patients treated with MWA directly followed by mastectomy for single breast tumors with a mean volume of 5.26 cm + 3.8 (range, 0.09 to 14.14 cm).[5]

Complete tumor ablation was found by microscopic evaluation in 37 of the 41 tumors ablated (90%; 95% CI 76.9 to 97.3%). Reversible thermal injuries to the skin and pectoralis major muscle occurred in three patients. Results from this study should be met with caution due to its small sample size and lack of comparison group. The MWA group had significantly lower hospitalization time ($p<0.001$) and better cosmetic results ($p<0.001$). No major complications occurred.

LUNG

SYSTEMATIC REVIEWS

Laeseke (2023) conducted a systematic review and meta-analysis that compared the efficacy of image guided thermal ablation, including MWA, to stereotactic body radiation therapy (SBRT) in patients with stage IA NSCLC among studies with at least 40 patients.[6] Comparative and single-arm studies, as well as single treatments from comparative studies were included in the meta-analysis. Studies that enrolled patients with recurrent NSCLC, or that used interventions as salvage treatments, were excluded. Key outcomes of interest were local tumor progression, overall survival, and disease-free survival. 40 image-guided thermal ablation study-arms (n=2,691 patients) and 215 SBRT study-arms (n=54,789 patients) were identified. Local tumor progression was lowest after SBRT at years one and two in single-arm pooled analyses (4% and 9% versus 11% and 18%) and at one year in meta–regressions when compared to ablative therapies (odds ratio [OR]=0.2, 95% CI = 0.07 to 0.63). Microwave ablation patients had the highest disease-free survival of all treatments in single-arm pooled analyses. In meta–regressions at two and three years, disease-free survival was significantly lower for radiofrequency ablation compared to MWA (OR=0.26, 95% CI = 0.12 to 0.58; OR=0.33, 95% CI = 0.16 to 0.66, respectively). Overall survival was similar across treatment types and time points. Older age, male patients, larger tumors, retrospective studies, and non-Asian study region were predictors of worse clinical outcomes. Among high quality studies, stage IA microwave ablation patients had lower local tumor progression, higher overall survival, and generally lower disease-free survival, compared to the main analysis of all NSCLC patients.

Chan (2021) reported a systematic review and meta-analysis comparing survival outcomes for surgical resection versus CT-guided percutaneous ablation (RFA and MWA) for stage 1 non-small cell lung cancer (NSCLC).[7] A total of eight studies with 792 patients met inclusion criteria. The difference between groups for one- to five-year overall survival (OS) and cancer-specific survival (CSS) and three- and five-year disease-free survival (DFS) were not statistically significant. However, differences between groups in one- and two-year DFS were statistically significant, favoring sublobar resection (OR 2.22, 95% CI 1.14 to 4.34; OR 2.60, 95% CI 1.21 to 5.57 respectively). According to a subgroup analysis, there was no significant difference in OS between lobectomy and MWA, but one- and two-year OS were significantly better in those treated with sublobar resection (wedge resection or segmentectomy) versus RFA (OR 2.85, 95% CI 1.33 to 6.10; OR 4.54, 95% CI 2.51 to 8.21, respectively).

Nelson (2019) included 12 retrospective observational studies of MWA in patients with primary or metastatic lung tumors.[8] The reviewers did not pool results due to clinical and methodological heterogeneity across the studies. The studies varied with regard to patient characteristics (tumor size, histology, number of treated nodules), outcome measures, and technical experience of surgeons performing the procedures. The primary outcome was local recurrence, and survival outcomes were not assessed. Overall, local recurrence rates ranged

from 9% to 37% across the studies. Newer reports and those that targeted smaller tumors showed more favorable efficacy rates. Results in patients with multiple tumors were not reported separately. Four studies reported results by tumor size; the local recurrence rate for large tumors (> 3 or 4cm depending on the study) were 50%, 75%, 36%, and 26%. In the same four studies, for small tumors (<3 or 3.5 cm depending on the study), local recurrence rates were 19%, 18%, 18%, and 5%, respectively. The most frequent adverse event with MWA was a pneumothorax requiring a chest tube. The reviewers concluded that MWA may be a useful tool in selected patients who are not ideal surgical candidates.

In a meta-analysis of observational studies, Yuan (2019) found higher overall survival for patients who received RFA compared to those who received MWA.[9] However, these estimates were not directly comparable because they came from different sets of studies, and the reviewers concluded that percutaneous RFA and MWA were both effective with a high safety profile. The studies used different patient eligibility criteria (e.g., tumor size, lesion number, age, follow-up). Subgroup analyses by tumor size or tumor number were not possible from the data reported.

Jiang (2018) conducted a network meta-analysis to determine the effectiveness of different ablation techniques in patients with lung tumors.[10] Tumor size, stage of disease, and primary versus metastatic disease were not accounted for in the analysis. For MWA, weighted average overall survival rates were 82.5%, 54.6%, 35.7% 29.6%, and 16.6% at one, two, three, four, and five years, respectively. According to the meta-analysis, RFA and MWA were more effective in decreasing the progression rate of lung malignancies than cryoablation (OR 0.04, 95% CI 0.002 to 0.38, p=0.005 and OR 0.02, 95% CI 0.002 to 0.24, p=0.001, respectively). Major complications were not significantly different between RFA, MWA, and cryoablation (p>0.05).

RANDOMIZED CONTROLLED TRIAL

In a 2017 RCT published by Macchi, 52 patients were randomized into a radiofrequency ablation group or a microwave ablation group.[11] Within each group, the technical and clinical success were measured along with survival and complication rates. The radiofrequency ablation group saw significant reduction in tumor size between 6 and 12 months and the microwave ablation group saw a significant reduction in tumor size from pre-therapy to 12 months including from 6 to 12 months. There was no significant difference in survival between the groups. The authors reported that the microwave ablation group experienced less pain than the radiofrequency ablation group (p=0.0043).

NONRANDOMIZED STUDIES

Hu (2020) reported a retrospective comparison of wedge resection and microwave ablation as a first-line treatment of stage I NSCLC.[12] A total of 223 consecutive patients with T1N0 NSCLC received first-line treatment either using wedge resection (n=155) or MWA (n=68). A propensity matched analysis, which yielded 56 pairs of patients, identified no significant differences in three- or five-year PFS (MWA 54.0% and 36.0%, respectively; wedge resection 66.0% and 56.0%, respectively; p=0.029) or OS (MWA 60.0% and 55.0%; wedge resection 81.0% and 72.0%, respectively; p=0.031). According to a subgroup analysis, local recurrence and PFS for NSCLCs that were contiguous to the pericardium were better in the wedge resection group than in the MWA group (p<0.05).

Das (2020) performed a retrospective analysis to compare the safety and efficacy of cryoablation and MWA for the treatment of NSCLC.[13] Patients who were treated with microwave ablation (n=56) or cryoablation (n=45) for stage IIIB or IV NSCLC were included. The primary endpoint was PFS, which was not significantly different between groups (10 months for cryoablation versus 11 months for MWA; p=0.36). The secondary endpoints were OS (27.5 months for cryoablation versus 18 months for MWA; p=0.07) and adverse events (p>0.05). Dividing the group by tumor size showed that for large tumors (>3 cm; p=0.04), but not for small tumors (≤3 cm; p0.79), the microwave ablation group had significantly longer median PFS.

Aufranc (2019) reported the efficacy and complication rate of cryoablation and MWA for the treatment of primary and secondary lung tumors.[14] The authors performed a retrospective analysis of 115 patients with primary (n=41) or secondary (n=119) lung tumors. Mean overall follow-up was 488 days. Ablation volumes, local recurrence, and mean length of hospital stay were not significantly different between groups at one month (24.1±21.7 cm^3 for RFA and 30.2±35.9 cm^3 for MWA; p=0.195; 6/79 in the radiofrequency group and 3/81 in the MWA group; p=0.049; 4.5±3.7 days for RFA and 4.7±4.6 days for MWA; p=0.76). However, the difference in pneumothoraces between groups was statistically significant (32/79 for radiofrequency and 20/81 for MWA; p=0.049).

In 2016, Vogl evaluated local tumor control, time to tumor progression, and survival rates among patients with lung metastatic colorectal cancer who underwent ablation therapy (N=109) performed using laser-induced thermotherapy (LITT), radiofrequency ablation (RFA), or microwave ablation (MWA).[15] Twenty-one patients underwent LITT (31 ablations), 41 patients underwent RFA (75 ablations), and 47 patients underwent MWA (125 ablations). Local tumor control was achieved in 17 of 25 lesions (68.0%) treated with LITT, 45 of 65 lesions (69.2%) treated with RFA, and 91 of 103 lesions (88.3%) treated with MWA. The progression-free survival rate at one, two, three, and four years was 96.8%, 52.7%, 24.0%, and 19.1%, respectively, for patients who underwent LITT; 77.3%, 50.2%, 30.8%, and 16.4%, respectively, for patients who underwent RFA; and 54.6%, 29.1%, 10.0%, and 1.0%, respectively, for patients who underwent MWA, with no statistically significant difference noted among the three ablation methods.

Other evidence regarding MWA for lung tumors is limited to nonrandomized retrospective studies.[16-32] These studies are all have limitations, including lack of comparison group, small sample size, short-term follow-up. Larger studies with a randomized design are needed to isolate the effect of MWA upon PFS and OS in patients with lung cancer.

PRIMARY RENAL TUMORS

SYSTEMATIC REVIEWS

Wu (2023) published a systematic review and meta-analysis of MWA for the treatment of renal cell carcinoma and larger (T1b) tumors.[33] Among 27 studies and 1584 patients with malignant renal tumors, pooled technical success and efficacy rates were 99.6% (95% confidence interval [CI], 98.0% to 100%) and 96.2% (95% CI, 93.8% to 98.2%), respectively. Local recurrence rate was 3.2% (95% CI, 1.9%-4.7%). At one, three, and five years, overall survival rates were 99.0% (95% CI, 97.5% to 99.9%), 96.0% (95% CI, 93.1% to 98.3%), and 88.1% (95% CI, 80.3% to 94.2%). In 204 patients with T1b tumors, pooled technical success and efficacy rates were 100% (95% CI, 96.6% to 100%) and 85.2% (95% CI, 71.0% to 95.8%). Local recurrence rate was 4.2% (95% CI, 0.9% to 8.9%). At one and three years, overall

survival rates were 94.3% (95% CI, 85.7% to 99.6%) and 89.3% (95% CI, 68.7% to 100%). Review authors concluded that MWA yielded favorable short- to intermediate-term oncologic outcomes with low complication rates.

Uhlig (2019) published a systematic review with meta-analyses to compare partial nephrectomy, radiofrequency ablation, cryoablation and microwave ablation and the effect on oncologic, perioperative and functional outcomes in studies published from 2005 to 2017.[34] Microwave ablation was a treatment in 344 of 24,077 patients and represented in 6 of 47 studies. The review included the single RCT (Guan 2012, described below) which is the only study with results for all three outcomes of interest. No new data was included but the review utilized a network meta-analyses technique. Microwave ablation when compared to partial nephrectomy, the comparator of interest, was reported to have a lower procedural complication rate but higher local recurrence and cancer-specific mortality rates.

In a 2014 systematic review and meta-analysis, Katsanos compared thermal ablation (MWA and RFA) with surgical nephrectomy for small renal tumors (mean size 2.5 cm).[35] Included in the analysis were one randomized study[36] on MWA and five cohort studies on RFA with a total of 587 patients. In the ablation group, the complication rates and renal function decline were significantly lower than in the nephrectomy group (p=0.04 and p=0.03, respectively). The local recurrence rate was 3.6% in both groups (risk ratio=0.92, 95% CI 0.4 to 2.14, p=0.79) and disease-free survival up to five years was not significantly different between groups (hazard ratio=1.04, 95% CI 0.48 to 2.24, p=0.92). The authors indicated additional RCTs were needed to compare MWA to nephrectomy and other ablative techniques.

Martin (2013) reported on a meta-analysis of MWA versus cryoablation for small renal tumors in 2013.[37] Included in the analysis were seven MWA studies (n=164) and 44 cryoablation studies (n=2989). The studies were prospective or retrospective, nonrandomized, noncomparative studies. The mean follow-up duration was shorter for MWA than cryoablation (17.86 months vs 30.22 months, p=0.07). While the mean tumor size was significantly larger in the MWA studies than the cryoablation studies (2.58 cm vs 3.13 cm, respectively, p=0.04), local tumor progression (4.07% vs 2.53%, respectively; p=0.46), and progression to metastatic disease (0.8% vs 0%, respectively; p=0.12) were not significantly different.

RANDOMIZED CONTROLLED TRIALS

In 2012, Guan reported on a prospective randomized study to compare the use of MWA to partial nephrectomy (the gold standard of nephron-sparing surgical resection) for solitary renal tumors less than 4 cm.[36] Forty-eight patients received MWA and 54 had partial nephrectomy. Patients in the MWA group had significantly fewer postoperative complications than the partial nephrectomy group (6 [23.5%] vs. 18 [33.3%]; p=0.0187). MWA patients also had significantly less postoperative renal function declines (p=0.0092) and estimated perioperative blood loss (p=0.0002) than partial nephrectomy patients. At last follow-up, estimated glomerular filtration rate declines in both groups were similar (p=1.0000). Disease-specific deaths did not occur and overall local recurrence-free survival by Kaplan-Meier estimates at three years were 91.3% for MWA and 96.0% for partial nephrectomy (p=0.5414). Studies with longer follow-up are needed in order to assess the benefits of MWA compared to nephrectomy.

NONRANDOMIZED STUDIES

Yu (2022) reported long-term follow-up of 323 consecutive patients with T1N0M0 renal cell carcinoma who underwent MWA.[38] Patients were analyzed by stage. A total of 275 cT1a

patients were followed for a median of 66.0 months (interquartile range [IQR] 58.4 to 73.6). In these patients, 10-year local neoplastic processes, cancer-specific survival, disease-free survival, and overall survival rates were 1.9%, 87.4%, 71.8, and 67.5%, respectively. A total of 48 cT1b patients were followed for a median of 30.4 months (IQR, 17.7 to 44.8). In these patients, five-year local tumor progression, cancer-specific survival, disease-free survival, and overall survival rates were 11.3%, 91.4%, 69.1, and 89.2%, respectively. Major complications were 3.5% in cT1a patients and 6.9% in cT1b patients.

Vanden Berg (2021) reported a case series of 101 patients with renal tumors treated with MWA.[39] All ablation procedures were performed by a single board-certified urologist/interventional radiologist. Median tumor size was 2.0 cm (IQR 1.5 to 2.6). All patients achieved technical success. All patients but one were discharged on the day of the procedure. Two Clavien-Dindo type-I complications, one type-II complication, and one type-III complication were reported. At a median radiographic follow-up of 376.5 days, two tumors had recurred.

John (2020) published a prospective case series of 113 patients treated with MWA for renal cell carcinoma.[40] The median tumor diameter was 25 mm (IQR 20 to 32 mm) and median follow-up was 12 months. One patient (0.9%) had local recurrence, which was treated with re-ablation. Two patients developed metastatic progression, one had a lung nodule at follow-up, and one had a possible local recurrence. Associations were identified between post-procedure complications and total ablation time (OR 1.152/min, 95% CI 1.040 to 1.277) and total ablation energy (OR 1.017/kJ, 95% CI 1.001 to 1.033).

An (2020) published a retrospective review of 114 patients with renal cell carcinoma who were treated with MWA.[41] Patients were divided by tumor location, either central (n=44) or peripheral (n=70). No significant differences were found between locations (17.7% vs. 11.7%, p=0.34) for overall adverse event rate or Grade II or higher adverse event rate (7.8% vs. 2.6%, p = 0.17). There was a statistically significant difference in rate of adjunctive maneuvers of hydrodissection and/or pyeloperfusion (53% for central tumors vs. 29% for peripheral tumors, p=0.006).

Acosta Ruiz (2020) reported the results of another retrospective review of MWA for renal tumors.[42] Ninety-three patients with 105 tumors were treated with CT-guided MWA. The median tumor size was 25 mm. The primary efficacy rate was 92.2%. Periprocedural complications occurred in 5.2% of sessions (four Clavien-Dindo I and one Clavien-Dindo IIIa) and one postprocedural Clavien-Dindo II complication was reported.

Guo (2021) reported a retrospective review of 106 patients with 119 T1a renal cell carcinoma tumors treated with MWA.[43] Complete response was achieved in 95.3% of patients (mean tumor diameter, 2.4 cm; range, 1 to 4 cm). Local tumor progression was observed in six patients at a mean of 20 months post-procedure. Local progression-free survival rates were 100%, 92.8%, and 90.6% at one, two, and three years, respectively. OS rates were 99%, 97.7%, and 94.6% at one, two, and three years respectively. Complications were reported in six patients (5.7%) within 30 days of the procedure, but none of these required intervention.

Aarts (2020) conducted another retrospective review of 100 patients with 108 T1 renal cell carcinomas treated with MWA.[44] The median tumor size in this study was 3.2 cm (interquartile range, 2.4 to 4 cm). Primary efficacy was achieved for 81% (88/108) of lesions overall, but primary efficacy rates were lower among patients with T1b tumors (52%) versus T1a tumors

(89%; p<0.001). Secondary efficacy was achieved for 97% (101/103). Over a median follow-up time of 19 months, local tumor recurrence was observed for 4 (4%) tumors.

Shapiro (2020) compared outcomes in patients with clinical T1b renal cell carcinoma treated with MWA, partial nephrectomy, or radical nephrectomy.[45] A retrospective analysis was completed of 40 MWA, 74 partial nephrectomy, and 211 radical nephrectomy patients. Median follow-up was 34, 35, and 49 months for MWA, partial nephrectomy, and radical nephrectomy, respectively. The decrease in post-treatment estimated glomerular filtration rate was significantly greater in radical nephrectomy patients (29%, p<0.001) than partial nephrectomy (3.2%) or microwave ablation (4.5%). The local recurrence rates were 5%, 1.4%, and 0.5% in the MWA, partial nephrectomy, and radical nephrectomy treatment groups, respectively. The estimated five-year local recurrence-free survival rates were 94.5%, 97.9%, and 99.2% for the MWA, partial nephrectomy, and radical nephrectomy treatment groups, respectively. Although the estimated five-year local recurrence-free survival rate was significantly lower for the MWA group, after a univariable Cox regression, local recurrence was not associated with microwave ablation treatment.

De Cobelli (2019) performed a retrospective evaluation of the comparative safety and effectiveness of cryoablation and MWA for the treatment of T1a renal tumors.[46] T1a renal cancer patients with either a contraindication to surgery or a refusal of surgery were treated at a single center for with either cryoablation (n=44) or MWA (n=28). Median follow-up was 20 and 22 months, for cryoablation and MWA, respectively. Technical success, defined as the absence of arterial enhancement in the ablation zone at the one-month cross-sectional imaging, was not significantly different between groups (92% vs. 94% for cryoablation and MWA, respectively; p=0.8), nor was the occurrence of complications (cryoablation 5/51, MWA 2/32; p=0.57), or disease recurrence (cryoablation 3/47, MWA 1/30; p=0.06). The median procedure time was significantly lower in the MWA group (110 min. and 40 min. for cryoablation and MWA, respectively; p=0.003).

Zhou (2019) compared the outcomes following three ablation techniques for the treatment of T1a biopsy-proven renal cell carcinoma.[47] A total of 297 patients were treated with radiofrequency ablation (n=244), cryoablation (n=26), and MWA (n=27). They were retrospectively assessed for adverse events, treatment efficacy, and therapeutic outcomes. Technical success rates were not significantly different between groups (p=0.33). The authors reported that primary efficacy one month following ablation was more likely following RF ablation and MW ablation than cryoablation. At the two-year follow-up, there were no reports of local recurrence, metastatic progression, or renal cell carcinoma-related deaths in any treatment group. Also at two years, there was also no significant change in estimated glomerular filtration rate compared with baseline (p=0.71).

Additional evidence regarding MWA treatment in patients with primary renal tumors primarily consists of several nonrandomized case studies, all of which are limited by lack of comparison and small sample size.[48-55] In addition, one study was also limited by short-term follow-up.[49]

OTHER TUMORS OR CONDITIONS

Wu (2022) conducted a systematic review and meta-analysis comparing MWA versus conventional surgery for the treatment of papillary thyroid microcarcinoma.[56] There were 13 included studies which were all non-randomized. There was no differences between the 2 groups in recurrence rate or lymph node metastasis; however, the MWA group did have a

shorter operation time, less intra-operative blood loss, shorter postoperative hospital stay, and few complications.

Nonrandomized studies of MWA for other indications are limited by lack of comparison group. Cui (2019) conducted a non-comparative systematic review and meta-analysis of five retrospective studies and two prospective studies in patients with benign thyroid nodules or papillary thyroid microcarcinoma and found that MWA improved nodule volume and symptom scores in these patients.[57] More recent studies also lack control groups or do not compare to standard of care.[58-61]

Examples of other indications include adrenal carcinoma,[62, 63] oligometastases,[64] bone tumors,[65-68] thyroid carcinoma,[69, 70] pancreatic cancer,[71] sinus mucoceles,[72] and other non-oncologic conditions (e.g., bleeding peptic ulcers, esophageal varices, secondary hypersplenism, myomas).

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

National comprehensive cancer network (NCCN) guidelines for non-small cell lung cancer (v4.2023) recommend “image-guided thermal ablation (e.g., cryotherapy, microwave, radiofrequency [as] an option for select patients.”[73] image-guided thermal ablation therapy is considered an option for the management of NSCLC lesions <3 cm as ablation for NSCLC lesions >3 cm has been associated with higher rates of local recurrence and complications.

AMERICAN COLLEGE OF CHEST PHYSICIANS

The American College of Chest Physicians (ACCP) 2013 evidence-based guidelines on the treatment of non-small cell lung cancer note the role of ablative therapies in the treatment of high-risk patients with stage I non-small cell lung cancer (NSCLC) is evolving. However, the ACCP does not recommend MWA for patients with NSCLC.[74]

SUMMARY

Surgical resection is the treatment of choice for primary non-small cell lung cancer (NSCLC) or metastatic tumors in the lung. For those patients who are unable to tolerate surgery, microwave ablation (MWA) may be a treatment option in certain cases. While available studies are limited by study design, accumulating evidence suggests that MWA may be similar to surgery in survival rates, and rates of procedure-related complications and mortality. Therefore, in patients with NSCLC or metastatic tumors in the lung who are ineligible for surgical treatment, MWA may be considered medically necessary when the policy criteria are met.

For patients with tumors that do not meet policy criteria, it appears that microwave ablation (MWA) may improve health outcomes, though more research is needed to know for sure. Therefore, MWA is considered investigational as a treatment of these tumors.

Sacroiliac Joint Fusion

Effective: January 1, 2024

Next Review: June 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

The sacroiliac (SI) joint is a strong weight bearing joint with a self-locking mechanism that provides stability with movement on the left and right side of the sacrum. Similar to other structures in the spine, it is assumed that the SI joint may be a source of low back pain but there are currently no reference standards for diagnosis. If conservative therapies fail to adequately treat symptoms, SI joint fusion may be used to stabilize the SI joint including open, percutaneous, and minimally invasive techniques.

MEDICAL POLICY CRITERIA

I. Sacroiliac joint fusion performed by an open procedure may be considered **medically necessary** when one of the following criteria is met:

   A. As an adjunct to sacrectomy or partial sacrectomy related to tumors involving the sacrum; or

   B. As an adjunct to the medical treatment of sacroiliac joint infection (e.g., osteomyelitis, pyogenic sacroiliitis)/sepsis; or

   C. As a treatment for severe traumatic injuries associated with pelvic ring fracture.

II. Sacroiliac joint fusion performed by an open procedure, for any other indication not listed above in Criterion I. is considered **not medically necessary**.

III. Minimally invasive fusion/stabilization of the sacroiliac joint may be considered **medically necessary** when ALL of the following criteria have been met:

A. Request is for a titanium triangular implant; and

B. Request is for an FDA-approved device; and

C. Clinical documentation that pain limits activities of daily living (ADL). ADLs are defined as feeding, bathing, dressing, grooming, meal preparation, household chores, and occupational tasks that are required for daily functioning; and

D. Patients have undergone and failed a minimum 6 months of intensive physician-directed non-operative treatment that must include medication optimization, activity modification, and active therapeutic exercise targeted at the lumbar spine, pelvis, sacroiliac joint, and hip; and

E. There is at least 75% reduction of pain following an image-guided, contrast-enhanced intra-articular sacroiliac joint injection on 2 separate occasions; and

F. A trial of a therapeutic sacroiliac joint injection (i.e., corticosteroid injection) has been performed on at least one occasion (see Policy Guidelines); and

G. A thorough physical examination demonstrates findings consistent with sacroiliac joint disease including a positive response to a cluster of three provocative tests (e.g., thigh thrust test, compression test, Gaenslen's test, distraction test, Patrick's sign, posterior provocation test); and

H. Diagnostic imaging studies include ALL of the following:

1. Imaging of the sacroiliac joint indicates evidence of injury and/or degeneration; and

2. Imaging of the sacroiliac joint excludes the presence of destructive lesions (e.g., tumor, infection) or inflammatory arthropathy of the sacroiliac joint and rules out concomitant hip pathology; and

3. Advanced imaging of the lumbar spine (CT or MRI) is performed to rule out neural compression or other degenerative conditions that can be causing low back or buttock pain and excludes the presence of destructive lesions or inflammatory arthropathy of the sacroiliac joint.

IV. Minimally invasive fusion/stabilization of the sacroiliac joint for the treatment of back pain presumed to originate from the sacroiliac joint is considered **investigational** in all other scenarios including but not limited to when Criterion III is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

A successful trial of controlled diagnostic SI joint or lateral branch blocks consists of two separate positive blocks on different days with local anesthetic only (no steroids or other drugs), or a placebo-controlled series of blocks, under fluoroscopic guidance, that has resulted in a reduction in pain for the duration of the local anesthetic used (e.g., three hours longer with bupivacaine than lidocaine). There is no consensus on whether a minimum of 50% or 75% reduction in pain would be required to be considered a successful diagnostic block, although

evidence supports a criterion standard of 75% to 100% reduction in pain with dual blocks. No therapeutic intra-articular injections (i.e., steroids, saline, other substances) should be administered for a period of at least four weeks before the diagnostic block. The diagnostic blocks should not be conducted under intravenous sedation unless specifically indicated (e.g., the patient is unable to cooperate with the procedure).

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Current Symptomology including indication for procedure (diagnostic or treatment of specific condition) and whether procedure will be open or minimally invasive
- Documentation of specific conservative pain management including length of time utilized including rheumatologic evaluation when indicated
- Documentation of diagnostic blocks including agents used, duration of action and if completed under imaging guidance
- If request is for minimally invasive fusion/stabilization with a titanium triangular implant provide the following; documentation of specifically how pain limits ADLs, failure of minimum of six months of specific nonoperative therapy attempted, percentage of pain reduction achieved using the specific image guided injections listed above on two separate occasions, trial of injection has been performed at least once, absence of generalized pain behavior/disorders, documentation of location of pain on spine/joint, documentation per physical exam of location of pain including tenderness, positive response to at least three provocative tests and diagnostic imaging studies/reports completed.
- Documentation of specific device being utilized if applicable

2. Lumbar Spinal Fusion, Surgery Policy No. 187

BACKGROUND

The sacroiliac (SI) joint is a joint between the sacrum and ilium of the pelvis. The SI joint is a strong weight bearing joint with a self-locking mechanism that provides stability with movement on the left and right side of the sacrum. Similar to other structures in the spine, it is assumed that the SI joint may be a source of low back pain.

Currently, there are no reference standards for the diagnosis of SI joint pain. SI joint pain is typically without any consistent, demonstrable radiographic or laboratory features and most commonly exists in the setting of morphologically normal joints. Clinical tests for SI joint pain may include various movement tests, palpation to detect tenderness, and pain descriptions by the patient. Research into sacroiliac joint pain has been inhibited by the lack of any criterion standard to measure its prevalence and against which various clinical examinations can be validated. Further confounding study of the SI joint is that multiple structures, such as posterior facet joints and lumbar discs, may refer pain to the area surrounding the SI joint.

There are many methods for the treatment of chronic SI joint pain including nonsurgical and surgical approaches. Conservative management may include nonsteroidal anti-inflammatory medications, prescription analgesics, spinal manipulation, physical therapy, a home exercise program, and evaluation and management of cognitive, psychological, or behavioral issues.

If conservative therapies fail to adequately treat symptoms, SI joint fusion may be used to stabilize the SI joint. Surgical approaches include open, percutaneous, and minimally invasive techniques. The open surgery technique involves the iliac crest bone and the sacrum being held together with plates and/or screws until fusion occurs between the two bones. The use of minimally invasive techniques to fuse the SI joint has increased over the last several years. Minimally invasive procedures use specially designed implants for the stabilization of the SI joint.

Some procedures have been referred to as SIJ fusion but may be more appropriately called fixation (this is because there is little to no bridging bone on radiographs). Devices for SIJ fixation/fusion that promote bone ingrowth to fixate the implants include a triangular implant (iFuse Implant System) and cylindrical threaded devices (Rialto, SImmetry, Silex, SambaScrew, SI-LOK). Some devices also have a slot in the middle where autologous or allogeneic bone can be inserted. This added bone is intended to promote fusion of the SIJ.

REGULATORY STATUS

Several percutaneous or minimally invasive fixation/fusion devices have received marketing clearance by the Food and Drug Administration. These include the Rialto™ SI Joint Fusion System (Medtronic), SIJ-Fuse (Spine Frontier), IFUSE® Implant System and iFuse-3D (SI Bone), SImmetry® Sacroiliac Joint Fusion System (Zyga Technologies), Silex™ Sacroiliac Joint Fusion System (XTANT Medical), SambaScrew® and FIREBIRD SI Fusion System (Orthofix), SImpact Sacroiliac Joint Fixation System (Life Spine), and the SI-LOK® Sacroiliac Joint Fixation System (Globus Medical). FDA Product Code: OUR.

Note: This policy does not address percutaneous sacroplasty which is addressed in the *Percutaneous Vertebroplasty and Kyphoplasty* policy (SUR107).

EVIDENCE SUMMARY

SI joint fusion performed by open procedure is considered standard of care to stabilize the sacroiliac joint due to trauma, infection, and tumors involving the sacrum. Therefore, the focus of the literature review is on the use of diagnostic blocks for the diagnosis of SI joint pain and the use of percutaneous or minimally invasive fusion techniques.

Due to the volume of published literature regarding minimally invasive sacroiliac joint fusion with varying study design and quality, the following is a summary of key references published to date. It is important to note that many of the systematic reviews include similar studies in addition to those studies being summarized below.

DIAGNOSTIC BLOCKS

The use of diagnostic blocks to evaluate SI joint pain builds on the experience of diagnostic block use in other joints to evaluate pain. Blinded studies with placebo controls (although difficult to conduct when dealing with invasive procedures) are ideally required for scientific validation of sacroiliac joint blocks, particularly when dealing with pain relief well-known to respond to placebo controls. In the typical evaluation of a diagnostic test, the results of SI

diagnostic block would then be compared with a criterion standard. However, there is no current criterion standard for SI joint injection. A search for systematic reviews, randomized controlled trials, and comparative studies on diagnostic blocks was conducted and is summarized below.

Systematic Reviews

In 2013, the American Society of Interventional Pain Physicians published an updated evidence review with guidelines on diagnosis of SIJ pain.[1] Various studies evaluating diagnostic blocks were reviewed in which the criteria for a positive test varied from 50% to 100% relief from either single or dual blocks. The most stringent criterion, 75% to 100% relief with dual blocks, was evaluated in seven studies. The prevalence of a positive test in the seven studies ranged from 10% to 44.4% in patients with suspected sacroiliac disease. The evidence for diagnostic sacroiliac intra-articular injections was considered to be good using 75% to 100% pain relief with single or dual blocks as the criterion standard.

A 2012 systematic review[2] evaluated the accuracy of diagnostic sacroiliac joint interventions. The methodological quality of the studies was evaluated and only the studies meeting at least 50% of the applicable appraisal inclusion criteria were included. A total of 17 studies met inclusion criteria with a range of diagnostic interventions and relief cutoff thresholds. Only one placebo-controlled study was identified with methodological limitations. The review concluded that there is good evidence for the use of controlled diagnostic local anesthetic blocks. Uncontrolled blocks had a false positive rate of approximately 20%. Overall, the systematic review concluded, based on what the authors determined to be good evidence, “there was no significant difference when 70% or greater relief is utilized as the criterion standard with dual blocks.” In addition, the systematic review concluded that “there is no evidence to support the use of ultrasound or landmark-guided injections for sacroiliac joint pain. These injections must be performed under fluoroscopic or radiologic guidance.” Limitations of this systematic review include the lack of high quality evidence, significant variation in interventions, and discrepancies in a gold standard to measure against.

A systematic review was commissioned by the American Pain Society and conducted by the Oregon Evidence-based Practice Center in 2009.[3] The systematic review concluded that no studies were identified that evaluated validity or utility of diagnostic sacroiliac joint block as a diagnostic procedure for low back pain with or without radiculopathy.

Randomized Controlled Trials

No RCTs identified after the above SRs were published.

Section Summary

Although there is no independent reference standard for the diagnosis of SIJ pain, SIJ blocks are considered the reference standard for the condition. The utility of this test ultimately depends on its ability to identify patients who benefit from treatment. Sacroiliac Joint Fusion

SACROILIAC JOINT FUSION

Systematic Reviews

Lingutla (2016) published a systematic review with meta-analysis evaluating SI joint fusion for low back pain where it has been determined that the cause of the pain is originating from the

sacroiliac joint and not the lumbar spine.[4] Six nonrandomized studies were included with a mean follow-up of 17.6 months. The authors concluded that all outcome measures showed a statistical improvement for alleviating pelvic girdle pain. However, the review consisted of nonrandomized studies with some methodological limitations. More research is needed for this patient population.

Zaidi (2015) conducted a systematic review of the evidence evaluating SI joint fusion interventions for treating SI joint pain or dysfunction.[5] A comprehensive literature search was conducted and the authors included five case series, eight retrospective studies, and three prospective studies with at least two patients (N=430). The mean duration of follow-up was 60 months with the most common pathology being SI joint degeneration/arthrosis followed by SI joint dysfunction, postpartum instability among other less common pathologies. Study participants reported satisfaction after the procedures which varied widely. The rates of reoperation for open surgery were 5% to 65% (mean 15%) and for minimally invasive 0% to 17% (mean 6%). Major complications ranged from 5% to 20% with one study reporting a 56% adverse event rate. The authors concluded that surgical intervention is beneficial for a subset of patients and that serious consideration of alternatives should be considered prior to surgery.

A 2012 systematic review found that the quality of evidence for surgical treatment (débridement, fusion) compared to injection treatment (corticosteroid, botulinum toxin, prolotherapy) for chronic sacroiliac pain was very low.[6] No studies were identified that directly compared surgery to injection therapy. Seven case series using a range of surgical techniques that evaluated a range of surgical treatments were included and summarized. The literature was considered heterogeneous and insufficient to evaluate the comparative effectiveness of surgical treatments compared to other treatments. Several surgical studies reported complications including but not limited to infections, nonunion, further surgery, and intraoperative fracture. Studies had small sample sizes and provided little information on determining successful fusion.

In 2010, Ashman[7] conducted a systematic review comparing fusion to denervation for chronic SI joint pain. Six case series on fusion were identified that evaluated a single treatment. As a result, no conclusions could be drawn for the comparative efficacy of the treatments.

Randomized Controlled Trials

No RCTs identified after the above SRs were published.

SIJ FUSION/FIXATION WITH A TRIANGULAR IMPLANT SYSTEM

Systematic Reviews

Chang (2022) published a systematic review of forty studies evaluating the use of minimally invasive SI joint fusion.[8] Minimally invasive SI joint fusion with the iFuse Implant System appeared to result in larger improvements in pain (two RCTs: MD for VAS -40.5 mm, 95% CI, -50.1 to -30.9; -38.1 mm, p<.0001) and larger improvements in physical function (mean difference in Oswestry Disability Index -25.4 points, 95% CI, -32.5 to -18.3; -19.8 points, p<.0001) compared to conservative management at six months. Improvements in pain and physical function for the RCTs appeared durable at one and two years of follow-up. Findings were similar in one CCS. The two RCTs also found significant improvements in QOL at six months and one year. AEs appeared higher in the fusion group at six months. The incidence of revision surgery varied by study; the highest was 3.8% at two years. Two CCSs compared the

effectiveness of alternative minimally invasive fusion procedures. One CCS compared iFuse to the Rialto SI Fusion System and reported no differences in pain, function, QOL, and revision surgeries from six months to one year. One CCS compared iFuse to percutaneous screw fixation and reported significantly fewer revisions among iFuse participants (mean difference -61.0%, 95% CI, -78.4% to -43.5%).

Hermans (2022) published a systematic review comparing minimally invasive joint fusion using titanium implants to conservative management in patients with SI joint dysfunction.[9] Three studies that included 388 patients were part of the review. The results from the pooled analysis showed that the fusion patients showed greater reduction in visual analog pain score and ODI outcomes compared to the ones who received conservative management. Adverse events reported across the studies were similar for both groups. The results of the study indicate that minimally invasive joint fusion is more effective than conservative management in patients with SIJ dysfunction.

Abbas (2022) published a systematic review evaluating the efficacy of SIJ fusion for low back pain caused by SIJ pathology.[10] Six studies were included with a total of 564 patients who received either SIJ fusion or conservative management. The results showed that the SIJ fusion patients had greater reductions in VAS and ODI outcomes compared to those receiving conservative management.

Tran (2019) published a systematic review comparing the effectiveness of minimally invasive joint fusion (e.g. utilizing the iFuse device) compared to screw-type surgeries. A total of twenty studies was pooled to calculate a standardized mean difference across pain, disability, and global/quality-of-life outcomes, including 14 studies evaluation the iFuse system and 7 studies evaluated cylindrical, threaded implants. Studies evaluating cylindrical threaded implants consisted of case series and cohort studies. Patients receiving these implants experienced significantly worse pain outcomes (p=0.03) compared to patients receiving iFuse, with a standardized mean difference of 1.28 and 2.04, respectively. A statistically significant difference in disability scores was reported between screw-type and iFuse implant groups (0.26 vs 1.68), with improved outcomes in the iFuse population. For global/quality-of-life outcomes, a statistically significant difference in scores was reported between screw-type and iFuse implants groups (0.60 vs 0.99 with improved outcomes in the iFuse population.

Heiney (2015) evaluated clinical outcomes and operative measures of minimally invasive sacroiliac joint fusion utilizing a lateral transarticular technique.[11] A total of 12 studies, including those for triangular implants were included. The authors concluded, for this particular technique, patients reported improvements in pain, disability, and quality of life scores.

Randomized Controlled Trials

Whang (2015) reported an industry-sponsored nonblinded RCT of the iFuse Implant System in 148 patients.[12] Twelve-month follow-up to this RCT was reported by Polly et al in 2015.[13] However, by 12 months, almost all patients in the control group had crossed over to SI JOINT fusion. Two-year follow-up of this trial was reported by Polly et al in 2016.[14] This last publication will be discussed in the case series section of this report. Trial inclusion was based on a determination of the SI JOINT as a pain generator from a combination of a history of SI JOINT-localized pain, positive provocative testing on at least three of five established physical tests, and at least a 50% decrease in SI JOINT pain after image-guided local anesthetic injection into the SI JOINT. The duration of pain before enrollment averaged 6.4 years (range,

0.47-40.7 years). A large proportion of subjects (37%) had previously undergone lumbar fusion, steroid SI JOINT infections (86%), and RFA (16%).

Patients were assigned 2:1 to minimally invasive SI joint fusion (n=102) or to nonsurgical management (n=46). Nonsurgical management included a stepwise progression of nonsurgical treatments, depending on individual patient choice. During follow-up, control patients received physical therapy (97.8%), intra-articular steroid injections (73.9%), and RFA of sacral nerve roots (45.7%). The primary outcome measure was six-month success rate, defined as the proportion of treated subjects with a 20-mm improvement in SI JOINT pain in the absence of severe device-related or neurologic adverse events or surgical revision. Patients in the control arm could crossover to surgery after six months. Baseline scores indicated that the patients were severely disabled, with VAS pain scores averaging 82.3 out of 100 and ODI scores averaging 61.9 out of 100 (0=no disability, 100=maximum disability).

At six months, success rates were 23.9% in the control group versus 81.4% in the surgical group (posterior probability of superiority >0.999). A clinically important (≥15-point) improvement in ODI score was found in 27.3% of controls compared with 75.0% of fusion patients. Measures of QOL (36-Item Short-Form Health Survey, EuroQol-5D) also improved to a greater extent in the surgery group. Of the 44 nonsurgical management patients still participating at six months, 35 (79.5%) crossed over to fusion. Compared to baseline, opioid use at six months decreased from 67.6% to 58% in the surgery group, and increased from 63% to 70.5% in the control group (p=0.082). At 12 months, opioid use was similar between groups (55% vs 52%, p=0.61). Although these results generally favored fusion, the trial is limited due to the high number of patients that crossed over from the control group to the fusion group. This limits the comparative long-term conclusions that can be drawn.

Sturesson (2016) reported another industry-sponsored nonblinded RCT of the iFuse Implant System in 103 patients.[15] Selection criteria were similar to those of the Whang trial, including at least 50% pain reduction on SI JOINT block. Mean pain duration was 4.5 years. Thirty-three percent of patients had undergone prior lumbar fusion. Nonsurgical management included physical therapy and exercises at least twice per week; interventional procedures (eg, steroid injections, RFA) were not allowed. The primary outcome was change in VAS pain score at six months.

Of 109 randomized subjects, six withdrew before treatment. All patient assigned to iFuse underwent the procedure, and follow-up at six months was in 49 of 51 patients in the control group and in all 52 patients in the iFuse group. At six months, VAS pain scores improved by 43.3 points in the iFuse group and by 5.7 points in the control group (p<0.001). ODI scores improved by 25.5 points in the iFuse group and by 5.8 points in the control group (p<0.001, between groups). QOL outcomes showed a greater improvement in the iFuse group than in the control group. Changes in pain medication use are not reported. Although these results favored fusion, with magnitudes of effect in a range similar to the Whang RCT, this trial was also not blinded and lacked a sham control. Outcomes were only assessed to six months. Six-month results for the Whang and Sturesson trials are shown in Table 1.

Table 1. Summary of 6-Month iFuse Results From Whang et al[12] and Sturesson et al[15]

Results	VAS Score		Success End Point		ODI Score		SF 36 PCS Score		EQ 5D TTO Index	
	Ctl	iFuse	Ctl	iFuse	Ctl	iFuse	Ctl	iFuse	Ctl	iFuse
Whang et al (2015)										
Baseline	82.2	82.3			61.1	62.2	30.8	30.2	0.47	0.44

Results	VAS Score		Success End Point		ODI Score		SF 36 PCS Score		EQ 5D TTO Index	
Follow-up	70.4	29.8	23.9%	81.4%[a]	56.4	31.9	32.0	42.8	0.52	0.72
Change	-12.1	-52.6[a]			-4.9	-30.3[a]	1.2	12.7	0.05	0.29
Sturesson et al (2016)										
Baseline	73.0	77.7								
Follow-up	67.8	34.4								
Change	-5.7	-43.3			-5.8	-25.5			0.11	0.37

The success end point was defined as a reduction in pain VAS score of ≥20, absence of device-related events, absence of neurologic worsening, and absence of surgical intervention.
Ctl: control; EQ-5D TTO: EuroQoL Time Tradeoff Index; ODI: Oswestry Disability Index; SF-36 PCS: 36-Item Short-Form Health Survey Physical Component Summary; VAS: visual analog scale.
[a] p<0.001.

Nonrandomized Studies

The Long Term Outcomes from INSITE and SIFI (LOIS) trial was a prospective single-arm study that enrolled patients who had participated in two of the studies described above for evaluation at three, four, and five years.[16] The primary success outcome, a reduction in VAS of at least 20 points in the absence of a serious device-related adverse event, neurologic worsening, or surgical revision, was obtained in 81.7% of patients at five years. The improvements in other clinical outcomes were maintained out to 5 years. Opioid use decreased over time, although the contribution of the opioid use agreement cannot be determined. Fifteen percent of patients were no working due to back pain. Radiolucencies suggesting implant failure were observed in 5% of cases and were associated with incorrect placement. Bridging bone was observed in 45% of sides at 12 months, 71% at 24 months, and 88% at 60 months.

The Study of Bone Growth in the Sacroiliac Joint after Minimally Invasive Surgery with Titanium Implants (SALLY) is a 5 year multicenter study that will assess non-inferiority of outcomes with a 3-D printed triangular implant as compared to the traditionally manufactured titanium coated implant.[17] Twelve month follow-up has been published for 46 of the 51 patients enrolled. The 6-month change in ODI met the non-inferiority margin, and secondary outcomes of pain, disability, and QOL were similar to those obtained in the INSITE, iMIA, and SIFI trials. Independent radiographic analysis showed bridging bone in 70% and 77% of sides imaged at 6 and 12 months, respectively, compared to 45% bridging bone in prior studies with the solid titanium coated implants. No breakage, migration, or subsidence was detected. However, there was no evidence that the increase in bridging bone led to an improvement in pain or functional outcomes compared to the milled implant at 12 months.

Two retrospective nonrandomized comparative studies were published in 2017. Vanaclocha (2017) found greater pain relief with SIJ fusion than with conservative management or SIJ denervation. [18] Spain and Holt (2017) reported a retrospective review of surgical revision rates following SIJ fixation with either surgical screws or the iFuse triangular implant. [19]Revision rates were lower with the iFuse device than observed with surgical screws.

Twelve-month results from the iMIA trial were reported by Dengler (2017).[20] Twenty-one patients in the conservative management group had little or no improvement in symptoms and crossed over to SIJ fusion after the 6-month visit. Fourteen (56%) of the 25 patients who remained in the conservative management group had at least a 20-point improvement in VAS back pain score (22.4% of patients assigned to conservative management). At 12 months, low back pain had improved by 42 points (SD=27.0) on a 100-point VAS in the SIJ fusion group compared with 14 (SD=33.4) points in the conservative management group (p<0.001). The

authors noted that there were methodological limitations including lack of blinding and subjective assessments of outcomes.

At 24 months back pain had improved by 45 points compared to 11 points in the control group, with 79% (37 of 47) of SIJ fusion patients achieving at least a 20 point improvement compared to 24% (11 of 46) of controls.[21] At 24 months there was an improvement of 26 points in ODI compared to 8 points in controls (p<0.001). Improvement of at least 20 points was observed in 64% of SIJ fusion group compared to 24% of the conservative management group.

Table 2. Extended Follow-Up From the INSITE and iMIA Trials

Outcome Measures	Baseline	6 Months (SD)	12 Months (SD)	24 Months (SD)
INSITE[22]				
Sacroiliac joint fusion pain score	82.3	29.8		26.7
Percent ≥20-point improvement pain				
Sacroiliac joint fusion ODI score	57.2	31.9		28.7
iMIA[20]				
Conservative management	73.0 (13.8)	67.8 (20.3)	58.9 (28.2)	
Leg pain				
Sacroiliac joint fusion	52.7 (31.5)	22.6 (25.1)	24.0 (27.8)	
Conservative management	55.6 (13.7)	50.2 (17.2)	46.9 (20.8)	
	57.5 (14.4)	32.0 (18.4)	32.1 (19.9)

Case Series With Good Reported Follow-Up Rates

Case series with good follow-up rates are more likely to provide valid estimates of outcomes. Principal results of the studies at 2- to 3-year follow-up are shown in Table 3.

Polly (2016) reported two-year outcomes from the RCT of SI JOINT fusion.[14] When reported, without an untreated control group, the study was a case series. Of 102 subjects originally assigned to SI JOINT fusion and treated, 89 (87%) were evaluated at two years. Although the clinical trial used a different composite end point, in this report, clinical outcomes were based on the amount of improvement in SI JOINT pain and in ODI scores. Improvement was defined as a change of 20 points in SI JOINT pain score and 15 points in ODI score. Substantial improvement was defined as a change in in 25 points in SI JOINT pain score or a score of 35 or less and an improvement of 18.8 points in ODI score. At 24 months, 83.1% and 82% had improvement and substantial improvement in SI JOINT pain score, and 68.2% and 65.9% had improvement and substantial improvement in ODI. By 24 months, the proportion taking opioids was reduced from 68.6% at baseline to 48.3%.

Results from a case series of 172 patients undergoing SI JOINT fusion reported to two years were published by Duhon (2016).[23, 24] Patients were formally enrolled in a single-arm trial (NCT01640353) with planned follow-up for 24 months. Success was defined as a reduction of VAS pain score of 20 mm (out of 100 mm), absence of device-related adverse events, absence of neurologic worsening, and absence of surgical reintervention. Enrolled patients had a mean VAS pain score of 79.8, a mean ODI score of 55.2, and had a mean pain duration of 5.1 years. At six months, 136 (80.5%) of 169 patients met the success end point, which met

the prespecified Bayesian probability of success rate. Mean VAS pain scores were 30.0 at six months and 30.4 at 12 months. Mean ODI scores were 32.5 at six months and 31.4 at 12 months. At two years, 149 (87%) of 172 patients were available for follow-up. VAS pain score at two years was 26.0 and ODI score was 30.9. Thus, 1-year outcomes were maintained at two years. Other outcomes (eg, QOL scores) showed similar maintenance or slight improvement compared to 1-year outcomes. Use of opioid analgesics decreased from 76.2% at baseline to 55% at two years. Over the 2-year follow-up, 8 (4.7%) patients required revision surgery.

Rudolph and Capobianco (2014) described 5-year follow-up for 17 of 21 consecutive patients treated at their institution between 2007 and 2009.[25] Of the four patients lost to follow-up, two had died and one had become quadriplegic due to severe neck trauma. For the remaining patients, mean VAS score (range, 0-10) improved from 8.3 before surgery to 2.4 at five years; 88.2% of patients had substantial clinical benefit, which was defined as a 2.5-point decrease in VAS score or a raw score less than 3.5. Mean ODI score at five years was 21.5. Imaging by radiograph and computed tomography showed intra-articular bridging in 87% of patients with no evidence of implant loosening or migration.

Rudolf (2012) retrospectively analyzed his first 50 consecutive patients treated with the iFuse Implant System.[26] There were 10 perioperative complications, including implant penetration into the sacral neural foramen (two patients) and compression of the L5 nerve (1 patient); these three patients required surgical retraction of the implant. At three years postsurgery, 1 patient required additional implants due to worsening symptoms. At a minimum of 24 months of follow-up (mean, 40 months), the treating surgeon was able to contact 45 patients. The mean pain score was two (1 to 10 scale), and 82% of patients had attained the minimal clinically important difference in pain score (defined as ≥ 2 of 10).

Case Series With Unknown Follow-Up Rates

The following case series did not report follow-up rates or study methodologies did not permit calculation of the complete number of patients treated.

Smith (2013) retrospectively compared open with minimally invasive SI JOINT fusion. Because all patients received fusion, this study should be interpreted as a case series, with attention paid to the minimally invasive fusion group.[27] Only patients with medical records documenting 12- or 24-month pain scales were included, resulting in 114 patients selected for the minimally invasive group. Losses to follow-up could not be determined. At 12 months, VAS pain scores decreased to a mean of 2.3 from a baseline of 8.1. At 24 months, mean VAS pain score was 1.7, but data for only 38 patients were analyzed. These improvements in VAS pain score were greater than those for open fusion, but conclusions of comparative efficacy should not be made given this type of study. Implant repositioning was performed in 3.5% of patients in the minimally invasive group.

A large (N=144) industry-sponsored, multicenter retrospective series was reported by Sachs et al in 2014.[28] Consecutive patients from 6 sites were included if preoperative and 12-month follow-up data were available. No information was provided on the total number of patients treated during the same time interval. Mean baseline pain score was 8.6. At a mean 16-month follow-up, VAS score was 2.7 (/10), an improvement of 6.1. Ten percent of patients reported an improvement of 1 point or less. Substantial clinical benefit, defined as a decrease in pain score by more than 2.5 points or a score of 3.5 or less, was reported in 91.9% of patients.

Sachs (2016) reported outcomes of 107 patients with a minimum follow-up of 3 years.[29] The number of potentially eligible patients was not reported, so the follow-up rate is unknown. Pain scores improved from a mean of 7.5 at baseline to 2.5 at a mean follow-up time of 3.7 years. ODI score at follow-up was 28.2, indicating moderate residual disability. Overall satisfaction rate was 87.9% (67.3% very satisfied, 20.6% somewhat satisfied). Revision surgery was reported in five (4.7%) patients. Without knowing the number of eligible patients, the validity of this study cannot be determined.

Table 3. Two- to 3-Year Outcomes of the iFuse Implant in Cohorts and Case Series

Studies and Outcomes	Mean Baseline Value	Mean 2- to 3-Year Value	Difference or % Achieving Outcome	Follow-Up Rate
Pain score (range, 0-10)	7.59	2.0	5.59	90% (45/50)
Duhon et al (2016)[23]				
	79.8		53.3	
Oswestry Disability Index score	55.2	30.9	24.5	
		40.7	8.9	
EQ-5D TTO score	0.43	0.71	0.27	
Pain score (range 0-10)	7.5	2.5		
		28.2		

All differences between baseline and 2- to 3-year values were statistically significant.
EQ-5D TTO Index: EuroQoL Time Tradeoff Index; SF-36: 36-Item Short-Form Health Survey.

Database Analysis

Schoell (2016) analyzed postoperative complications tracked in an administrative database of minimally invasive SIJ fusions to determine complications coded in postoperative claims. Using the Humana insurance database, patients with complications were identified using ICD-9 codes corresponding to a surgical complication within 90 days or 6 months if the codes were used for the first time. Of 469 patients, the overall incidence of complications was 13.2% at 90 days and 16.4% at 6 months. For specific complications, the infection rate was 3.6% at 90 days and the rate of complications classified as nervous system complications was 4.3%. Authors noted that the infection rate observed was consistent with the infection rates reported by Polly et al (2015), 20 but much higher than those reported for other types of minimally invasive spine procedures. The incidence of complications in this study may differ from those reported by registries. However, determining the true incidence of adverse events after procedures from either registries or insurance claims data can be difficult due to uncertainty about the completeness of reporting in registries and the accuracy of coded claims in claims databases.

Cher (2015) reported rates of implant revision using the Humana insurance database of procedures.[30] Between April 2009 and July 2014, 11,416 cases with the iFuse system took place. After minor adjustments of numbers to account for non-recommended uses and inability to match revision cases, the cumulative revision rate at 4 years was 3.54%. Overall, 24% of revision surgeries occurred in the first month and 63% occurred within the first 12 months. One-year revision rates fell over time (9.7% to 1.4% from 2009 to 2014).

Adverse Events

From 9/1/2016 to 12/8/2017 a total of 47 MAUDE database injury reports were identified

(product code OUR). Many reports were for revisions needed and/or user error/wrong placement e.g. too deep, wrong size device, with a few noting infection or hematoma.

From January 2010 through August 2016, a total of 438 MAUDE database injury reports were identified (product code OUR): 355 mentioned revision, 188 malposition, 32 radicular pain, 24 impingement or impingement, and 14 infection.

Summary

For individuals who SIJ pain who receive SIJ fusion/fixation with a triangular implant, the evidence includes two non-blinded RCTs of minimally invasive fusion and 2 case series with more than 85% follow-up at 2 to 3 years. Relevant outcomes are symptoms, functional outcomes, quality of life, medication use, and treatment-related morbidity. Both RCTs reported superior short-term results for fusion, however, a preferable design for assessing pain outcomes would be independent, blinded assessment of outcomes or, when feasible, a sham-controlled trial. Longer term follow-up from these RCTs indicated that the results obtained at six months persist to two years. Two additional cohort studies or case series, with sample sizes ranging from 45 to 149 patients and low dropout rates (<15%), have also shown reductions in pain and disability at two years. One small case series showed outcomes that persisted to five years. The cohort studies and case series are consistent with the durability of treatment benefit. Analysis of an insurance database reported an overall incidence of complications to be 16.4% at six months and cumulative revision rate at four years of 3.54%. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

SIJ FUSION/FIXATION WITH A CYLINDRICAL THREADED IMPLANT

Systematic Reviews

No systematic reviews identified for SIJ Fusion/Fixation with a Cylindrical Threaded Implant that are not already addressed.

Randomized Controlled Trials

Rappoport (2017) reported on an industry-sponsored prospective study of SIJ fusion with a cylindrical threaded implant (SI-LOK).[31] The study included 32 patients with a diagnosis of SIJ dysfunction who had failed nonoperative treatment, including medication, physical therapy, and therapeutic injections. A diagnostic injection was performed to confirm the source of pain to the SIJ. The procedure included drilling to prepare for screw insertion and implantation of three screws, at least one of which was slotted. The slotted screws were packed with autogenous bone graft from the drill reamings. Pain and disability scores were reduced following device implantation, and revisions within the first 12 months of the study were low (n=2). Follow-up will continue through two years

Table 4. Pain and Disability Scores After Implantation With a Cylindrical Threaded Implant

Outcome Measures	Baseline	3 Months (SD)	6 Months (SD)	12 Months (SD)	p
Low back pain	55.8 (26.7)	28.5 (21.6)	31.6 (26.9)	32.7 (27.4)	<0.01
Left leg pain	40.6 (29.5)	19.5 (22.9)	16.4 (25.6)	12.5 (23.3)	<0.01
Right leg pain	40.0 (34.1)	18.1 (26.3)	20.6 (25.4)	14.4 (21.1)	<0.05
Oswestry Disability Index	55.6 (16.1)	33.3 (16.8)	33.0 (16.8)	34.6 (19.4)	<0.01

Adapted from Rappoport et al (2017).[31]

Summary

There is limited evidence on fusion of the SIJ with devices other than the triangular implant. One-year results from a prospective cohort of 32 patients who received a cylindrical slotted implant showed reductions in pain and disability similar to results obtained for the triangular implant. However, there is uncertainty in the health benefit of SIJ fusion/fixation with this implant design. Therefore, controlled studies with a larger number of patients and longer follow-up are needed to evaluate this device.

PRACTICE GUIDELINE SUMMARY

NORTH AMERICAN SPINE SOCIETY

The North American Spine Society (NASS) published coverage recommendations for percutaneous sacroiliac joint fusion in 2015.[32] NASS indicated that there was relatively moderate evidence. In the absence of high-level data, policies reflect the multidisciplinary experience and expertise of the committee members in order to present reasonable standard practice indications in the United States. NASS recommended coverage when all of the following criteria are met:

1. "[Patients] have undergone and failed a minimum 6 months of intensive nonoperative treatment that must include medication optimization, activity modification, bracing and active therapeutic exercise targeted at the lumbar spine, pelvis, SI JOINT and hip including a home exercise program.
2. Patient's report of typically unilateral pain that is caudal to the lumbar spine (L5 vertebra), localized over the posterior SI JOINT, and consistent with SI JOINT pain.
3. A thorough physical examination demonstrating localized tenderness with palpation over the sacral sulcus (Fortin's point, ie, at the insertion of the long dorsal ligament inferior to the posterior superior iliac spine or PSIS) in the absence of tenderness of similar severity elsewhere (eg, greater trochanter, lumbar spine, coccyx) and that other obvious sources for their pain do not exist.
4. Positive response to a cluster of 3 provocative tests (eg, thigh thrust test, compression test, Gaenslen's test, distraction test, Patrick's sign, posterior provocation test). Note that the thrust test is not recommended in pregnant patients or those with connective tissue disorders.
5. Absence of generalized pain behavior (eg, somatoform disorder) or generalized pain disorders (eg, fibromyalgia).
6. Diagnostic imaging studies that include ALL of the following:
    a. Imaging (plain radiographs and a CT [computed tomography] or MRI [magnetic resonance imaging]) of the SI joint that excludes the presence of destructive lesions (eg, tumor, infection) or inflammatory arthropathy that would not be properly addressed by percutaneous SI JOINT fusion.
    b. Imaging of the pelvis (AP [anteroposterior] plain radiograph) to rule out concomitant hip pathology.
    c. Imaging of the lumbar spine (CT or MRI) to rule out neural compression or other degenerative condition that can be causing low back or buttock pain.
    d. Imaging of the SI joint that indicates evidence of injury and/or degeneration.

7. At least 75% reduction of pain for the expected duration of the anesthetic used following an image-guided, contrast-enhanced intra-articular SI JOINT injection on 2 separate occasions.
8. A trial of at least one therapeutic intra-articular SI JOINT injection (ie, corticosteroid injection)."

INTERNATIONAL SOCIETY FOR THE ADVANCEMENT OF SPINE SURGERY

The International Society for the Advancement of Spine Surgery (ISASS) published a policy statement on minimally invasive sacroiliac joint fusion. These recommendations were updated in 2016.[33] ISASS lists criteria for determining a patient's eligibility regarding minimally invasive SI joint fusion. However, the statement has several limitations including but not limited to the literature review methods are not transparent, there is no formal assessment of the quality of the evidence, and there is not a clear link between the recommendations and supporting evidence. ISASS recommendations state that patients who have all of the following criteria may be eligible for minimally invasive SI JOINT fusion:

- "Significant SI joint pain … or significantly limitations in activities of daily living because of pain from the SI joint(s).
- "SI joint pain confirmed with … at least three positive physical provocation examination maneuvers that stress the SI joint.
- "Confirmation of the SI joint as a pain generator with ≥ 75% acute decrease in pain immediately following fluoroscopically guided diagnostic intra-articular SI joint block using local anesthetic.
- "Failure to respond to at least six months of non-surgical treatment consisting of non-steroidal anti-inflammatory drugs and/or … one or more of the following: … physical therapy…. Failure to respond means continued pain that interferes with activities of daily living and/or results in functional disability;
- "Additional or alternative diagnoses that could be responsible for the patient's ongoing pain or disability have been considered, investigated and ruled out."

AMERICAN SOCIETY OF INTERVENTIONAL PAIN PHYSICIANS (ASIPP)

The ASIPP guidelines published in 2013 have a recommendation for diagnostic sacroiliac joint injections which were based on a systematic review of the evidence.[1] The guideline indicates that sacroiliac joint blocks appear to be the evaluation of choice to provide appropriate diagnosis, due to the inability to make the diagnosis of sacroiliac joint-mediated pain with noninvasive tests. The ASIPP guidelines conclude and recommend the following for diagnostic sacroiliac joint blocks:

- The evidence for diagnostic intraarticular sacroiliac joint injections is good with 75% to 100% pain relief as the criterion standard with controlled local anesthetic or placebo blocks, and fair due to the limitation of the number of studies with 50% to 74% relief with a dual block.

- Controlled sacroiliac joint blocks with placebo or controlled comparative local anesthetic blocks are recommended when indications are satisfied with suspicion of sacroiliac joint pain.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS TASK FORCE ON CHRONIC PAIN MANAGEMENT AND THE AMERICAN SOCIETY OF REGIONAL ANESTHESIA AND PAIN MEDICINE PRACTICE

In 2010, the American Society of Anesthesiologists Task Force on Chronic Pain Management and the American Society of Regional Anesthesia and Pain Medicine Practice updated their guidelines for chronic pain management.[34] The guidelines recommend that diagnostic sacroiliac joint injections or lateral branch blocks may be considered for the evaluation of patients with suspected sacroiliac joint pain.

AMERICAN PAIN SOCIETY (APS)

The 2009 practice guidelines from the APS were based on a systematic review that was commissioned by the APS and conducted at the Oregon Evidence-based Practice Center.[3, 35] The APS guideline states that there is insufficient evidence to evaluate the validity or utility of diagnostic sacroiliac joint block as a diagnostic procedure for low back pain with or without radiculopathy.

NATIONAL INSTITUTE FOR HEALTH AND CARE EXCELLENCE (NICE)

NICE guidance was published in April 2017 on minimally invasive SIJ fusion surgery for chronic sacroiliac pain.[36] The recommendations included:

1.1 “Current evidence on the safety and efficacy of minimally invasive sacroiliac (SI) joint fusion surgery for chronic SI pain is adequate to support the use of this procedure…..

1.2 Patients having this procedure should have a confirmed diagnosis of unilateral or bilateral SI joint dysfunction due to degenerative sacroiliitis or SI joint disruption.

1.3 This technically challenging procedure should only be done by surgeons who regularly use image-guided surgery for implant placement. The surgeons should also have had specific training and expertise in minimally invasive SI joint fusion surgery for chronic SI pain.

SUMMARY

Sacroiliac joint fusion or fixation performed by open procedure is considered standard of care for traumatic injuries, tumors involving the sacrum, and SI joint infection/sepsis as outlined in the Medical Policy Criteria and therefore may be considered medically necessary. Sacroiliac joint fusion performed by an open procedure for any other indication is considered not medically necessary.

There is enough research to show that minimally invasive fusion/stabilization of the sacroiliac joint using an FDA-approved titanium triangular implant improves health outcomes. Additionally, clinical guidelines based on research recommend the use of minimally invasive fusion/stabilization of the sacroiliac joint using a titanium triangular implant. Therefore, minimally invasive fusion/stabilization of the sacroiliac joint using an FDA-approved titanium triangular implant may be considered medically necessary when policy criteria are met.

There is not enough research to show that minimally invasive fusion/stabilization of the sacroiliac joint using any other device or when policy criteria are not met improves health

outcomes including but not limited to the use of a non-FDA approved device or a device that is not a titanium triangular implant. Therefore, minimally invasive fusion/stabilization of the sacroiliac joint using any other device including but not limited to a non-FDA approved device or a device that is not a titanium triangular implant or when policy criteria are not met is considered investigational.

Left-Atrial Appendage Closure Devices for Stroke Prevention in Atrial Fibrillation

Effective: March 1, 2024

Next Review: November 2024
Last Review: January 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Left atrial appendage (LAA) closure devices have been developed as a nonpharmacologic alternative to anticoagulation for stroke prevention in atrial fibrillation.

MEDICAL POLICY CRITERIA

I. The use of the WATCHMAN or Amplatzer Amulet device for percutaneous left atrial appendage closure may be considered **medically necessary** for the prevention of stroke in patients with atrial fibrillation when the following criteria are met:
   A. There is an increased risk of stroke and systemic embolism based on $CHADS_2$ or CHA_2DS_2-VASc score and systemic anticoagulation therapy is recommended; and
   B. Clinical documentation that the patient is suitable for short-term anticoagulation but unable to take long-term oral anticoagulation.

II. The use of any other device for left atrial appendage closure or when Criterion I. is not met is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

The balance of risks and benefits associated with implantation of the Watchman device for stroke prevention, as an alternative to systemic anticoagulation with warfarin, must be made on an individual basis.

Bleeding is the primary risk associated with systemic anticoagulation. A number of risk scores have been developed to estimate the risk of significant bleeding in patients treated with systemic anticoagulation. An example is the HAS-BLED score, which is validated to assess the annual risk of significant bleeding in patients with atrial fibrillation treated with warfarin (Pisters et al, 2010). Scores range from 0 to 9, based on a number of clinical characteristics (see Table PG1).

Risk of major bleeding in patients with scores of 3, 4, and 5 has been reported at 3.74 per 100 patient-years, 8.70 per 100 patient-years, and 12.5 per 100 patient-years, respectively. Scores of 3 or greater are considered to be associated with high risk of bleeding, potentially signaling the need for closer monitoring of patients for adverse risks, closer monitoring of international normalized ratio, or differential dose selections of oral anticoagulants or aspirin (January et al, 2014).

Table PG1. Clinical Components of the HAS-BLED Bleeding Risk Score

Letter	Clinical Characteristics	Points Awarded
H	Hypertension	1
A	Abnormal renal and liver function (1 point each)	1 or 2
S	Stroke	1
B	Bleeding	1
L	Labile international normalized ratios	1
E	Elderly (>65 y)	1

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could our impact review and decision outcome:

- History and Physical/Chart Notes
- Documentation of FDA approved device to be utilized
- Documentation that supports an increased risk of stroke and systemic embolism based on CHADS2 or CHA2DS2-VASc score and systemic anticoagulation therapy is recommended
- Documentation long-term risks of systemic anticoagulation outweigh the risks of the device implantation

CROSS REFERENCES

None

BACKGROUND

Stroke is the most serious complication of atrial fibrillation (AF). The estimated incidence of

stroke in untreated patients with AF is 5% per year. Stroke associated with AF is primarily embolic in nature, tends to be more severe than the typical ischemic stroke, and causes higher rates of mortality and disability. As a result, stroke prevention is one of the main goals of AF treatment.

Stroke in AF occurs primarily as a result of thromboembolism from the left atrium. The lack of atrial contractions in AF leads to blood stasis in the left atrium, and this low flow state increases the risk for thrombosis. The area of the left atrium with the lowest blood flow in AF, and therefore the highest risk of thrombosis, is the left atrial appendage (LAA). The LAA is the region responsible for an estimated 90% of left atrial thrombi.

The main treatment for stroke prevention in AF is anticoagulation, which has proven efficacy. The risk for stroke among patients with AF is stratified on the basis of several factors. A commonly used score, the CHADS2 score, assigns 1 point each for the presence of heart failure, hypertension, age 75 years or older, diabetes, or prior stroke or transient ischemic attack. The CHADS2-VASc score includes sex, more age categories, and the presence of vascular disease, in addition to the risk factors used in the CHADS2 score. Warfarin is the predominant agent in clinical use. A number of newer anticoagulant medications, including dabigatran, rivaroxaban, and apixaban, have recently received U.S. Food and Drug Administration (FDA) approval for stroke prevention in nonvalvular AF and have demonstrated noninferiority to warfarin in clinical trials. While anticoagulation is effective for stroke prevention, there is an increased risk of bleeding. Also, warfarin requires frequent monitoring and adjustments, as well as lifestyle changes. Other anticoagulants e.g. apixaban and dabigatran do not require monitoring. However, unlike warfarin, the antithrombotic effects of these anticoagulants are not always reversible with hemostatic drugs. Guidelines from the American College of Chest Physicians recommend the use of oral anticoagulation for patients with AF who are at high risk of stroke (i.e., CHADS2 score ≥2), with more individualized choice of antithrombotic therapy in patients with lower stroke risk.[1]

Bleeding is the primary risk associated with systemic anticoagulation. A number of risk scores have been developed to estimate the risk of significant bleeding in patients treated with systemic anticoagulation. An example is the HAS-BLED score, which is validated to assess the annual risk of significant bleeding in patients with AF treated with warfarin.[2] The score ranges from 0 to 9, based on a number of clinical characteristics, including the presence of hypertension, renal and liver function, history of stroke, bleeding, labile international normalized ratios (INRs), age, and drug/alcohol use. Scores of 3 or greater are considered to be associated with high risk of bleeding, potentially signaling the need for closer monitoring of the patient for adverse risks, closer monitoring of INRs, or differential dose selections of oral anticoagulants or aspirin.[3]

Surgical removal, or exclusion, of the LAA is often performed in patients with AF who are undergoing open heart surgery for other reasons. Percutaneous LAA closure devices have been developed as a nonpharmacologic alternative to anticoagulation for stroke prevention in AF. The devices may prevent stroke by occluding the LAA, thus preventing thrombus formation.

Several versions of LAA occlusion devices have been developed. The WATCHMAN™ left atrial appendage system (Boston Scientific, Maple Grove, MN) is a self-expanding nickel titanium device. It has a polyester covering and fixation barbs for attachment to the endocardium. Implantation is performed percutaneously through a catheter delivery system,

using venous access and transseptal puncture to enter the left atrium. Following implantation, patients are anticoagulated with warfarin or alternative agents for approximately 1 to 2 months. After this period, patients are maintained on antiplatelet agents (i.e., aspirin and/or clopidogrel) indefinitely. The Lariat® Loop Applicator is a suture delivery device that is intended to close a variety of surgical wounds in addition to left atrial appendage closure. The Cardioblate® closure device developed by Medtronic is currently being tested in clinical studies. The Amplatzer® cardiac plug (St. Jude Medical, Minneapolis, MN), is FDA-approved for closure of atrial septal defects but not LAA closure device. A second-generation device, the Amplatzer Amulet, has been developed. The Percutaneous LAA Transcatheter Occlusion device (eV3, Plymouth, MN) has also been evaluated in research studies but has not received FDA approval.

REGULATORY STATUS

In 2009, the WATCHMAN™ Left Atrial Appendage Closure Technology (Boston Scientific, Marlborough, MA) was originally considered by the FDA for approval based on the results the results of the Left Atrial Appendage Versus Warfarin Therapy for Prevention of Stroke in Patients with Atrial Fibrillation (PROTECT-AF) randomized controlled trial (RCT). The device underwent three panel reviews before it was approved by FDA through the premarket approval process in March 2015. This device is indicated to reduce the risk of thromboembolism from the left atrial appendage (LAA) in patients with nonvalvular atrial fibrillation who:

- Are at increased risk for stroke and systemic embolism based on CHADS2 or CHA2DS2-VASc scores and are recommended for anticoagulation therapy;
- Are deemed by their physicians to be suitable for warfarin; and
- Have an appropriate rationale to seek a nonpharmacologic alternative to warfarin, taking into account the safety and effectiveness of the device compared to warfarin.

The Amplatzer™ Amulet™ Left Atrial Appendage Occluder (Abbott) received FDA approval in 2021 through the premarket approval process based on results from the Amplatzer Amulet Left Atrial Appendage Occluder Randomized Controlled Trial (Amulet IDE Trial).[4]

The Atriclip™ LAA Exclusion System was cleared for marketing by the FDA through the 510(k) process. The FDA indicates the device is indicated for the occlusion of the heart's left atrial appendage, under direct visualization, in conjunction with other open cardiac surgical procedures. Direct visualization, in this context requires that the surgeon is able to see the heart directly, without assistance from a camera, endoscope, etc., or any other viewing technology. This includes procedures performed by sternotomy (full or partial as well as thoracotomy (single or multiple).[5]

At least one other device has been studied for LAA occlusion, but are not approved in the US for percutaneous closure of the LAA. In 2006, the Lariat® Loop Applicator device (SentreHEART, Redwood City, CA), a suture delivery system, was cleared for marketing by the FDA through the 510(k) process. The intended use is to facilitate suture placement and knot tying in surgical applications where soft tissues are being approximated or ligated with a pretied polyester suture.

EVIDENCE SUMMARY

The standard treatment for stroke prevention in atrial fibrillation is anticoagulation, which has proven effectiveness. In order to determine the safety and effectiveness of left atrial

appendage (LAA) closure devices for the prevention of stroke in atrial fibrillation, large, well-designed randomized controlled trials (RCTs) that compare LAA to no therapy (patients with a prohibitive risk for oral anticoagulation), oral anticoagulation, or open surgical repair are needed. For chronic conditions such as atrial fibrillation, RCTs with long-term follow-up are necessary in order to determine the durability of any beneficial treatment effects.

The evidence on the efficacy of LAA closure devices consists of numerous nonrandomized studies of various occlusion devices, and two published RCTs of the WATCHMAN™ device that compared LAA closure with warfarin anticoagulation. The evidence for each device is summarized separately since the devices are not similar in design and may have unique considerations.

WATCHMAN™ DEVICE

The review of the evidence related to the efficacy of the WATCHMAN™ device is based, in part, on a Blue Cross Blue Shield Association (BCBSA) TEC Assessment developed in June 2014, which evaluated use of the WATCHMAN™ device for patients who were eligible and ineligible for anticoagulation therapy and determined that it does not meet Technology Evaluation Criteria.[6] In addition, the PROTECT-AF and the PREVAIL RCTs evaluated the WATCHMAN™ device. The PROTECT-AF study by Holmes reported outcomes for 18 months of follow-up.[7] Noninferiority criteria were met and then the results of the final analysis were published by Reddy at a mean follow-up of 2.3 years.[8] The FDA reviewed the trial data in 2009 but the data was at a slightly earlier time point than the Holmes analyses. The FDA revealed several concerns during their review that were not reported by the peer reviewed published evidence.[9] As a result, the FDA in coordination with the trial sponsors, developed the PREVAIL trial which had different entry criteria. Study participants from the PROTECT-AF trial were included in the analysis of the PREVAIL trial if they met inclusion criteria. The quality of the two RCTs were assessed as fair by the BCBSA TEC report indicating important methodological limitations in both studies. BCBSA TEC assessment reports the following regarding the quality of the PROTECT-AF and PREVAIL trials:

> “Subject characteristics were balanced between groups. Losses to follow-up in the PROTECT-AF trial were not reported in peer-reviewed publications, and, according to FDA documents, appear to be unbalanced between treatment groups. Losses to follow-up are not clearly reported in FDA documents on the PREVAIL trial, but also appear to be unbalanced between treatment groups. Patients receiving the WATCHMAN™ device underwent more intensive surveillance for thrombosis after device implantation, and continued anticoagulation if concerns about thrombosis arose. Although this was part of the treatment protocol, it makes determinations of efficacy less certain, because there could be a benefit to imaging surveillance alone.”

SYSTEMATIC REVIEWS AND TECHNOLOGY ASSESSMENTS

Jaiswal (2023) published a systematic review of three RCTs comparing the WATCHMAN device to the Amplatzer Amulet device in patients having percutaneous LAAC.[10] A total of 2150 patients were included and results showed that the odds of experiencing procedure-related complications was significantly higher in the Amulet device group (OR 1.80 [1.21-2.67], p <0.001). The odds of all-cause mortality (OR, 0.75 (95% CI: 0.49–1.16), *p* = .20), stroke (OR, 0.79 [0.47–1.34], *p* = .39), systemic/pulmonary embolism (OR, 1.34 [0.30–6.04], *p* = .70), and major bleeding (OR, 1.10 [0.83–1.48], *p* = .50) were comparable between the two devices. The odds of device related thrombus (OR, 0.72 [0.46–1.14], *p* = .17) was comparable between both

the group of patients, however the incidence of peri device leak was significantly lower in AA group (OR, 0.41 [0.26–0.66], $p < .001$) compared with WATCHMAN group of patients.

Blue Cross Blue Shield Association (BCBSA) TEC Assessment developed in June 2014 evaluated the use of the WATCHMAN™ device for patients who were eligible and ineligible for anticoagulation therapy and determined that the WATCHMAN™ device did not meet Technology Evaluation Criteria. Although the WATCHMAN™ device and other LAA closure devices would ideally represent an alternative to oral anticoagulation for the prevention of stroke in patients with AF, during the postimplantation period, the device may be associated with increased thrombogenicity and, therefore, anticoagulation is used during the periprocedural period. Most studies evaluating the WATCHMAN™ device have included patients who are eligible for anticoagulation. There are two main RCTs for the WATCHMAN™ device and the quality of the two RCTs were assessed as fair by the BCBSA TEC report indicating important methodological limitations in both studies. The TEC assessment made the following conclusions about the use of LAA closure in patients without contraindications to anticoagulation:

> "We identified two randomized controlled trials (RCTs) and one case series evaluating the WATCHMAN™ device. The RCTs were noninferiority trials and compared LAAC with anticoagulation. The first trial showed a lower rate of a composite outcome (stroke, death, and embolism) in patients receiving LAAC and met noninferiority criteria compared with anticoagulation, but FDA review noted problems with patient selection, potential confounding with other treatments, and losses to follow-up. The second trial, which incorporated the first trial's results as a discounted informative prior in a Bayesian analysis, showed similar rates of the same composite outcome but did not meet noninferiority criteria. The second trial met its second principal outcome noninferiority criteria in one of two analyses and a performance goal for short-term complication rate. When assessing the results of both trials, the relative performance of LAAC and anticoagulation is uncertain."[6]

In addition, the BCBSA TEC concluded that the evidence is insufficient to make conclusions about improvement in net health outcomes compared to established alternatives.

There are several meta-analyses but the most rigorous is a patient level meta-analysis by Holmes. Holmes (2015) reported results of a patient-level meta-analysis that included data from the industry-sponsored PROTECT AF and PREVAIL trials.[11] The PROTECT AF and PREVAIL registries were designed to include patients with similar baseline characteristics as their respective RCTs. The meta-analysis included a total of 2,406 patients, 1,877 treated with the WATCHMAN™ device and 382 treated with warfarin alone. Mean patient follow-up durations were 0.58 years and 3.7 years, respectively, for the PREVAIL continued access registry and the PROTECT AF continued access registry. In a meta-analysis of 1,114 patients treated in the RCTs, compared with warfarin, LAA closure met the study's noninferiority criteria for the primary composite efficacy end point of all-cause stroke, systemic embolization, and cardiovascular death (hazard ratio [HR], 0.79, 95% confidence interval [CI], 0.52 to 1.2; p=0.22). All-cause stroke rates did not differ significantly between groups (1.75 per 100 patient-years for LAA closure vs 1.87 per 100 patient-years for warfarin; HR=1.02; 95% CI, 0.62 to 1.7; p=0.94). However, LAA closure–treated patients had higher rates of ischemic stroke (1.6 events/100 patient-years vs 0.9 events/100 patient-years; HR=1.95, p=0.05) when procedure-related strokes were included, but had lower rates of hemorrhagic stroke (0.15

events/100 patient-years vs 0.96 events/100 patient-years; HR=0.22; 95% CI, 0.08 to 0.61; p=0.004).

A second patient-level meta-analysis of the two RCTs evaluated bleeding outcomes.[12] There were a total of 54 episodes of major bleeding, with the most common types being gastrointestinal (GI) bleed (31/54 [57%]) and hemorrhagic stroke (9/54 [17%]). On combined analysis, the rate of major bleeding episodes over the entire study period did not differ between groups. There were 3.5 events per 100 patient-years in the WATCHMAN™ group compared with 3.6 events per 100 patient-years in the anticoagulation group, for a rate ratio (RR) of 0.96 (95% CI, 0.66 to 1.40; p=0.84). However, there was a reduction in bleeding risk for the WATCHMAN™ group past the initial periprocedural period. For bleeding events occurring more than seven days postprocedure, the event rates were 1.8 per 100 patient-years in the WATCHMAN™ group compared with 3.6 per 100 patient-years in the anticoagulation group (RR=0.49; 95% CI, 0.32 to 0.75; p=0.01). For bleeding events occurring more than six months post procedure (the time at which antiplatelet therapy is discontinued for patients receiving the WATCHMAN™ device), the event rates were 1.0 per 100 patient-years in the WATCHMAN™ group compared with 3.5 per 100 patient-years in the anticoagulation group (RR=0.28; 95% CI, 0.16 to 0.49; p<0.001).

Randomized Controlled Trials

The first RCT published was the PROTECT AF study,[7] which was a randomized, unblinded trial that evaluated the noninferiority of an LAA closure device compared with warfarin for stroke prevention in AF. The trial randomized 707 patients from 59 centers in the United States and Europe to the WATCHMAN™ device or warfarin treatment in a 2:1 ratio. Mean follow-up was 18±10 months. The primary efficacy outcome was a composite end point of stroke (ischemic or hemorrhagic), cardiovascular or unexplained death, or systemic embolism. There was also a primary safety outcome, a composite end point of excessive bleeding (intracranial or gastrointestinal [GI] bleeding) and procedure-related complications (pericardial effusion, device embolization, and procedure-related stroke). There were noted limitations to this study including inclusion of patients with low stroke risk (CHADS2 scores of 1), high rates of adjunctive antiplatelet therapy use in both groups, and generally poor compliance with warfarin therapy in the control group.

The primary efficacy outcome occurred at a rate of 3.0 per 100 patient years in the LAA closure group compared with 4.9 per 100 patient years in the warfarin group (rate ratio [RR], 0.62; 95% credible interval [CrI], 0.35 to 1.25). Based on these outcomes, the probability of noninferiority was greater than 99.9%. For the individual components of the primary outcome, cardiovascular/unexplained death and hemorrhagic stroke were higher in the warfarin group. In contrast, ischemic stroke was higher in the LAA closure group at 2.2 per 100 patient years compared with 1.6 per 100 patient years in the warfarin group (RR=1.34; 95% CrI, 0.60 to 4.29).

The primary safety outcome occurred more commonly in the LAA closure group, at a rate of 7.4 per 100 patient years compared with 4.4 per 100 patient years in the warfarin group (RR=1.69; 95% CrI, 1.01 to 3.19). The excess in adverse event rates for the LAA closure group was primarily the result of early adverse events associated with placement of the device. The most frequent type of complication related to LAA closure device placement was pericardial effusion requiring intervention, which occurred in 4.8% of patients (22/463).

Longer term follow-up from the PROTECT AF study was reported by Reddy (2013).[13] At a mean follow-up of 2.3 years, the results were similar to the initial report. The relative risk for the composite primary outcome in the WATCHMAN™ group compared with anticoagulation was 0.71, and this met noninferiority criteria with a confidence of greater than 99%. Complications were more common in the WATCHMAN™ group, with an estimated rate of 5.6%/year in the WATCHMAN™ group compared with 3.6%/year in the warfarin group. Outcomes through four years of follow-up were reported by Reddy et al in 2014.[14] Mean follow-up was 3.9 years in the LAA closure group and 3.7 years in the warfarin group. In the LAA closure group, warfarin was discontinued in 345 of 370 patients (93.2%) by the 12 month follow-up evaluation. During the follow-up period, the relative risk for the composite primary outcome in the WATCHMAN™ group compared with anticoagulation was 0.60 (8.4% in the device group vs 13.9% in the anticoagulation group; 95% CrI, 0.41 to 1.05), which met the noninferiority criteria with a confidence of greater than 99.9%. Fewer hemorrhagic strokes occurred in the WATCHMAN™ group (0.6% vs 4.0%; RR=0.15; 95% CrI, 0.03 to 0.49), and fewer cardiovascular events occurred in the WATCHMAN™ group (3.7% vs 0.95%; RR=0.40; 95% CrI, 0.23 to 0.82). Rates of ischemic stroke did not differ significantly between groups, but WATCHMAN™ group patients had lower all-cause mortality than anticoagulation group patients (12.3% vs 18.0%; HR=0.66; 95% CI, 0.45 to 0.98; p=0.04).

Alli (2013) reported quality-of-life parameters, as measured by change in scores on the Short-Form 12-Item Health Survey from baseline to 12-month follow-up, for a subset of 547 subjects in the PROTECT AF study.[15] For the subset of PROTECT AF subjects included in the present analysis, at baseline, control group subjects had a higher mean CHADS2 score (2.4 vs 2.2; p=0.052) and were more likely to have a history of coronary artery disease (49.5% vs 39.6%; p=0.028). For subjects in the WATCHMAN™ group, the total physical score improved in 34.9% and was unchanged in 29.9%; for those in the warfarin group, the total physical score improved in 24.7% and was unchanged in 31.7% (p=0.01).

A second RCT, the PREVAIL trial, was conducted after the 2009 FDA decision on the WATCHMAN™ device to address some of the limitations of the PROTECT AF study, including its inclusion of patients with low stroke risk (CHADS2 scores of 1) and generally poor compliance with warfarin therapy in the control group. Results from the PREVAIL trial were initially presented in FDA documentation, and published in peer-reviewed form by Holmes et al in 2014.[11] In the PREVAIL trial, 461 subjects enrolled at 41 sites were randomized in a 2:1 fashion to either the WATCHMAN™ device or control, which consisted of either initiation or continuation of warfarin therapy with a target international normalized ratio (INR) of 2.0 to 3.0. Subjects had nonvalvular AF and required treatment for prevention of thromboembolism based on a CHADS2 score of two or higher (or ≥1 with other indications for warfarin therapy based on American College of Cardiology/American Heart Association/European Society of Cardiology guidelines) and were eligible for warfarin therapy. In the device group, warfarin and low-dose aspirin were continued until 45 days postprocedure; if a follow-up echocardiogram at 45 days showed occlusion of the LAA, warfarin therapy could be discontinued. Subjects who discontinued warfarin were treated with aspirin and clopidogrel for six months post device implantation and with 325 mg aspirin indefinitely after that.

Three noninferiority primary efficacy end points were specified: (1) occurrence of ischemic or hemorrhagic stroke, cardiovascular or unexplained death, and systemic embolism (18-month rates); (2) occurrence of late ischemic stroke and systemic embolization (beyond seven days postrandomization, 18-month rates); and (3) occurrence of all-cause death, ischemic stroke, systemic embolism, or device- or procedure-related events requiring open cardiac surgery or

major endovascular intervention (eg, pseudoaneurysm repair, arteriovenous fistula repair, or other major endovascular repair) occurring within seven days of the procedure or by hospital discharge, whichever was later. The 18-month event rates were determined using Bayesian statistical methods to integrate data from the PROTECT-AF study. All patients had a minimum follow-up of six months. For randomized subjects, mean follow-up was 11.8 months and median follow-up was 12.0 months (range, 0.03-25.9 months).

The first primary end point, the 18-month modeled RR between the device and control groups was 1.07 (95% CrI, 0.57 to 1.89). Because the upper bound of the 95% CrI was above the preset noninferiority margin of 1.75, the noninferiority criteria were not met. For the second primary end point of late ischemic stroke and systemic embolization, the 18-month RR between the device and control groups was 1.6 (95% CrI, 0.5 to 4.2), with an upper bound of the 95% CrI above the preset noninferiority margin of 2.0. The rate difference between the device and control groups was 0.005 (95% CrI, -0.019 to 0.027). The upper bound of the 95% CrI was lower than the noninferiority margin of 0.0275, so the noninferiority criterion was met for the rate difference. For the third primary end point, major safety issues, the noninferiority criterion was met.

Reddy (2017) published a study on the five-year outcomes after left atrial appendage closure, for patients who participated in the PREVAIL and/or PROTECT AF trials.[16] When evaluating the five-year findings the authors stated that if procedure related strokes are excluded, ischemic stroke and systemic embolism differences did not vary significantly (HR: 1.40; 95% CI: 0.76 to 2.59; p = 0.28). But, hemorrhagic stroke was significantly reduced with left atrial appendage closure (HR: 0.20; 95% CI: 0.07 to 0.56; p = 0.0022). The authors go on to state patients enrolled in the studies had to be able to take oral anticoagulants; thus, the results do not tell you anything about patients unable to take oral anticoagulants. Since the PREVAIL and/or PROTECT AF trials, novel oral anticoagulants have become routinely prescribed and have not been compared to left atrial appendage closure. They stated additional studies are needed to compare left atrial appendage closure to other oral anticoagulants and to determine outcomes for patients unable to take oral anticoagulants. There are studies underway. It is important to note that there is potential conflict of interest with several authors.

Nonrandomized Studies

Saw (2017) evaluated safety and effectiveness of the WATCHMAN™ for 106 patients who cannot take anticoagulants and who had nonvalvular atrial fibrillation.[17] 97.2% of the patients had successful LAA closure, with one device embolization, one implant being placed too deep, and one cardiac perforation requiring repair prior to device implantation. The major combined safety event rate was 1.9% (one death and one device embolization). Follow-up occurred 210 ± 182 days, noting two transient ischemic events. The authors stated that their early experience is that the WATCHMAN™ is safe and effective for patients who cannot be on anticoagulation therapy, but that there were study limitations including a small sample size, varied antithrombotic therapy and device surveillance, and both the device and events were not adjudicated. Additional studies must evaluate how the Watchman™ device impacts healthcare outcomes.

Main (2016) evaluated follow-up transesophageal (TEE) studies for how often device related thrombus (DRT) occurred in patients in the PROTECT-AF trial.[18] In all, 93 follow-up TEEs in 35 patients (33 at 45-day follow-up, 33 at six-month follow-up, and 27 at one-year follow-up) were assessed. The assessment process included a three-phase adjudication (an interactive

training program, an interpretation process, development of DRT criteria, and a final determination of DRTs related to the Watchman™ device). This assessment found device related DRTs in 5.7% of the patients, with DRTs not as common at 45 days, when patients continued on Warfarin. The authors noted study limitations, including but not limited the fact that event adjudication studies tend to underestimate events that occur, the TEE studies varied in clinical quality, and anticoagulant routine data was not completely documented. In addition, there is potential conflict of interest identified in the article.

A number of small published case series are primarily intended to establish safety and feasibility of the device.[19-23] A larger case series of 143 patients from Europe was published in 2011.[21] The case series reported successful implantation in 96% (137/143) of patients and serious complications in 7.0% of patients (10/143). Complications included stroke (n=3), device embolization (n=2), and pericardial effusion (n=5). Another larger case series was reported by Reddy et al[22], primarily focusing on the adverse event rate from a registry of 460 patients who received the WATCHMAN™ device. Serious pericardial effusion occurred in 2.2% of patients, and there were no deaths or periprocedural strokes reported. Matsuo et al reported results from a case series of 179 patients who underwent LAA closure at a single center, most (n=172) of whom received a WATCHMAN™ device.[24] Device deployment was successful in 98.9% of patients. The overall complication rate was 11.2%; major complications occurred in 3.3% (tamponade in two cases; possible transient ischemic attack [TIA] in one case; device dislocation in three cases). At 45-day follow-up, 99.4% of patients (164/166) had closure of the LAA.

Reddy (2016) evaluated adverse events for the WATCHMAN™ since it was FDA approved.[25] Adverse events were identified by procedural data collected by the manufacturer clinical specialist present during surgery. Implantation was deemed successful in 95% of consecutive cases (3,653 out of 3,822 total). The complications included 39 pericardial tamponades (1.02%; 24 treated percutaneously, 12 surgically and 3 fatal), three procedure-related strokes (0.078%), nine device embolizations (0.24%; 6 requiring surgical removal), and three procedure-related deaths (0.078%).

Bonnet published safety and efficacy data for the WATCHMAN™ device from a small single center registry study.[26] There were 23 total patients (mean CHA2DS2-VASc score: 5). The procedural success rate was 95.7% (95% confidence interval: 77.3-100.0) and the reported efficacy was 90.9% (95% confidence interval: 71.0-98.7). No adverse events were reported during or after hospitalization.

Figini (2016) published retrospective results from a single center in Italy between 2009 and 2015.[27] The study included 165 patients in which 99 received the Amplatzer Cardiac Plug (ACP) and 66 the WATCHMAN™ system. The mean follow-up was 15 months. A total of five patients died and one patient had an ischemic attach. There were no episodes of definitive stroke recorded or reported. However, there were twenty-six leaks ≥1 mm detected (23%) and were not found to correlate with clinical events. The authors noted that further investigation is warranted for the small peri-device flow.

There is uncertainty about the role of the WATCHMAN™ device in patients with AF who have absolute contraindications to oral anticoagulants. Reddy et al[8] conducted a multicenter, prospective, nonrandomized trial to evaluate the safety and efficacy of LAA closure with the WATCHMAN™ device in patients with nonvalvular AF with a CHADS2 score 1 or higher who were considered ineligible for warfarin. Postimplantation, patients received 6 months of

clopidogrel or ticlopidine and lifelong aspirin therapy. Thirteen patients (8.7%) had a procedure- or device-related serious adverse event, most commonly pericardial effusion (three patients). Over a mean 14.4 months of follow-up, all-cause stroke or systemic embolism occurred in four patients.

Chun (2013) compared the WATCHMAN™ device with the Amplatzer cardiac plug among patients with nonvalvular AF in a prospective cohort study, who were at high risk for stroke and had a contraindication to or were not willing to accept oral anticoagulants.[28] Eighty patients were assigned to LAA occlusion with the WATCHMAN™ or the Amplatzer device. After device implantation, either preexisting oral anticoagulation therapy or dual platelet inhibition with aspirin and clopidogrel was continued for six weeks. A follow-up transesophageal echocardiogram was performed at six weeks postprocedure; if a device-related thrombus had formed, patients received intensive antithrombotic therapy for six weeks. Aspirin was continued indefinitely for all patients. The primary end point of successful device implantation occurred in 98% of patients. There were no statistically significant differences in procedure time, fluoroscopy time, or major safety events between the two groups. At a median 364 days of follow-up, there were no cases of stroke/TIA or other bleeding complications.

The EWOLUTION WATCHMAN™ registry is intended to evaluate procedural success, long-term outcomes, and adverse events in real-world settings. This registry compiles data from patients receiving the WATCHMAN™ device at 47 centers in 13 countries. A publication from the EWOLUTION registry in 2016 reported on 30-day outcomes of device implantation in 1,021 patients.[29] The overall population had a risk of bleeding that was substantially higher than that for patients in the RCTs. Over 62% of patients included in the registry were deemed ineligible for anticoagulation by their physicians. Approximately one-third of patients had a history of major bleeding, and 40% had HAS-BLED scores of 3 or greater, indicating moderate-to-high risk of bleeding. Procedural success was achieved in 98.5% of patients, and 99.3% of implants demonstrated no blood flow or minimal residual blood flow postprocedure. Serious adverse events due to the device or procedure occurred at an overall rate of 2.8% (95% CI, 1.9% to 4.0%) at 7 days and 3.6% (95% CI, 2.5% to 4.9%) at 30 days. The most common serious adverse event was major bleeding.

Network Analyses

Sahay (2017) performed a network meta-analysis to evaluate the safety and effectiveness of LAAC versus other strategies to prevent stroke in AF patients.[30] Nineteen RCTs with 87,831 patients were evaluated. The authors stated that although LAAC was found to be better than anticoagulant therapy and similar to novel anticoagulants, the results should be carefully analyzed.

Bajaj (2016) conducted a network meta-analysis of published RCTs evaluating multiple novel oral anticoagulants and left atrial appendage closure devices (WATCHMAN™) which have been tested against dose-adjusted vitamin K antagonists for stroke prophylaxis in non-valvular atrial fibrillation.[31] At the time of the analysis, there were no direct comparisons of these strategies from RCTs. Six RCTs were included in the analysis (N=59,627). Safety and efficacy outcomes were evaluated for six treatment strategies. The analysis showed that all prophylaxis strategies had similar rates of ischemic stroke. The authors also reported that in a cluster analyses, assessing safety and efficacy, apixaban, edoxaban and dabigatran ranked best followed by vitamin K antagonists and rivaroxaban, whereas the WATCHMAN™ left atrial

appendage closure device ranked last. All of these strategies had different safety outcomes. The authors concluded that more RCTs are needed that directly compare treatment strategies.

Tereshchenko (2016) published a network meta-analysis that included 21 RCTs (96,017 nonvalvular AF patients; median age, 72 years; 65% males; median follow-up, 1.7 years) in which the safety and efficacy of novel oral anticoagulants (NOACs) (apixaban, dabigatran, edoxaban, and rivaroxaban); vitamin K antagonists (VKA); aspirin; and the WATCHMAN™ device were evaluated.[32] The primary efficacy outcome was the combination of stroke and systemic embolism and the primary safety outcome was the combination of major extracranial bleeding and intracranial hemorrhage. The authors concluded that "in comparison to placebo/control, use of aspirin (odds ratio [OR], 0.75 [95% CI, 0.60-0.95]), VKA (0.38 [0.29-0.49]), apixaban (0.31 [0.22-0.45]), dabigatran (0.29 [0.20-0.43]), edoxaban (0.38 [0.26-0.54]), rivaroxaban (0.27 [0.18-0.42]), and the WATCHMAN™ device (0.36 [0.16-0.80]) significantly reduced the risk of any stroke or systemic embolism in nonvalvular AF patients, as well as all-cause mortality (aspirin: OR, 0.82 [0.68-0.99]; VKA: 0.69 [0.57-0.85]; apixaban: 0.62 [0.50-0.78]; dabigatran: 0.62 [0.50-0.78]; edoxaban: 0.62 [0.50-0.77]; rivaroxaban: 0.58 [0.44-0.77]; and the WATCHMAN™ device: 0.47 [0.25-0.88])."

Section Summary

The evidence for the use of the WATCHMAN™ device for stroke prevention in patients with nonvalvular atrial fibrillation who are candidates for oral anticoagulation mainly includes two noninferiority RCTs (PROTECT-AF and PREVAIL) and patient-level meta-analysis of these trials. Both RCTs compare the WATCHMAN™ device to anticoagulation and report on composite outcomes. The first RCT reported noninferiority between the two groups for a composite outcome of stroke, cardiovascular/unexplained death, or systemic embolism up to four years of follow-up. However, there are documented issues with patient selection criteria (i.e., population low risk for stroke), losses to follow-up, and inconsistency between the two groups in the use of other treatments that may have impacted the findings. The second RCT did not demonstrate noninferiority for the same composite outcome as the first trial (stroke, cardiovascular/unexplained death, or systemic embolism). However, the trial reported noninferiority of the WATCHMAN™ device to warfarin for late ischemic stroke and systemic embolization. The meta-analysis of the two trials reported a periprocedural risk of ischemic stroke with the WATCHMAN™ device and a lower risk of hemorrhagic stroke over the long term.

The published RCTs and meta-analysis report mixed results for the primary composite outcome and risk of safety events. In addition, the two RCTs have methodological limitations that may impact not only the RCT but also the meta-analysis findings which includes unblinding, differing stroke risk among study participants, loss of patients to follow-up, and poor compliance to Warfarin in the comparison groups. The current evidence base does not consistently demonstrate a net improvement in health outcomes (balance of benefit and harms) compared with established treatments for preventing stroke in patients with AF who are eligible to receive systemic anticoagulation.

The evidence for patients where the use of oral anticoagulants is not feasible consists of small nonrandomized studies with methodological limitations. These studies report on the placement of the device but many of them do not report on the *comparative* efficacy and safety of LAA closure in preventing strokes in this population. More high quality, comparative evidence is needed.

AMPLATZER AMULET DEVICE

Randomized Controlled Trials

Two randomized noninferiority trials (SWISS-APERO and Amulet IDE, described below) have been reported comparing the Amplatzer Amulet and Watchman devices, but neither included an anticoagulant group. A third trial (PRAGUE-17) compared either the Amulet or Watchman device with anticoagulants, but did not report subgroup analysis according to the device.

SWISS-APERO Trial

The Comparison of Amulet Versus Watchman/FLX Device in Patients Undergoing Left Atrial Appendage Closure (SWISS-APERO) trial conducted by Galea (2022) compared the Amulet and Watchman devices in 221 participants with non-valvular AF.[33] The enrolled participants were at high risk for stroke (mean CHA2DS2-VASc score 4.3; 39% had a history of prior stroke) and bleeding (mean HAS-BLED score 3.1; 88% had a history of bleeding requiring medical evaluation). Participants were primarily male (70%) and mean age was 77 years. Outcome assessment focused on successful closure, based on a composite outcome of either treatment group crossover during the LAAC procedure or residual LAA patency at 45 days post-intervention, based on CT angiography. The study found no difference in treatment between groups in the composite outcome (RR, 0.97; 95% CI 0.80 to 1.16). Major procedure-related complications were more common with the Amulet versus the Watchman device (9.0% vs. 2.7%; p=.047) There were six deaths during the trial, including two in the Amulet group (1.8%) and four in the Watchman group (3.6%; p=.409). Limitations of the study include the lack of an anticoagulant control group and the short duration of follow-up, although planned trial follow-up is ongoing. In addition, the actual Watchman device used was changed during the course of the trial due to a new device (Watchman FLX) version becoming available.

Amulet IDE Trial

Lakkireddy (2021) reported the results of the Amplatzer Amulet Left Atrial Appendage Occluder IDE Trial (Amulet IDE) comparing the Amulet and Watchman devices.[34] The study enrolled 1,878 patients with non-valvular AF at high-risk for stroke (mean CHA2DS2-VASc score 4.5 and 4.7) and bleeding (mean HAS-BLED score 3.2 and 3.3). The mean age of enrolled patients was 75 years and 59% were male; race and ethnicity were not reported. Twenty-eight percent of enrolled participants had a history of major bleeding and 19 percent had a history of stroke. The primary efficacy endpoint was a composite that included ischemic stroke or systemic embolism, while the safety analysis included a primary composite outcome of all-cause mortality, major bleeding or procedure-related complications. Duration of follow-up was 18 months for efficacy outcomes and 12 months for safety outcomes. After 18 months, there was no difference in the composite efficacy outcome between the Amulet and Watchman devices (HR, 0.00; 95% CI, -1.55 to 1.55). Results were consistent in showing no difference between groups when considering ischemic stroke and systemic embolism as individual outcomes. There was also no difference between Amulet and Watchman groups for a secondary composite outcome that included any stroke, systemic embolism or sudden cardiac death (HR, -2.12; 95% CI, -4.45 to 0.21), nor were there differences between groups when these outcomes were considered individually. In terms of safety, there was no difference between the Amulet and Watchman groups for the composite safety outcome at 12 months (HR, -0.14; 95% CI, -3.42 to 3.13). When outcomes were considered separately, there was also no difference between the Amulet and Watchman groups for all-cause mortality or major bleeding. Procedure-related complications were more likely to occur with the Amulet versus

the Watchman devices (HR, 1.86; 95% CI, 1.11 to 3.12). Follow-up is planned to continue through 2024.

PRAGUE-17 Trial

The PRAGUE-17 trial found that the use of either the Watchman device or the Amplatzer Amulet was noninferior to direct oral anticoagulants for the primary composite endpoint that included ischemic or hemorrhagic stroke, TIA, systemic embolism, clinically significant bleeding, significant peri-procedural or device-related complications, or cardiovascular mortality in high-risk patients with AF.[35] Four year outcomes of the PRAGUE-17 trial were published (2022) and showed that LAAC remains noninferior to DOACs for preventing major cardiovascular, neurological, or bleeding events. Furthermore, nonprocedural bleeding was significantly reduced with LAAC.[36]

Section Summary: Amplatzer Amulet

Two RCTs compared the Amulet and Watchman devices, one of which was a short-term trial that assessed periprocedural outcomes at 45 days. The second trial comparing the Amulet and Watchman devices found the Amulet device to be noninferior to the Watchman device after 18-months follow-up for a composite efficacy outcome that included ischemic stroke or systemic embolism and for a composite safety outcome that included all-cause mortality, major bleeding or procedure-related complications. The primary mechanism of action endpoint of device closure at 45 days was observed in 98.9% of Amulet subjects and 96.8% of Watchman subjects. The 97.5% lower confidence bound was 0.41%, which was greater than the predefined non-inferiority margin of -3% ($p<0.0001$). Therefore, device closure with the Amulet device was non-inferior to the Watchman device.

One additional RCT evaluated the use of either the Amplatzer Amulet or Watchman device versus anticoagulants; subgroup analyses according to the device were not performed. After up to 4 years of follow-up, the study found LAA closure with either the Watchman or Amulet was noninferior to anticoagulants for a composite outcome that included stroke, TIA, systemic embolism, clinically significant bleeding, significant periprocedural or device-related complications, or cardiovascular mortality. The summary of the clinical evidence provides a reasonable assurance that the Amulet device is effective for reducing the risk of thrombus embolization from the LAA in select patients with non-valvular atrial fibrillation.

LARIAT® DEVICE

The available evidence on the efficacy of the Lariat device for LAA closure consists of a number of small case series.

Litwinowicz (2018) published a non-randomized, non-comparative single-center study of 139 patients undergoing LAAC with the LARIAT® device.[37] The study's primary outcomes were risk of thromboembolism, severe bleeding, and mortality with an average follow-up time of 4.2 years. The results of the study indicated that the rate of thromboembolisms is 0.6% and the severe bleeding rate was 0.8%. The reported mortality rate was 1.6%. The authors concluded that LAAC using this device is a safe and effective treatment for stroke prevention and bleed risk reduction in this population. The authors also noted the significant limitations with this study including the lack of control group, variability in post-procedure anticoagulation, and relying on calculated stroke or bleeding risks for analyses.

Gianni (2016) published a retrospective multicenter study of 98 patients who underwent LAA ligation with the LARIAT® device.[38] How many times and what the clinical implications of a leak were assessed. A transesophageal echocardiography assessed leaks during the procedure, at six and 12 months and after thromboembolic events. Leaks were detected in 5%, 15%, and 20% respectfully in patients at the three evaluation periods. The authors stated that because incomplete occlusion can occur, appropriate long-term surveillance should be performed, along with the addition of anticoagulant therapy or percutaneous transcatheter closure as needed.

A SR of published studies on the Lariat device was published in 2016.[39] No RCTs were identified. Five case series were selected, with a total of 309 patients (range, 4-154 patients) treated. The combined estimate of procedural success was 90.3%. One (0.3%) death was reported and seven (2.3%) patients required urgent cardiac surgery. The reviewers also searched the MAUDE database for adverse events and found 35 unique reports. Among the 35 reported complications, there were five deaths and 23 cases of emergency cardiac surgery.

Individual case series continue to be published, including a large case series of 712 consecutive patients from 18 U.S. hospitals.[40] This series reported a procedural success rate of 95% and complete closure in 98%. There was one death and emergent cardiac surgery was required in 1.4%.

A large case series was reported by Price (2014) in a retrospective multicenter study of early outcomes after use of the Lariat device.[41] This study included 154 patients with a median CHADS2 score of 3. Device success, defined as suture deployment and a residual shunt less than 5 mm, was achieved in 94% of patients. Procedural success, defined as device success and no major complication (death, MI, stroke, major bleeding, or emergency surgery) at hospital discharge, was achieved in 86% of patients. Fifteen patients (10%) had at least one major periprocedural complication, and 10% had significant pericardial effusion. Of the 134 patients (87%) who had out-of-hospital outcome data available, the composite out-of-hospital outcome of death, MI, or stroke occurred in four patients (2.9%).

Gianni (2016) published a retrospective, multicenter study including 98 consecutive patients which evaluated the incidence and clinical implications of leaks (acute incomplete occlusion, early and late reopening) following LAA ligation with the LARIAT device.[38] Leaks were detected in 5 (5%), 14 (15%), and 19 (20%) patients at the three time points. A total of five patients developed neurological events (four strokes and one transient ischemic attack). Three occurred late and were associated with small leaks (< 5mm). The authors concluded that “incomplete occlusion of the LAA after LARIAT ligation is relatively common and may be associated with thromboembolic events.

Bartus (2013) reported results of a case series that enrolled 89 patients with AF and either a contraindication to warfarin or previous warfarin failure.[42] A total of 85 of 89 (96%) had successful left atrial ligation, and 81 of 89 (91%) had complete closure immediately. There were three access-related complications, two cases of severe pericarditis postoperatively, one late pericardial effusion, and two cases of unexplained sudden death. There were two late strokes, which the authors did not attribute to an embolic source. At 1-year follow-up, complete closure was documented by echocardiography in 98% of available patients (n=65). In a smaller, earlier series from the same research group,[43] 13 patients were treated with the Lariat device, 11 of whom were treated as part of percutaneous radiofrequency ablation for AF. One of the 11 procedures was terminated due to unsuccessful placement, and the other 10

procedures were successful, with complete closure verified on echocardiography. There was one procedural complication in which the snare could not be removed and were retrieved by thoracoscopy.

Stone (2013) reported outcomes for 27 patients with AF, a high stroke risk (CHADS2 score ≥2), and contraindications or intolerance to anticoagulation who underwent percutaneous LAA ligation with the Lariat device.[44] Acute procedural success was 92.6%; periprocedural complications included 3 cases of pericarditis and 1 periprocedural stroke associated with no long-term disability. A follow-up transesophageal echo was performed in 22 patients at an average of 45 days postprocedure, which demonstrated successful LAA exclusion in all 22. Follow-up was for an average of four months, during which time one stroke and no deaths occurred.

Massumi (2013)[45] reported on 21 patients with AF and contraindications to anticoagulation. A total of 20 of 21 patients had successful atrial closure, which was documented by echocardiography to be intact at a mean follow-up of 96 days. No patients had a stroke during a mean follow-up of approximately one year. Complications were reported in 5 of 21 patients. One patient had right ventricular perforation and tamponade requiring surgical intervention. One patient developed pleuroperidicarditis that required multiple drainage procedures. Three additional patients developed pericarditis within 30 days of the procedure.

Section Summary

The current studies on the Lariat device are limited to small nonrandomized studies. While these studies report high procedural success, interpretation is limited due to methodological limitations such as small sample size, lack of randomized treatment allocation, and lack of a control group for comparison. Larger-scaled trials are needed to confirm the efficacy and safety of the Lariat device.

AMPLATZER® CARDIAC PLUG DEVICE

Cruz-Gonzales (2020), in their retrospective registry study, aimed to evaluate the safety and efficacy of LAA occlusion for patients with nonvalvular AF with prior stroke or TIA despite anticoagulant therapy (resistant stroke [RS]).[46] They assessed data from the Amplatzer Cardiac Plug multicenter registry on 1047 consecutive patients with nonvalvular AF undergoing LAA occlusion. There were no significant differences in baseline characteristics between the 2 groups. The RS group had a significantly higher mean CHA2-DS2-VASc score (5.5±1.5 in the RS group vs. 4.6±1.6 in the non-stroke group) and HAS-BLED score (3.9±1.3 vs. 3.1±1.2). There were no significant differences between groups in procedural success or periprocedural major safety events. At one-year follow-up, the observed annual rate of stroke of TIA was 2.6% in the RS group and 1.2% for the non-stroke group.

Additional available evidence on use of the Amplatzer device for left atrial occlusion consists of a number of case series, most of which included less than 40 patients.[19, 47-51] Another case series, Nietlispach, attempted LAA occlusion in 152 patients from a single institution.[52] Amplatzer Cardiac Plugs were used in 120 patients and nondedicated devices were used in 32 patients. Short-term complications occurred in 9.8% of patients (15/152). Longer-term adverse outcomes occurred in 7% of patients including two strokes, one peripheral embolization, and four episodes of major bleeding. Device embolization occurred in 4.6% (7/152) of patients.

Berti (2016) evaluated consecutive, high-risk patients (n=110) with non-valvular atrial fibrillation and contraindications to oral anticoagulants.[53] There was a mean follow-up of 30±12 months. Procedures were performed using the Amplatzer Cardiac Plug or Amulet. Berti reports procedural success (technical success without major procedure-related complications) was achieved in 96.4%. The rate of major procedural complications was 3.6% (three cases of pericardial tamponade requiring drainage and one case of major bleeding). The annual rate of ischemic stroke and other thromboembolic events were 2.2% and 0%, respectively. The annual rate for major bleeding was 1.1%.

Additional case series of patients treated with the Amplatzer device were published including patients from different countries.[19, 27, 47, 48, 54-56] Many of the case series reported high procedural success, as well as various complications such as vascular complications, air embolism, esophageal injury, cardiac tamponade, and device embolization.

Several studies have reported the use of the Amplatzer device in patients with a contraindication to oral anticoagulation therapy. The largest study reported outcomes, up to four years postprocedure, for 134 patients with nonvalvular AF and a long-term contraindication to oral anticoagulation treated with the Amplatzer device.[57] Patients had a median CHA2DS2-VASc score of 4 and were generally considered at high risk for bleeding complications. Postprocedural antithrombotic therapy was tailored to the patient's individual risk profile, but the authors described that, generally, short-term dual antiplatelet therapy (1-2 months) and subsequent indefinite single antiplatelet therapy were prescribed after successful device implantation. Procedural success occurred in 93.3%, and three major procedure-related complications (two cases of cardiac tamponade, one case of pericardial effusion requiring drainage or surgery) occurred. Over a mean follow-up of 680 days, observed annual rates of ischemic strokes and any thromboembolic events were 0.8% and 2.5%, respectively.

Meerkin (2013) reported outcomes for 100 patients with AF, a CHADS2 score of 2 or higher, and a contraindication to oral warfarin who were treated with the Amplatzer device at a single institution.[58] All patients were treated with heparin during the procedure; they were maintained on clopidogrel for one month postprocedure and daily aspirin indefinitely. Successful deployment occurred in all patients. There were two significant periprocedural complications, including one pericardial effusion with tamponade and one case of acute respiratory distress with pulmonary edema.

Wiebe (2014) reported results of a retrospective cohort of 60 patients with nonvalvular AF who had a CHADS2-VASc score of at least 1 and contraindications to warfarin anticoagulation who underwent percutaneous LAA closure with the Amplatzer device.[50] Contraindications to warfarin included contraindications as defined in the warfarin product label, a history of severe bleeding while receiving anticoagulant therapy, as well as a history of bleeding tendencies in the absence of anticoagulation or blood dyscrasia, along with patients who were unable to maintain a stable INR and those with a known hypersensitivity to warfarin or a high-risk of falling who were also included. Patients received heparin during the closure procedure; they were maintained on clopidogrel for 3 months postprocedure and daily aspirin indefinitely. Device implantation was successful in 95% of patients. Over a median follow-up of 1.8 years, no patients experienced a stroke. The rate of major bleeding complications was 1.9%/year of follow-up.

Urena (2013) reported results from a similar cohort of 52 patients with nonvalvular AF who had a CHADS2-VASc score of at least 2 and contraindication to oral anticoagulation therapy who

underwent percutaneous LAA closure with the Amplatzer device.[51] Device implantation was successful in all but one patient. There were no periprocedural strokes or death. Over the follow-up period (mean, 20 months), rates of death, stroke, and systemic embolism were 5.8% (3/52), 1.9% (1/52), and 0%, respectively.

Figini (2016) published retrospective results from a single center in Italy between 2009 and 2015.[27] The study included 165 patients in which 99 received the Amplatzer Cardiac Plug (ACP) and 66 the WATCHMAN™ system. The mean follow-up was 15 months. A total of five patients died and one patient had an ischemic attach. There were no episodes of definitive stroke recorded or reported. However, there were twenty-six leaks ≥1 mm detected (23%) and were not found to correlate with clinical events. The authors noted that further investigation is warranted for the small peri-device flow.

Other smaller case series of patients with contraindication to oral anticoagulation include studies by Danna,[47] which included 37 patients and reported a 1-year stroke rate of 2.94%, and Horstmann,[59] which included 20 patients and reported no episodes of strokes over a mean follow-up of 13.6 months.

Gloekler (2015)[60] compared outcomes for nonvalvular AF patients treated with the first-generation Amplatzer cardiac plug (n=50) and those treated with the second-generation Amulet device (n=50) in a retrospective analysis of prospectively collected data. There were no significant differences between devices in terms of safety outcomes.

Section Summary

All of the nonrandomized studies report high procedural success, but also report various complications such as vascular complications, air embolism, esophageal injury, cardiac tamponade, and device embolization. Well designed, large RCTs are needed to confirm the efficacy and safety of this device.

PLAATO DEVICE

Bayard (2010) reported on 180 patients with nonrheumatic atrial fibrillation and a contraindication to warfarin and who were treated with the PLAATO (Percutaneous Left Atrial Appendage Transcatheter Occlusion) device.[61] Placement was successful in 90% of patients. Two patients died within 24 hours of the procedure (1.1%), and six patients had cardiac tamponade (3.3%), with two required surgical drainage. During a follow-up of 129 patient-years, three strokes were reported for a rate of 2.3% per year. Other case reports and small case series report complications, including multiple reports of thrombus formation at the site of device placement.[61, 62]

Section Summary

The nonrandomized studies report high procedural success, but also report various complications. Well designed, large RCTs are needed to confirm the efficacy and safety of this device.

ATRICLIP DEVICE

Ad (2015) reported on 24 patients that received the Atriclip PRO. Ninety five percent of patients had nonparoxysmal AF.[63] The clip did not deploy in one patient but the procedural success was 95%. Another study reported on 30 procedures for the Atriclip.[64] The device was

successfully placed in 28 of the 30 patients and the study didn't report any adverse events at follow-up. A multicenter study reported on a total of 71 patients receiving the Atriclip device.[65] Safety of the device was assessed at 30 days and there was a three month follow-up for efficacy. One patient was not able to receive the Atriclip device but procedural success was confirmed in 67 of 70 patients. Significant adverse events were reported in 34 of 70 patients. There was no adverse events from the device itself and no perioperative mortality. At the three month follow-up, one patient passed away and 60 of 61 patients still had successful occlusion.

Section Summary

Nonrandomized studies report high procedural success, but also report various complications. Well designed, large RCTs are needed to confirm the efficacy and safety of this device.

EVALUATIONS OF MULTIPLE DEVICES

Hanif (2017) published a SR of RCTs to compare the risk of stroke in patients with left atrial appendage occlusion (LAAO) versus anticoagulant, antiplatelet, or placebo therapy.[66] The impact on operative time, major bleeding, and mortality were assessed. Although LAAO was found to be better than anticoagulant therapy for stroke and mortality, the authors stated the evidence had methodological limitations.

Health Quality Ontario (2017) performed a SR evaluating both clinical and cost effectiveness of left atrial appendage closure devices versus novel anticoagulants e.g. dabigatran or versus Warfarin.[67] .Five studies compared novel anticoagulants to Warfarin and two compared left atrial appendage closure to Warfarin. The authors concluded that moderate quality evidence indicates left atrial appendage closure is as effective as novel oral anticoagulants for patients with nonvalvular AF, but is cost effective only for patients who cannot take anticoagulants.

Lempereur (2017) published a SR evaluating device associated thrombosis (DAT) for the Watchman™, Amplatzer™ Cardiac Plug (ACP), and Amulet devices from 2008-2015.[68] Thirty studies were included. The mean frequency of DAT after LAAO was 3.9% for all devices (82/2118). The reported frequency of DAT six weeks after implant was similar for WM and ACP/Amulet (2.0 versus 2.6%, respectively, $P = 0.60$). The reported frequency of events did not appear to change over time. The conclusion was that DAT was an infrequent complication of LAAO as it occurs mostly in the early post procedure, and there is a low rate of neurological complications. But, the authors stated their review had limitations including lack of a standard definition for DAT amongst studies and that the review was based only on published data. Therefore unpublished, underreported and/or underdiagnosed DATs would impact the review outcomes. Additional larger multicenter studies are needed to determine risks, complications, and treatment efficacy of LAAO.

Wei (2016) published a SR evaluating two RCTs (PROTECT AF and PREVAIL) and 36 observational studies on the safety and effectiveness of left atrial appendage occlusion (LAAO) devices.[69] The systems mainly involved in the studies included PLAATO, the Amplatzer® Cardiac Plug device, and WATCHMAN™. Other devices such as nondedicated Amplatzer® occluders, and WaveCrest® were also reviewed. Procedure failure was 0.02 (95% CI: 0:02-0.03), with no heterogeneity amongst studies. All-cause mortality was 0.03 (95% CI: 0.02-0.03) and cardiac/neurological mortality was 0 (95% CI: 0.00-0.01), with low pooled results and no heterogeneity amongst studies. The frequency of stroke/transient ischemic attack was 0.01 (95% CI: 0.01-0.01), with no heterogeneity amongst studies. The frequency of thrombus on devices was 0.01 (95% CI: 0.01-0.02), with no heterogeneity amongst studies. Major

hemorrhagic event complications were 0.01 (95% CI: 0.00-0.01), with no heterogeneity amongst studies. Of the devices, most did not differ in the frequency of events except all-cause mortality and cardiac/neurological mortality was higher for the PLAATO group and thrombus occurred more often in the ACP group and less often in the PLATTO group. The authors stated LAAO is safe and effective and there is a low rate of failure, for patients not able to be on long-term anticoagulant therapy. However, the authors stated their study had limitations, including but not limited to the definition of safety and effectiveness varied amongst studies, there were only two RCTs, two large studies did not report cardiac or neurological death frequencies, and the data on specific devices was not always easy to assess.

Li (2016) published a SR to report how effective and safe LAAO devices were for greater than one year, when compared to novel oral anticoagulants (NOACs).[70] They evaluated six RCTs and 27 observational studies. The authors stated the RCTs showed that LAAO was not better than NOACs for stroke prevention (odds ratio 0.86), but did show LAAO patients had less hemorrhagic events at follow-up. An analysis of the observational studies showed that LAAO patients had a lower rate of both thromboembolic events (1.8 per 100 patient-years versus 2.4 events per 100 patient-years) and major bleeding (2.2 events per 100 patient-years versus 2.5 events per 100 patient-years). During longer follow-up periods patients with LAAO had less thromboembolic events (2.1, 1.8, and1.0 events per 100 person-years for 1, 1-2, and > 2 years respectively). The authors stated the SR had limitations, including but not limited to different follow-up durations between LAAO and NOAC groups and number of patients who received LAAO was less than those receiving NOACs. They stated additional studies with consistent homogeneity could assess healthcare outcomes and assist in confirming this study's findings.

Xu conducted a comprehensive literature search for studies evaluating patients after receiving an occlusion device.[25] Studies were included if they had at least 10 patients followed for at least six months. Twenty five total studies were included with only two RCTs and the rest were cohort studies (N= 2,779). Xu performed a meta-analysis of stroke events and adverse events after patients received an occlusion device. Xu reported that the adjusted incidence rate of stroke was 1.2/100 person-years (PY) (95% confidence interval [CI], 0.9-1.6/100 PY) and the ischemic and hemorrhagic stroke rates were 1.1/100 PY (95% CI, 0.8-1.4/100 PY) and 0.2/100 PY (95% CI, 0.1-0.3/100 PY), respectively. Additionally, the combined efficacy outcomes (stroke or transient ischemic attacks [TIAs], systemic embolism, or cardiovascular death) was 2.7/100 PY (95% CI, 1.9- 3.4/100 PY). The most common adverse events were major bleeding and pericardial effusions at a rate of 2.6% (95% CI, 1.5%-3.6%) and 2.5% (95% CI, 1.8%-3.2%), respectively.

Sahay conducted a SR of the evidence with a network meta-analysis of all RCTs (N=19) with a total of 87,831 patients.[71] The network analysis evaluated the safety and efficacy of left atrial appendage closure compared to other strategies for stroke prevention in atrial fibrillation.[71] The network meta-analysis includes direct and indirect comparisons for these various treatment strategies. The analysis compared treatment strategies to warfarin as a common comparator group. The authors reported that "…using warfarin as the common comparator revealed efficacy benefit favoring LAAC as compared with placebo (mortality: HR 0.38, 95% CI 0.22 to 0.67, p<0.001; stroke/SE: HR 0.24, 95% CI 0.11 to 0.52, p<0.001) and APT (mortality: HR 0.58, 95% CI 0.37 to 0.91, p=0.0018; stroke/SE: HR 0.44, 95% CI 0.23 to 0.86, p=0.017) and similar to NOAC (mortality: HR 0.76,= 95% CI 0.50 to 1.16, p=0.211; stroke/SE: HR 1.01, 95% CI 0.53 to 1.92, p=0.969)." The rates for major bleeding were comparable. The authors further note that caution should be taken in interpreting these results

as more studies are needed to further substantiate the findings especially in light of the wide confidence intervals.

Betts (2016) evaluated the feasibility and long term efficacy of LAAO using a retrospective multicenter registry (July 2009-November 2014).[72] The devices included the WATCHMAN™ (63%), Amplatzer™ Cardiac Plug (34.7%), Lariat (1.7%) and Coherex WaveCrest (0.6%). A total of 371 patients were included and the overall procedure success was 92.5% with major adverse events in 3.5% of patients. The authors reported "an annual 90.1% relative risk reduction (RRR) for ischemic stroke, an 87.2% thromboembolic events RRR, and a 92.9% major bleeding RRR were observed, if compared with the predicted annual risks based on CHADS2, CHA2DS2-Vasc, and HAS-BLED scores, respectively, over a follow-up period of 24.7 ± 16.07 months. In addition, the authors reported higher success rates and a reduction in acute major complications in the second half of recruitment.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF CARDIOLOGY, HEART RHYTHM SOCIETY, AND SOCIETY FOR CARDIOVASCULAR ANGIOGRAPHY AND INTERVENTIONS

In 2015, the American College of Cardiology (ACC), Heart Rhythm Society (HRS), and Society for Cardiovascular Angiography and Interventions published an overview of the integration of percutaneous LAA closure devices into the clinical practice of patients with AF.[73] The overview was organized around questions related to the sites of care delivery for LAA closure devices, training for proceduralists, necessary follow-up data collection, identification of appropriate patient cohorts, and reimbursement. The statement provides general guidelines for facility and operator requirements, including the presence of a multidisciplinary heart team, for centers performing percutaneous LAA closures. The statement does not provide specific recommendations about the indications and patient populations appropriate for percutaneous LAA closure.

AMERICAN COLLEGE OF CARDIOLOGY, THE AMERICAN HEART ASSOCIATION, AND HEART RHYTHM SOCIETY[3, 74]

The 2019 ACC/AHA/HRS focused update of the 2014 guidelines on the management of patients with AF recommends surgical occlusion of the LAA with the WATCHMAN device as an alternative to long-term anticoagulation therapy (Class IIB, Level of Evidence: B-NR).

AMERICAN COLLEGE OF CHEST PHYSICIANS (ACCP)

2018 American College of Chest Physicians guidelines (updated from 2012) recommend that CHA2DS2VASc be used to evaluate stroke risk, and patients initially identified as having a low stroke risk should not be given antithrombotic therapy. In addition, they recommend bleeding risk assessments be given to every patient at every patient contact and that "potentially modifiable bleeding risk factors" should be the initial focus.

SUMMARY

There is enough research to show that the WATCHMAN or Amplatzer Amulet device for left atrial appendage closure results in improved health outcomes for the prevention of stroke in patients with atrial fibrillation. Clinical guidelines based on evidence recommend the use of

the WATCHMAN device for left atrial appendage closure in certain patients. Therefore, the use of the WATCHMAN or Amplatzer Amulet device for left atrial appendage closure may be considered medically necessary for the prevention of stroke in patients with atrial fibrillation who are at an increased risk of stroke.

There is not enough research to show that left atrial appendage closure devices improve health outcomes when policy criteria are not met. No evidence-based practice guidelines recommend the use of devices other than the WATCHMAN or Amplatzer Amulet device. Therefore, the use of left atrial appendage closure devices is investigational when policy criteria are not met including the use of devices other than the WATCHMAN or Amplatzer Amulet device.

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Transcatheter aortic valve implantation (also known as transcatheter aortic valve replacement) is an alternative to open valve replacement surgery for patients with aortic stenosis and to nonsurgical therapy for patients with a prohibitive risk for surgery.

MEDICAL POLICY CRITERIA

I. For patients with native valve aortic stenosis, transcatheter aortic valve implantation with an U.S. Food and Drug Administration (FDA)-approved transcatheter heart valve system may be considered **medically necessary** when all of the following criteria (A. – D.) are met:

   A. New York Heart Association heart failure class II, III, or IV symptoms; and

   B. Left ventricular ejection fraction greater than 20%; and

   C. Aortic valve is not unicuspid or bicuspid; and

   D. Severe aortic stenosis, defined as any one or more of the following:

      1. An aortic valve area of less than or equal to 1 cm^2, or

      2. An aortic valve area index of less than or equal to 0.6 cm^2/m^2, or

3. A mean aortic valve gradient greater than or equal to 40 mmHg, or
4. A peak aortic-jet velocity greater than or equal to 4.0 m/s.

II. For patients with a bioprosthetic aortic valve, transcatheter aortic valve replacement (i.e., valve-in-valve) with an FDA-approved transcatheter heart valve system (e.g., Edwards SAPIEN™ or Medtronic CoreValve System™) may be considered **medically necessary** when all of the following criteria (A. – D.) are met:

A. Failure of a surgical bioprosthetic aortic valve (stenosed or insufficient); and

B. New York Heart Association heart failure class II, III, or IV symptoms; and

C. Left ventricular ejection fraction greater than 20%; and

D. There is clinical documentation that the patient is either of the following:

1. Not a candidate for open surgery, or
2. At high risk for open surgery, defined as either of the following, as documented by the ordering provider:
   a. Society of Thoracic Surgeons predicted operative risk score of 8% or higher (see Policy Guidelines), or
   b. An expected mortality risk of 15% or higher for open surgery

III. Transcatheter aortic valve implantation or replacement is considered **investigational** when Criteria I. or II. is not met, including for all other indications and for non-FDA-approved devices.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

For the use of the SAPIEN or CoreValve devices, severe aortic stenosis is defined by the presence of one or more of the following criteria:

- An aortic valve area of less than or equal to 1 cm^2
- An aortic valve area index of less than or equal to 0.6 cm^2/m^2
- A mean aortic valve gradient greater than or equal to 40 mmHg
- A peak aortic-jet velocity greater than or equal to 4.0 m/s.

The Society of Thoracic Surgeons risk calculator can be found at http://riskcalc.sts.org/stswebriskcalc/calculate.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Documentation of symptoms, associated diagnoses and treatments
- The name of the valve system to be implanted

- Documentation of aortic valve stenosis (e.g., valve area, mean aortic valve gradient)
- In the case of valve-in-valve implantation, documentation that supports determination that patient is not a candidate or is high-risk for open surgery

BACKGROUND

AORTIC STENOSIS

Aortic stenosis is defined as narrowing of the aortic valve opening, resulting in obstruction of blood flow from the left ventricle into the ascending aorta. Progressive calcification of the aortic valve is the most common etiology in North America and Europe, while rheumatic fever is the most common etiology in developing countries.[1] Congenital abnormalities of the aortic valve, most commonly a bicuspid or unicuspid valve, increase the risk of aortic stenosis, but aortic stenosis can also occur in a normal aortic valve. Risk factors for calcification of a congenitally normal valve mirror those for atherosclerotic vascular disease, and include advanced age, male gender, smoking, hypertension, and hyperlipidemia.[1] Thus, the pathogenesis of calcific aortic stenosis is thought to be similar to that of atherosclerosis, i.e., deposition of atherogenic lipids and infiltration of inflammatory cells, followed by progressive calcification.

The natural history of aortic stenosis involves a long asymptomatic period, with slowly progressive narrowing of the valve until the stenosis reaches the severe stage. At this stage, symptoms of dyspnea, chest pain, and/or dizziness/syncope often occur, and the disorder progresses rapidly.

Aortic stenosis does not cause substantial morbidity or mortality when the disease is mild or moderate in severity. By the time it becomes severe, there is an untreated mortality rate of approximately 50% within two years.[2] Open surgical replacement of the diseased valve with a bioprosthetic or mechanical valve is an effective treatment for reversing aortic stenosis, and artificial valves have demonstrated good durability for up to 20 years.[2] However, these benefits are accompanied by perioperative mortality of approximately 3% to 4% and substantial morbidity,[2] both of which increase with advancing age.

Many patients with severe, symptomatic aortic stenosis are poor operative candidates. Approximately 30% of patients presenting with severe aortic stenosis do not undergo open surgery due to factors such as advanced age, advanced left ventricular dysfunction, or multiple medical comorbidities.[3] For patients who are not surgical candidates, medical therapy can partially alleviate the symptoms of aortic stenosis but does not affect the underlying disease progression. Percutaneous balloon valvuloplasty can be performed, but this procedure has less than optimal outcomes.[4] Balloon valvuloplasty can improve symptoms and increase flow across the stenotic valve but is associated with high rates of complications such as stroke, myocardial infarction, and aortic regurgitation. Also, restenosis can occur rapidly, and there is no improvement in mortality.

Transcatheter Aortic Valve Implantation

Transcatheter aortic valve implantation (TAVI), also known as transcatheter aortic valve replacement (TAVR), has been developed in response to this unmet need and was originally intended as an alternative for patients for whom surgery was not an option due to prohibitive surgical risk or for patients at high-risk for open surgery. The procedure is performed percutaneously, most often through the transfemoral artery approach. It can also be done through the subclavian artery approach and transapically using mediastinoscopy. Balloon valvuloplasty is first performed to open the stenotic area. This is followed by passage of a bioprosthetic artificial valve across the native aortic valve. The valve is initially compressed to allow passage across the native valve and is then expanded and secured to the underlying aortic valve annulus. The procedure is performed on the beating heart without cardiopulmonary bypass.

REGULATORY STATUS

Multiple manufacturers have transcatheter aortic valve devices with FDA approval:

- Edwards SAPIEN Transcatheter Heart Valve System™ (Edwards Lifesciences)
    - Edwards SAPIEN™ Transcatheter Heart Valve, Model 9000TFX
    - Edwards SAPIEN XT Transcatheter Heart Valve (model 9300TFX) and accessories
    - SAPIEN 3 THV System, a design iteration
    - SAPIEN 3 Ultra THV System, a design iteration
      Note: In August 2019, FDA issued a recall for the Edwards SAPIEN 3 Ultra Transcatheter Heart Valve System (Recall event ID: 83293) due to "reports of burst balloons which have resulted in significant difficulty retrieving the device into the sheath and withdrawing the system from the patient during procedures".

- Medtronic CoreValve System™ (Medtronic CoreValve)
    - Medtronic CoreValve Evolut R System™ (design iteration for valve and accessories)
    - Medtronic CoreValve Evolut PRO System™ (design iteration for valve and accessories, includes porcine pericardial tissue wrap)
    - Medtronic CoreValve Evolut PRO+ System™ (design iteration)

- LOTUS Edge™ Valve System (Boston Scientific)

  Note: In January 2021, Boston Scientific Corporation announced a global, voluntary recall of all unused inventory of the LOTUS Edge™ Valve System due to complexities associated with the product delivery system.[5] There are no safety concerns for patents who have the LOTUS Edge™ Valve System currently implanted. Boston Scientific has chosen to retire the entire LOTUS product platform immediately rather than develop and reintroduce an enhanced delivery system. All related commercial, clinical, research and development, and manufacturing activities will cease.

- Portico™ with FlexNav™ (Abbott Medical)

Other transcatheter aortic valve systems are under development. The following repositionable valves are under investigation:

- JenaValve™ (JenaValve Technology); designed for transapical placement

EVIDENCE SUMMARY

TAVI OUTCOMES IN PATIENTS AT PROHIBITIVE RISK FOR OPEN SURGERY

Systematic Reviews

Systematic reviews assessing whether TAVI improves outcomes for patients who are not suitable candidates for open surgery consist of summaries of case series. A systematic review sponsored by the Agency for Healthcare Research and Quality (2010, archived) evaluated 84 publications (total n=2,375 patients).[6] Implantation was successful in 94% of patients overall, with higher success rates reported in more recent publications. The aggregate 30-day survival was 89% across all studies. Adverse event rates were reported in the larger case series, with an estimated 30-day rate of major cardiovascular adverse event and stroke of 8%.

A systematic review by Figulla (2011) included studies that enrolled symptomatic patients with severe aortic stenosis who had a mean age of 75 years or older, reported on 10 or more patients, and had a follow-up duration of 12 months or more.[7] Twelve studies met these criteria and were compared with a group of 11 studies that treated severe aortic stenosis with nonsurgical therapy. The procedural success in these studies ranged from 86% to 100%, and the 30-day mortality ranged from 5.3% to 23%. The combined mean survival rate at one year was 75.9% (95% confidence interval [CI] 73.3% to 78.4%). This one-year survival rate compared favorably with medical therapy, which was estimated to be 62.4% (95% CI 59.3% to 65.5%).

Randomized Controlled Trials

<u>SAPIEN and SAPIEN XT</u>

The Placement of AoRTic TraNscathetER Valve Trial Edwards SAPIEN Transcatheter Heart Valve (PARTNER) randomized controlled trial (RCT) was a pivotal multicenter trial of TAVI performed in the United States, Canada, and Germany, using the SAPIEN™ system. Leon (2010) reported on trial results for patients with severe aortic stenosis who were not candidates for open surgery, referred to as the PARTNER B trial.[8] To be classified as unsuitable for open surgery, patients had to have a predicted probability of 50% or higher for death or a serious irreversible condition at 30 days postsurgery. This probability was determined by two surgeon investigators using clinical judgment and the Society of Thoracic Surgery (STS) Risk Score. The executive committee of the PARTNER trial reviewed all patient selection decisions and approved the classification of patients as unsuitable for surgery. A total of 3,105 patients were screened for aortic valve surgery, and 12% of them were included in the cohort of patients deemed unsuitable for surgery.

In the trial, 358 patients were randomized to TAVI or usual care. TAVI was performed by the transfemoral approach under general anesthesia. Standard therapy was determined by treating clinicians. In most cases (83.8%), standard treatment included balloon valvuloplasty of the aortic valve. A small number of patients (6.7%) underwent open surgical valve replacement, despite the high risk, and another 2.2% of patients underwent TAVI at a center outside the United States not participating in the trial. The primary outcome was death from any cause during the trial (median follow-up 1.6 years). A coprimary endpoint was the composite of time to death from any cause or time to repeat hospitalization related to aortic stenosis or TAVI. Secondary endpoints were cardiovascular mortality, New York Heart Association (NYHA) functional class, the rates of hospitalizations due to aortic stenosis or

TAVI, the six-minute walk test (6MWT), valve performance as measured by echocardiography, and procedural complications (e.g., myocardial infarction [MI], stroke, acute kidney injury [AKI], vascular complications, bleeding).

The mean age of enrolled patients was 83.2 years. Some baseline imbalances in the patient population indicated that the standard therapy group might have had a higher severity of illness. Standardized scores of surgical risks were higher in the standard therapy group. The logistic EuroSCORE was significantly higher in the standard therapy group than in the TAVI group (30.4 vs. 26.4, p=0.04), and the STS score was numerically higher but was not statistically significant (12.1 vs. 11.2, respectively, p=0.14). Significantly more patients in the standard therapy group had chronic obstructive pulmonary disease (52.5% vs. 41.3%, p=0.04) and atrial fibrillation (48.8% vs. 32.9%, p=0.04), and there was a nonsignificant trend for more patients in the standard therapy group having a lower ejection fraction (51.1% vs. 53.9%) and frailty, as determined by prespecified criteria (28.0% vs. 18.1%), all respectively.

Death from any cause at one year after enrollment was lower for the TAVI group (30.7% vs. 49.7%, p<0.001). This represents a 19% absolute risk reduction, a 38.2% relative risk (RR) reduction, and a number needed to treat of 5.3 to prevent one death over a one-year follow-up. Most secondary outcomes also favored the TAVI group. Cardiovascular death was lower in the TAVI group (19.6% vs. 44.1%, p<0.001). The composite of all-cause mortality and repeat hospitalizations was reached by 42.5% of the patients in the TAVI group compared with 70.4% in the standard therapy group. Symptoms and functional status were also superior in the TAVI group. The percentage of patients in NYHA class I or II at one year was higher for the TAVI group (74.8% vs. 42.0%, p<0.001), and there was a significant improvement in the 6MWT for the TAVI group but not for the standard therapy group (between-group comparisons not reported). Subgroup analysis did not report any significant differences in outcomes according to clinical and demographic factors.

Complication rates were higher for the TAVI group. Stroke or transient ischemic attack (TIA) at one year was more than twice as frequent for the TAVI group (10.6% vs. 4.5%, p=0.04). Major bleeding and vascular complications occurred in a substantial percentage of patients undergoing TAVI (22.3% vs. 11.2%, p=0.007) and were significantly higher than in the standard therapy group (32.4% vs. 7.3%, p<0.001).

Quality of life (QoL) outcomes from this trial were reported by Reynolds (2011), and were evaluated using the Kansas City Cardiomyopathy Questionnaire (KCCQ) summary score, the 12-Item Short-Form Health Survey (SF-12), and the EuroQoL (EQ-5D).[9] The number of participants who completed the QoL measures was not clearly reported; estimates from graphical representation show that between 149 and 170 patients in the TAVI group and 138 and 157 patients in the medical therapy group completed baseline QoL measures. At follow-up time points of 30 days, six months, and 12 months, change in the QoL scores was greater for the TAVI group. At 30 days, the mean difference in the KCCQ score was 13.3 points (95% CI 7.6 to 19.0, p<0.001). This mean difference increased at later time points to 20.8 points (95% CI 14.7 to 27.0, p<0.001) at six months and to 26.0 points (95% CI 18.7 to 33.3, p<0.001) at 12 months. Changes in the SF-12 and EQ-5D measures showed similar patterns.

Two-year outcomes from the PARTNER trial were reported by Makkar (2012).[10] Mortality at two years was 43.3% in the TAVI group compared with 68.0% in the medical therapy group (hazard ratio [HR] 0.58, 95% CI 0.36 to 0.92, p=0.02). Cardiovascular mortality was also lower

with TAVI (31.0%) than with medical therapy (62.4%, p<0.001). The rate of hospitalization over the two-year period was lower with TAVI (35.0%) than with medical therapy (72.5%, p<0.001).

Svensson (2014) reported detailed mortality outcomes for both arms of the PARTNER trial: the PARTNER B RCT (previously described), which compared surgical repair with TAVI in prohibitive surgical risk patients, and the PARTNER A RCT, which compared surgical repair with TAVI in high surgical risk patients (described next).[11] For the 358 patients considered inoperable and enrolled in the PARTNER B trial, 237 patients had died at last follow-up. Those randomized to standard therapy exhibited an early peak in mortality that was higher than those randomized to TAVI, and that persisted beyond six months. Compared with standard therapy, the estimated net lifetime benefit added by transfemoral TAVI was 0.50 years (90% CI 0.30 to 0.67).

Kapadia (2014) reported on three-year outcomes for 358 prohibitive-risk patients randomized to standard therapy or TAVI in the PARTNER trial, along with all outcomes (early and long-term) for randomized inoperable PARTNER patients, including 91 subjects in the randomized PARTNER continued-access study.[12] Analysis of the pooled randomized patients was anticipated in the study protocol. At the three-year follow-up for the pivotal trial subjects, all-cause mortality was 54.1% in the TAVI group and 80.9% in the standard therapy group (HR 0.53, 95% CI 0.41 to 0.68, p<0.001). The incidence of stroke was higher in the TAVI group (15.7%) than in the standard therapy group at three years (5.5%, HR 3.81, 95% CI 1.26 to 6.26, p=0.012). However, at three years, the incidence of the composite of death or stroke was significantly lower in the TAVI group (57.4% vs. 80.9%, HR 0.60, 95% CI 0.46 to 0.77, p<0.001). Survivors at three years who had undergone TAVI were more likely to have NYHA class I or II symptoms than those who had received standard therapy. In the pooled sample, at the two- and three-year follow-ups, mortality was lower for patients who had undergone TAVI than in those who had standard therapy (at two years: 44.8% vs. 64.3%, at three years: 54.9% vs. 78.0%, all p<0.001).

Webb (2015) reported on a multicenter RCT comparing a newer-generation SAPIEN XT system with the original SAPIEN system in 560 patients with severe, symptomatic aortic stenosis considered at prohibitive risk for open surgery.[13] The trial used a noninferiority design; for its primary endpoint, a composite of all-cause mortality, major stroke, and rehospitalization at one year in the intention-to-treat population, the RR between the SAPIEN and SAPIEN XT groups was 0.99 (p<0.002), which met the criteria for noninferiority.

Kapadia (2019) reported an analysis of stroke risk and its association with QoL after surgical aortic valve replacement (SAVR) versus TAVR from a propensity-matched study of 1,204 pairs of patients in the PARTNER trials.[14] The analysis focused only on as-treated SAVR and transfemoral TAVR. The incidence of stroke by 30 days was 5.1% in SAVR versus 3.7% in TAVR; incidence of 30-day major stroke was 3.9% versus 2.2% (p=0.018). In both groups, risk of stroke peaked in the first post-procedure day but then remained low out to 48 months. Major stroke was associated with a decline in QoL as measured by the KCCQ at one year.

Huded (2022) reported on rehospitalization rates from the PARTNER trial, finding no effect modification by transcatheter versus surgical aortic valve replacement.[15]

Nonrandomized Studies

Many case series of TAVI have been published in the last 10 years, most of which have included patients that were not candidates for open surgery. However, the selection process

for TAVI has largely been subjective, with the expert opinion of the surgeons and/or cardiologists as the main factor determining suitability for open surgery. As a result, there may be overlap in these series with patients who are surgical candidates, but the distinction cannot be gleaned easily from the reported studies.

Some of the larger and/or prospective case series are discussed next, including the series reporting on the pivotal trials leading to devices' approvals.

CoreValve Extreme Risk Study

Popma (2014) published results of the CoreValve Extreme Risk Study pivotal trial, which was designed to evaluate the CoreValve self-expanding valve among patients with severe aortic stenosis who were considered to be at extreme risk (NYHA class ≥II) for SAVR.[16] A patient was judged to be at extreme risk if two cardiac surgeons and one interventional cardiologist at the clinical site estimated a 50% or greater risk for mortality or irreversible morbidity at 30 days with surgical repair. The study's primary endpoint was the 12-month rate of all-cause mortality or major stroke in the "attempted implant" population. This population included all patients who underwent a documented valve implant via an iliofemoral approach. The study defined an objective performance goal of 43% for all-cause mortality or major stroke at 12 months postprocedure. This goal was based on two sources: (1) a weighted meta-analysis of seven balloon aortic valvuloplasty studies, which yielded a rate of 12-month all-cause mortality or major stroke of 42.7% (95% CI 34.0% to 51.4%); and (2) an adjusted estimate based on the lower 95% confidence bound of 43% in the standard therapy arm of inoperable patients in the PARTNER trial.

There were 489 patients included in the attempted implant analysis population of 506 patients recruited (11 of whom exited the study before treatment, six of whom did not complete the procedure with iliofemoral access). The Kaplan-Meier estimate of the primary endpoint (all-cause mortality or major stroke) was 26.0% (upper bound of 95% CI 29.9%), which was lower than the prespecified performance goal of 43% ($p<0.001$). The rate of all-cause mortality at one year following enrollment was 24.3%, while the rate of major stroke at 12 months was 4.3%. These rates are comparable or better than those seen in the TAVI arm of the PARTNER pivotal trial, although patients in the PARTNER pivotal trial had a higher baseline STS score (12.1% in the PARTNER trial vs. 10.3% in the CoreValve Extreme Risk trial).

Two-year results from the CoreValve study were reported by Yakubov (2015).[17] The Kaplan-Meier estimate of all-cause mortality or major stroke was 38.0% (upper bound of 95% CI 42.6%). The incremental rates between years one and two were 12.3% for all-cause mortality, 7.9% for cardiovascular mortality, and 0.8% for stroke. Baron (2017) reported on three-year results of the QoL data.[18] The QoL improvements following TAVR were largely sustained through three years with clinically meaningful (≥10 points) improvements in the KCCQ overall summary score at three years observed in greater than 83.0%. At five years of follow-up, the Kaplan-Meier rate of death or major stroke was 72.6%, and the KCCQ remained improved compared with pre-TAVI scores.[19]

Osnabrugge (2015) reported on health status outcomes for the 471 patients who underwent TAVI via the transfemoral approach.[20] On average, general and disease-specific QoL scores both showed substantial improvements after TAVI. However, 39% of patients had a poor outcome at six months (22% death, 16% very poor QOL, 1.4% QoL declined).

Reardon (2014) reported on outcomes for the group of patients enrolled in the CoreValve study who received the device through an approach other than the iliofemoral.[21] Inclusion criteria and procedures were the same as for the primary CoreValve Extreme Risk Trial. One hundred fifty patients with prohibitive iliofemoral anatomy were included and received the CoreValve device through an open surgical approach via the subclavian artery (n=70) or a direct aortic approach via a median hemisternotomy or right thoracotomy (n=80). Included patients were elderly (mean age 81.3 years) and significantly symptomatic, with 92% of subjects having NYHA class III or IV heart disease. At 30 days postprocedure, 23 (15.3%) patients met the primary endpoint of all-cause mortality or major stroke; of the 23 patients, 17 (11.3%) died, and 11 (7.5%) experienced a major stroke. At 12 months postprocedure, 59 (39.4%) patients met the primary endpoint; of those, 54 (36%) died, and 13 (9.1%) experienced a major stroke. The 30-day mortality of 11.3% was higher than that reported in the studies of TAVI using a transfemoral or an iliofemoral approach (PARTNER B RCT and the CoreValve Extreme Risk Pivotal Trial) but similar to the 30-day mortality reported by the patients treated with a transapical approach (PARTNER A trial).

Post-approval Registries

Mack (2013) reported on outcomes after TAVI from 224 hospitals participating in the Edwards SAPIEN device post-FDA approval registry.[22] From November 2011 to May 2013, the registry included 7,710 patients who underwent TAVI placement, of whom 1,559 (20%) patients were considered inoperable and 6,151 (80%) were considered high-risk but operable. Of those considered inoperable, 1,139 underwent device placement via transfemoral access, while 420 underwent device placement via nontransfemoral access. In-hospital mortality was 5.4% and 7.1% for the inoperable patients who underwent TAVI via transfemoral and nontransfemoral access, respectively. Thirty-day clinical outcomes were reported for 694 inoperable patients; of those, 30-day mortality was 6.7% and 12.6% for patients who underwent TAVI via transfemoral and nontransfemoral access, respectively.

Additional Case Series

The prospective nonrandomized Treatment of Aortic Stenosis With a Self-Expanding Transcatheter Valve: the International Multi-Centre ADVANCE study had central adjudication of endpoints and adverse events to evaluate the CoreValve implants in individuals with severe symptomatic aortic stenosis who were considered inoperable or at higher risk for SAVR.[23] The study enrolled 1,015 patients, of whom 996 were implanted, most (88.4%) by the iliofemoral approach, with 9.5% and 2.1% by the subclavian and direct aortic approaches, respectively. For the study's primary endpoint of major adverse cardiac and cerebrovascular events (MACCE; a composite of all-cause mortality, MI, stroke, or reintervention), rates were 8.0% (95% CI 6.3% to 9.7%) at 30 days and 21.2% (95% CI 18.4% to 24.1%) at 12 months. The all-cause mortality rate was 4.5% (95% CI 3.2% to 5.8%) at 30 days and 17.9% (95% CI 15.2% to 20.5%) at 12 months. Overall, strokes occurred in 3.0% (95% CI 2.0% to 4.1%) at 30 days and in 4.5% (95% CI 2.9% to 6.1%) at 12 months. A new permanent pacemaker was implanted in 26.3% (95% CI 23.5% to 29.1%) and in 29.2% (95% CI 25.6% to 32.7%) of patients at 30-day and 12-month follow-ups, respectively. Patients were grouped into three categories of surgical risk based on logistic EuroSCORE values (≤10%, >10% to ≤20%, and >20%). Thirty-day survival did not differ significantly across risk groups, but 12-month rates of MACCE, all-cause mortality, cardiovascular mortality, and death from any cause or major stroke were higher for higher surgical risk patients.

The two largest series included in the Agency for Healthcare Research and Quality review[6] (described previously) reported on 646 patients treated with the CoreValve[24] and 339 patients treated with the SAPIEN valve.[25] The CoreValve study by Piazza (2008) was notable in that it used more objective patient selection criteria than is common in this literature.[24] Their criteria for eligibility included: (1) logistic EuroSCORE of 15% or higher, (2) age of 75 or older, or (3) age of 65 or older with liver cirrhosis, pulmonary insufficiency, pulmonary hypertension, previous cardiac surgery, porcelain aorta, recurrent pulmonary emboli, right ventricular insufficiency, previous chest burns, or radiation precluding open surgery, or body mass index of 18 kg/m^2 or less. Procedural success was 97%, and 30-day survival was 92%. The 30-day combined rate of death, MI, or stroke was 9.3%. The Canadian study by Rodes-Cabau (2010) used the SAPIEN valve.[25] This study had subjective inclusion criteria, relying on the judgment of the participating surgeons to determine eligibility for TAVI. The procedural success rate was 93.3%, and the 30-day mortality was 10.4%. The authors also reported a mortality rate of 22.1% at a median follow-up of eight months.

Additional series have described experiences with TAVI in European centers. Zahn (2011), in a large case series from Germany, reported on 697 patients treated with the CoreValve system.[26] Procedural success was 98.4%, and 30-day mortality was 12.4%. Another large case series from Italy included 663 patients treated with the CoreValve device.[27] Procedural success was 98%, and mortality at one year was 15%.

Section Summary: TAVI Outcomes in Patients at Prohibitive Risk for Open Surgery

Numerous case series have demonstrated the feasibility and short-term efficacy for TAVI in patients who are not surgical candidates. In the PARTNER B trial, there was a large decrease in all-cause mortality and cardiovascular mortality at one year for TAVI compared with standard therapy. Subsequent publications from this same trial reported that the mortality benefit was maintained at two years and that QoL was improved for the TAVI group. Baseline between-group differences were present, indicating that the TAVI group may have been healthier. While these differences are unlikely to account for the degree of mortality benefit reported, they may have resulted in an overestimation of the mortality benefit. The CoreValve Extreme Risk Study pivotal trial also demonstrated mortality rates much lower than the prespecified performance goal and comparable or better than those seen in the TAVI arm of the PARTNER pivotal trial.

The benefit in mortality was accompanied by an increased stroke risk as well as substantial increases in vascular complications and major bleeding. There is also uncertainty concerning the generalizability of these results because patient selection was primarily determined by the cardiovascular surgeons and/or cardiologists. It is not known whether this type of decision making is reliable across the range of practicing clinicians.

TAVI OUTCOMES IN PATIENTS AT HIGH RISK FOR OPEN SURGERY

Systematic Reviews

A meta-analysis of four RCTs was published by Panoulas (2018) to determine whether sex differences had any impact on mortality rates for TAVI and SAVR.[28] The four RCTs comprised of 3,758 patients (2,052 men, 1,706 women); all patients had severe aortic stenosis. The study revealed that among women undergoing TAVI, a significantly lower mortality rate was found than in women undergoing SAVR at the one-year mark; in fact, women undergoing TAVI were found to have a 31% lower mortality rate than women undergoing SAVR, again at the one-year

mark (odds ratio [OR] 0.68, 95% CI 0.50 to 0.94). There was no statistical difference in mortality in men undergoing TAVR versus men undergoing SAVR. An updated meta-analysis by Dagan (2021) identified eight RCTs including 8,040 patients (41.4% female).[29] Similar results were found to the 2018 analysis with lower one-year mortality and improved safety with TAVI compared with SAVR in women.

Villablanca (2016) reported on a meta-analysis and meta-regression of long-term outcomes (more than one year) of TAVI compared with SAVR for severe aortic stenosis.[30] Trial methods were described in the meta-analysis protocol, which was registered with PROSPERO.[30] The review was limited to studies comparing TAVI with surgical repair, with subgroup analyses for high- and intermediate-risk patients. Overall, four RCTs (n=3,806 patients) and 46 observational studies (n=40,441 patients) were included, with a median follow-up of 21.4 months. Two of the RCTs were conducted in high-risk patients and are described in detail below (PARTNER 1[31] and CoreValve High Risk Trial[32]). Results from the subgroup analyses focused on high-risk patients are shown in Table 1.

Table 1. TAVI Versus Surgical Repair in High-Risk Patients

Outcomes	TAVI[a]	Surgical Repair[a]	RR for TAVI vs. Surgical Repair (95% CI)	I^2, %
30-day postprocedure mortality	508/8,552 (5.9%)	804/29,323 (2.7%)	1.02 (0.76 to 1.36)	72.3
All-cause mortality	3,625/8,803 (41.1%)	5,438/29,450 (18.6%)	1.16 (0.87 to 1.53)	96.6
Stroke incidence	191/4,293 (4.4%)	213/4,348 (4.9%)	0.79 (0.66 to 0.95)	0
Myocardial infarction incidence	57/2,820 (2.0%)	59/2,746 (2.1%)	0.91 (0.64 to 1.29)	21.5
Vascular complication incidence	203/2,489 (8.2%)	35/2,682 (1.3%)	5.5 (2.42 to 12.4)	67.5
Residual regurgitation incidence	268/2,831 (9.5%)	36/2,823 (1.3%)	6.3 (4.55 to 8.71)	0
Requirement for permanent pacemaker incidence	527/3,449 (15.3%)	236/3,653 (6.4%)	1.68 (0.94 to 3.00)	83.2
New-onset AF incidence	165/1,192 (13.8%)	376/1,281 (29.4%)	0.38 (0.26 to 0.55)	64.6
Major bleeding incidence	321/2,074 (15.4%)	416/2,298 (18.1%)	0.73 (0.65 to 0.83)	24.2
Acute kidney injury incidence	294/3,446 (8.5%)	396/3,528 (11.2%)	0.73 (0.53 to 1.01)	68.4

Adapted from Villablanca (2016).[30]
AF: atrial fibrillation; CI: confidence interval; RR: relative risk; TAVI: transcatheter aortic valve implantation.
[a] Values are n/N (%).

Earlier systematic reviews focused largely on nonrandomized comparative studies because only one RCT had been published at the time of the reviews (the PARTNER trial). Panchal (2013) reported on results from a meta-analysis of 17 studies that included 4,659 patients: 2,267 treated with TAVI and 2,392 treated with open surgery.[33] Patients in the TAVI group were more severely ill, as evidenced by a EuroSCORE for predicted 30-day mortality, which was higher by a mean of 3.7 points compared with patients undergoing open surgery. On combined analysis, there were no differences between groups for 30-day mortality, mortality at longest follow-up, cardiovascular mortality, MI, stroke, or TIA. Patients in the open surgery group had a higher incidence of major bleeding complications (RR 1.42, 95% CI 1.20 to 1.67, p<0.001). In a similar meta-analysis (2013) that included 17 studies reporting on 4,873

patients, there were no differences between TAVI and open surgery in early mortality (OR 0.92, 95% CI 0.70 to 1.2) or mid-term mortality, defined as between three months and three years (HR 0.99, 95% CI 0.83 to 1.2).[34]

Randomized Controlled Trials

SAPIEN PARTNER A Trial

Smith (2011) published results from the cohort of patients in the PARTNER trial of the SAPIEN valve who were at high-risk for open surgery, but still suitable candidates.[35] The inclusion and exclusion criteria were generally the same as those for the prior cohort, except that these patients were classified as high-risk for surgery rather than unsuitable for surgery. For high-risk, patients had to have a predicted perioperative mortality of 15% or higher, as determined by a cardiac surgeon and cardiologist using clinical judgment. An STS Risk Score of 10 or higher was included as a guide for high-risk, but an STS Risk Score threshold was not a required criterion for enrollment. The executive committee of the PARTNER trial reviewed all patient selection decisions and approved the classification of patients as high-risk for surgery. A total of 3,105 patients were screened for aortic valve surgery, and 22.5% of them were included in the cohort of patients deemed high-risk for surgery.

There were 699 patients randomized to TAVI or surgical aortic valve repair. The primary hypothesis was that TAVI was noninferior to open AVR, using a one-sided noninferiority boundary of 7.5% absolute difference in mortality at one year. Patients were first evaluated to determine if they were eligible for TAVI via the transfemoral approach. Four hundred ninety-two patients were eligible for transfemoral TAVI; the remaining 207 were categorized as the transapical placement cohort. Within each cohort (transfemoral and transapical), patients were randomized to surgical aortic valve repair (n=351) or TAVI (n=348).

The primary outcome was death from any cause at one-year follow-up. A second powered endpoint was noninferiority at one year for patients undergoing TAVI by the transfemoral approach. Secondary endpoints were cardiovascular mortality, NYHA functional class, rehospitalizations, 6MWT, valve performance as measured by echocardiography, and procedural complications (MI, stroke, AKI, vascular complications, bleeding). Mean age of enrolled patients was 83.6 years in the TAVI group and 84.5 years in the open AVR group. Other baseline demographic and clinical characteristics were generally well-balanced, except for a trend toward an increased percentage of patients in the TAVI group with a creatinine level greater than 2.0 mg/dL (11.1% vs. 7.0%, p=0.06).

Death from any cause at one year following enrollment was 24.2% for the TAVI group and 26.8% for the open AVR group (between-group difference, p=0.44). The upper limit of the 95% CI for the between-group difference was a 3.0% excess mortality in the TAVI group, which was well within the noninferiority boundary of 7.5%. Thus, the criterion of noninferiority was met (p=0.001). For the subgroup of patients who underwent TAVI by the transfemoral approach, results were similar, with 22.2% mortality in the TAVI group and 26.4% mortality in the open AVR group (p=0.002 for noninferiority). The secondary outcomes of cardiovascular mortality (14.3% vs. 13.0%, p=0.63) and rehospitalizations (18.2% vs. 15.5%, p=0.38) did not differ significantly between the TAVI and the open AVR groups, respectively. The percentage of patients in NYHA class I or II at one year was similar between groups at one year, as was an improvement on the 6MWT. On subgroup analysis, there was a significant effect for sex, with women deriving greater benefit than men (p=0.045), and a significant effect for prior coronary

artery bypass graft, with patients who had not had prior coronary artery bypass graft deriving greater benefit in the TAVI group.

Certain complication rates showed significant differences between groups. Stroke or TIA at one year was higher for the TAVI group (8.3% vs. 4.3%, respectively, p=0.04). Vascular complications occurred in 18.0% of patients undergoing TAVI compared with 4.8% in the open AVR group (p=0.01), and major vascular complications were also higher in the TAVI group (11.3% vs. 3.5%, p=0.01). On the other hand, major bleeding was more common in the open group (25.7%) compared with the TAVI group (14.7%, p=0.01).

Five-year results from the PARTNER trial were reported by Mack (2015).[31] At five-year follow-up, in the intention-to-treat population, the risk of death from any cause did not differ significantly between patients treated with TAVI (67.8%) and those treated with surgical repair (62.4%, HR 1.04, 95% CI 0.86 to 1.24, p=0.76). As reported in the original PARTNER trial findings, moderate or severe aortic regurgitation – primarily paravalvular regurgitation – was more common among TAVI-treated patients. Among TAVI-treated patients, the presence of aortic regurgitation was associated with increased five-year mortality risk (72.4% for moderate or severe aortic regurgitation vs. 56.6% for mild aortic regurgitation or less, p=0.003).

Reynolds (2012) published QoL results from the PARTNER A trial.[36] QOL outcomes were evaluated using the KCCQ summary score, the SF-12, and the EQ-5D. Of 699 patients in the trial, 628 completed baseline QoL measures. Patients in both the TAVI group and the SAVR group demonstrated significant improvements in all QoL measures over the 12 months following treatment. The TAVI group had superior improvement at one month on the KCCQ (mean difference 9.9, 95% CI 4.9 to 14.9, p<0.001), but this difference was no longer present at 6 or 12 months. A similar pattern of results was reported for the SF-12 and EQ-5D measures.

Genereux (2014) published a follow-up study from the PARTNER A trial reporting on bleeding complications.[37] Using an as-treated approach, this analysis included 313 patients treated with surgical repair, 240 patients treated with transfemoral TAVI, and 104 patients treated with transapical TAVI. Seventy-one (22.7%) patients treated with surgery had major bleeding complications within 30 days of the procedure, compared with 27 (11.3%) of those treated with transfemoral TAVI and 9 (8.8%) of those treated with transapical TAVI (p<0.001).

U.S. CoreValve High-Risk Study

Adams (2014) published results of the U.S. CoreValve High Risk Study.[38] This RCT compared SAVR with TAVI using the CoreValve device in patients who had severe aortic stenosis and were considered at increased risk of death during surgery. The study randomized 795 patients in a 1:1 ratio to TAVI or open AVR. Patients were considered to be at “increased surgical risk” if two cardiac surgeons and one interventional cardiologist estimated that the risk of death within 30 days of surgery was 15% or more and that the risk of death or irreversible complications within 30 days after surgery was less than 50%. The primary analysis was based on the as-treated population, which included all patients who underwent attempted implantation. For the study’s primary outcome, the rate of death from any cause at one year was lower in the TAVI group (14.2%) than in the surgical group (19.1%, absolute risk reduction, 4.9%, upper boundary of 95% CI -0.4%, which was less than the predefined noninferiority margin of 7.5%-point difference between groups, noninferiority, p<0.001, superiority, p=0.04). Major vascular complications and permanent pacemaker implantations were significantly more frequent in the TAVI group than in the surgical group: at 30 days, major

vascular complications occurred in 5.9% of the TAVI group compared with 1.7% of the surgical group (p=0.003), while permanent pacemaker implantation was required in 19.8% of the TAVI group compared with 7.1% of the surgical group (p<0.001). In contrast to the PARTNER trial, the TAVI group did not have a higher rate of any stroke at one year postprocedure (8.8%) than the surgical group (12.6%, p=0.10).

Two-year follow-up results from the U.S. CoreValve High Risk Study were published by Reardon (2015).[32] At that point, the mortality benefits seen with TAVI were maintained.

A three-year follow-up analysis was reported by Deeb (2016), which found sustained improvements in the TAVI-treated group for all-cause mortality, stroke, and MACCE compared with the surgical group.[39] At three years, 37.3% (n=142) of TAVI-treated patients experienced all-cause mortality or stroke, which was significantly less than the 46.7% (n=160) of surgical patients for the same outcome (p=0.006). In the TAVI group, MACCE was observed in 40.2% (n=153) of patients; in the surgical group, MACCE occurred in 47.9% (n=164) of patients (p=0.025). Other outcomes that were improved in the TAVI group compared with surgery were life-threatening or disabling bleeding, AKI, aortic valve area, and mean aortic valve gradient. More TAVI-treated patients required implantation of a pacemaker (28.0%) than did surgical patients (14.5%, p<0.001); also, more patients in the TAVI group (6.8%) had moderate atrial regurgitation than in the surgery group (0.0%) at three years. The authors noted the improvement in mean aortic valve gradient for both cohorts (TAVR 7.62 mmHg vs. SAVR 11.40 mmHg, p<0.001).

Additional analyses of the U.S. CoreValve High Risk Study have focused on the impact of patient and prosthesis mismatch[40] and health status.[41]

Conte (2017) analyzed both periprocedural and early complications (0-3 days and 4-30 days postoperative, respectively) in patients from the U.S. CoreValve High Risk Study.[42] There were no statistically significant differences in all-cause mortality, stroke, MI, or major infection in either the periprocedural period (0-3 days) or between 4 and 30 days postprocedure. Major vascular complication rate within three days was significantly higher with TAVR (6.4% vs. 1.4%, p=0.003). Life-threatening or disabling bleeding (12.0% vs. 34.0%, p<0.001), encephalopathy (7.2% vs. 12.3%, p=0.02), atrial fibrillation (8.4% vs. 18.7%, p<0.001), and AKI (6.1% vs. 15.0%, p<0.001) were significantly higher with SAVR.

Gleason (2019) reported five-year follow-up of the CoreValve High Risk Trial and estimated similar five-year survival (55.3% for TAVR vs. 55.4% for SAVR) and stroke rates (12.3% for TAVR versus 13.2% for SAVR) in high-risk patients. Valve reintervention were uncommon; freedom from valve reintervention was 97.0% for TAVR and 98.9% for SAVR.[43]

REPRISE III

The Repositionable Percutaneous Replacement of Stenotic Aortic Valve Through Implantation of Lotus Valve System–Randomized Clinical Evaluation (REPRISE III) trial was an RCT comparing two different TAVR platforms: the mechanically expanded Lotus valve (which was discontinued in January 2021) and self-expanding CoreValve. Thirty-day and one-year results were reported in the Summary of Safety and Effectiveness compiled by the FDA and two-year results were published by Reardon (2019).[44 45] The trial enrolled 912 patients (n=607 in Lotus, n=305 in CoreValve) with high/extreme risk and severe, symptomatic aortic stenosis between September 2014, and December 2015 at 55 centers in North America, Europe, and Australia. An early-generation CoreValve device was used. Follow-up is scheduled to continue for up to

five years. Patients were required to have an STS-prom risk score of ≥8% or another indicator of high or extreme risk. The mean age was 83 years and the mean STS-PROM score was 6.8%. The primary safety outcome was a composite of all-cause mortality, stroke, life-threatening and major bleeding events, stage 2 or 3 AKI, or major vascular complications at 30 days. The primary effectiveness outcome was a composite of all-cause mortality, disabling stroke, or moderate or greater paravalvular aortic regurgitation at one year. At 30 days, the incidence of the primary safety outcome was 20% versus 17% for Lotus versus CoreValve (risk difference [RD] 3.1%, 95% CI -2.3 to 8.5) and met the criteria for noninferiority. All of the individual components of the 30-day primary safety outcome were similar between the two groups. The incidence of the primary effectiveness outcome was 16% versus 26% in Lotus versus CoreValve (RD -10.2%, 95% CI -16.3 to 4.0) and met the criteria for noninferiority. At two years, all-cause death was 21% vs. 22.5% with Lotus versus CoreValve (HR 0.94, 95% CI 0.69 to 1.26) and all-cause mortality or disabling stroke was 23% vs. 27% with Lotus versus CoreValve (HR 0.81, 95% CI 0.61 to 1.07). Placement of a new permanent pacemaker was more common in the Lotus group (42% vs. 26%, HR 1.9, 95% CI 1.4 to 2.5). Valve thrombosis was also more common in the Lotus group (3% vs. 0%). Repeated procedures were more common in the CoreValve group (0.6% vs. 2.9%, HR 0.19, 95% CI 0.05 to 0.70), as was valve migration (0.0% vs. 0.7%) and embolization (0.0% vs. 2.0%).

PORTICO IDE

The Portico Re-sheathable Transcatheter Aortic Valve System US Investigational Device Exemption (PORTICO IDE) trial enrolled patients with severe aortic stenosis at high or extreme surgical risk.[46] Patients were randomized to a Portico valve (n=381) or another FDA-approved valve (n=369). The primary efficacy endpoint was a composite of all-cause mortality and stroke at one year, and the primary safety endpoint was a composite of all-cause mortality, disabling stroke, life-threatening bleeding, AKI, or major vascular complications. Overall, the mean age was 83 years with females comprising 52.7% of patients. Additional demographic characteristics were not reported. The primary efficacy endpoint at one year was similar between groups (14.8% in the Portico group vs. 13.4% with other valves, absolute difference 1.5%, 95% CI -3.6 to 6.5). For the composite safety endpoint at 30 days, the event rate was higher with the Portico valve (13.8% vs 9.6%, absolute difference 4.2%, 95% CI -0.4 to 8.8). At two years, the rates of death or disabling stroke were similar between groups.

Nonrandomized Studies

Since the publication of the pivotal RCTs and systematic reviews described previously, a number of nonrandomized studies have compared surgical with TAVR.[47-49] Given the availability of RCT evidence, these studies provide limited additional information on the efficacy of TAVI.

Section Summary: TAVI Outcomes in Patients at High Risk for Open Surgery

The most direct evidence related to the use of TAVI compared to SAVR for aortic stenosis in patients who are at high but not prohibitive risk of surgery comes from two industry-sponsored RCTs. The PARTNER RCT in high-risk patients who were eligible for SAVR reported no differences between TAVI and open AVR in terms of mortality at one year and most major secondary outcomes. The noninferiority boundaries for this trial included an upper limit of 7.5% absolute increase in mortality. The reported mortality for the TAVI group was lower than that for the open group, although not significantly better. QoL was also similar at one year between the TAVI and AVR groups. Stroke and TIA were significantly more common for the TAVI

group, occurring at a rate of almost two times that reported for open surgery. Other secondary outcomes were similar between groups, except for higher rates of vascular complications in the TAVI group and higher rates of major bleeding in the open surgery group. As in the first PARTNER cohort, there is concern about the generalizability of results because the patient selection process relied largely on the judgment of surgeons and cardiologists participating in the trial. The U.S. CoreValve High Risk Study reported that TAVI was noninferior to open surgical repair. Although unlike the PARTNER A trial, stroke rates were not higher in patients who underwent TAVI, a requirement for permanent pacemaker was more common in the TAVI group. Follow-up analyses of the U.S. CoreValve High Risk Study showed sustained improvements in the TAVI group for the outcome of all-cause mortality and a number of secondary outcomes. The incidence of pacemaker implantation continued to be higher in TAVI-treated patients.

The Portico valve was compared with other FDA-approved valves. Although more safety events were noted at 30 days, the valves had comparable outcomes at two years.

TAVI OUTCOMES IN PATIENTS AT INTERMEDIATE RISK OR LOW RISK FOR OPEN SURGERY

Systematic Reviews

Several systematic reviews and meta-analyses were published in 2017 through 2020,[50-63] including many overlapping RCTs and observational studies.

In a Cochrane review, Kolkailah (2019) evaluated the literature on TAVI versus SAVR for severe aortic stenosis in patients with low surgical risk.[64] The review included four studies (n=2,818) and one ongoing study. Results revealed that there is probably little or no difference between TAVI and SAVR with regard to the following short-term outcomes: all-cause mortality (RR 0.69, 95% CI 0.33 to 1.44), stroke (RR 0.73, 95% CI 0.42 to 1.25), myocardial infarction (RR 0.82, 95% CI 0.42 to 1.58), and cardiac death (RR 0.71, 95% CI 0.32 to 1.56). TAVI may potentially reduce the risk of short-term hospitalization as well (RR 0.64, 95% CI 0.39 to 1.06) and result in an increased risk of permanent pacemaker implantation (RR 3.65, 95% CI 1.50 to 8.87). TAVI reduces the risk of atrial fibrillation (RR 0.21, 95% CI 0.15 to 0.3), AKI (RR 0.3, 95% CI 0.16 to 0.58), and bleeding (RR 0.31, 95% CI 0.16 to 0.62) compared to SAVR.

Garg (2017) published a systematic review and meta-analyses that included RCTs and prospective observational studies comparing TAVI with SAVR published between January 2000 and March 2017 including low-to-intermediate surgical risk patients with severe aortic stenosis.[52] Five RCTs (n=4,425 patients) were included and are discussed in the following section. The meta-analytic results pooling the RCTs are shown in Table 2.

Table 2. TAVI Versus Surgical Repair in Low- or Intermediate-Risk Patients

Outcomes	TAVI	Surgical Repair	RR for TAVI vs. Surgical Repair (95% CI)	p	I^2
30-day mortality	3.1	3.0	1.04 (0.73 to 1.47)	0.84	0
Stroke incidence	7.3	8.1	0.91 (0.74 to 1.11)	0.35	0
Acute kidney injury incidence	1.8	4.7	0.38 (0.26 to 0.54)	<0.001	0
Myocardial infarction incidence	3.1	3.1	1.00 (0.71 to 1.41)	1.00	0
Major vascular complication incidence	7.3	3.2	3.09 (1.51 to 6.35)	0.002	66
Requirement for permanent pacemaker incidence	20.0	7.9	3.10 (1.44 to 6.66)	0.004	92

Adapted from Garg (2017).[52]
Values are percent unless other noted.
CI: confidence interval; RR: relative risk; TAVI: transcatheter aortic valve implantation.

Zhou (2016) reported on a meta-analysis comparing TAVI with surgical repair in patients at low or intermediate risk of open surgery.[65] Seven studies were included: three RCTs (Nordic Aortic Intervention Trial [NOTION; 2015],[66]Transapical Transcatheter Aortic Valve Implantation vs. Surgical Aortic Valve Replacement in Operable Elderly Patients with Aortic Stenosis [STACCATO; 2012],[67] Leon [2016][68]) and four observational studies (total n=6,214 patients, 3,172 [51.0%] treated with TAVI). The main meta-analytic results are summarized in Table 3. Importantly, this review included a meta-analytic result for mortality at one year.

Table 3. TAVI Versus Surgical Repair in Low- or Intermediate-Risk Patients

Outcomes	TAVI	Surgical Repair	RR for TAVI vs. Surgical Repair (95% CI)	p	I^2
Short-term postprocedure mortality	2.59	3.94	0.63 (0.37 to 1.08)	0.09	56
Short-term cardiovascular mortality	1.96	3.15	0.51 (0.23 to 1.15)	0.11	68
Acute kidney injury incidence	1.92	4.8	0.34 (0.17 to 0.67)	0.002	61
Stroke incidence	3.57	4.90	0.72 (0.56 to 0.92)	0.01	42
Myocardial infarction incidence	0.7	1.7	0.51 (0.23 to 0.69)	<0.001	10
Major vascular complication incidence	7.2	3.6	3.54 (1.42 to 8.81)	0.006	86
Requirement for permanent pacemaker incidence	11.9	6.1	2.79 (1.49 to 5.23)	0.001	88
All-cause mortality (one year)	10.1	12.2	0.82 (0.58 to 1.16)	0.26	67

Adapted from Zhou (2016).[65]
Values are percent unless other noted.
CI: confidence interval; OR: odds ratio; TAVI: transcatheter aortic valve implantation.

Earlier systematic reviews came to similar conclusions.[69 70] Siemieniuk (2016) also reported on a systematic review and meta-analysis comparing TAVI with surgical repair in patients at low- or intermediate-risk of open surgery, with the aim of evaluating valve durability and need for reinterventions.[71]

Overall, the results suggest that for intermediate and low operative risk patients, periprocedural and short-term (one-year) mortality rates do not differ significantly between TAVI and open aortic valve repair. However, like the high- and prohibitive-risk populations, TAVI is associated with higher rates of major vascular complications, paravalvular regurgitation, and need for permanent pacemakers, but lower rates of major bleeding.

RANDOMIZED CONTROLLED TRIALS

Eight RCTs including patients with severe aortic stenosis who were at low and/or intermediate risk for open surgery have been published. The RCTs are summarized in Tables 4 and 5 and the following paragraphs.

Table 4. Characteristics of RCTs Comparing TAVI With SAVR in Patients at Low and Intermediate Surgical Risk

					Interventions

Mixed Risk Populations Including Intermediate- and Low-Risk Patients

A previous RCT, the STACCATO trial, was designed to compare transapical TAVI using the SAPIEN valve with surgical aortic valve repair in operable patients with isolated aortic stenosis, without selection based on the predicted risk of death after surgery. However, the trial was prematurely terminated due to an increase in adverse events in the TAVI arm. The available results were reported by Nielsen (2012).[67] The trial was limited by a design that assumed a low event rate (2.5%). Also, operators' experience with the device and implantation techniques at the time of the trial might not be representative of current practice.

Reardon (2016) reported on an analysis of patients from the U.S. Pivotal High Risk Trial who had STS score less than 7.0% at baseline.[75] The trial was described in a previous section on high surgical risk. Of the 750 total patients in the trial, 383 (202 TAVR, 181 SAVR) had an STS PROM score of 7% or less, with a median STS PROM score of 5.3%. All-cause mortality at

two years for TAVR versus SAVR in the subgroup with STS score less than 7.0 was 15% (95% CI 9% to 20%) vs. 26% (95% CI 20% to 33%, p=0.01). The rates of stroke at two years for TAVR versus SAVR were 11% versus 15% (p=0.50).

Thyregod (2015) reported on the results of the NOTION RCT, which compared TAVI with surgical repair in 280 patients with severe aortic stenosis who were 70 years or older, regardless of the predicted risk of death after surgery.[66] Patients randomized to TAVI underwent implantation of the CoreValve self-expanding prosthesis by the femoral (preferred) or subclavian route. The trial was powered to detect an absolute risk reduction of 10% or a RR reduction of 66.7% in the primary outcome at one year. At baseline, 81.8% of the study population was considered to be at low risk (STS Risk Score <4). Some of the main findings from NOTION are summarized in Table 5. In addition, TAVI-treated patients had lower rates of major or life-threatening bleeding (11.3% vs. 20.9%, p=0.03), cardiogenic shock (4.2% vs. 10.4%, p=0.05), stage 2 or 3 AKI (0.7% vs. 6.7%, p=0.01), and new-onset or worsening atrial fibrillation (16.9% vs. 57.8%, p<0.001) than surgical repair patients, all respectively. Both groups showed improvements in NYHA functional class. However, more TAVI-treated patients were in NYHA functional class II at one-year follow-up (29.5% vs. 15.0%, p=0.01).

In a two-year follow-up of the NOTION trial, Søndergaard (2016) reported slight improvements in the TAVI-treated group (n=142) compared with the surgical repair group (n=134), although between-group differences were almost exclusively not statistically significant.[72] For the composite rate of death at two years, the between-group difference was also statistically insignificant (18.8% of surgical repair patients vs. 15.8% of TAVI-treated patients, p=0.43). A similar difference was observed for all-cause mortality (8.0% of patients treated with TAVI experienced all-cause mortality vs. 9.8% of the surgical repair patients, p=0.54). Cardiovascular mortality rates, stroke rates, and MI were likewise marginally improved in the TAVI-treated patients, although the only significant difference was found for atrial fibrillation and permanent pacemaker implantation. For the former outcome, there were 60.0% of surgical patients, compared with 22.7% of TAVI patients (p<0.001); for the latter, only 4.2% of surgical patients received implantation versus 41.3% of the TAVI group (p<0.001). As a secondary outcome, moderate aortic regurgitation was improved at two years for the TAVI group (15.4%) compared with the surgical group (0.9%, p<0.001). The authors noted that the variety of risk levels observed in the patients limited their results, as did the exclusion of patients with coronary artery disease. Further, the trial was limited by its lack of power for subgroup analyses, and its inability to reveal any significant differences between groups with certainty. Overall, the results showed that TAVI-treated patients had comparable, if not improved, outcomes when treated alongside patients who received SAVR.

Results after five years of follow-up were reported by Thyregod (2019).[73] There were no significant differences between TAVR and SAVR in the incidence of the composite primary outcome (38.0% vs. 36.3%, p=0.86) or any of the components of the composite. The incidence of moderate/severe total aortic regurgitation (8.2% vs. 0.0%, p<0.001) and a new pacemaker (43.7% vs. 8.7%, p<0.001) were both higher in the TAVR group. Four patients had prosthetic re-intervention. Søndergaard (2019) compared the durability of TAVR versus SAVR after six years of follow-up from NOTION. At six years, the rates of all-cause mortality were similar for TAVR (42.5%) and SAVR (37.7%) patients. The rate of moderate to severe structural valve deterioration was higher for SAVR than TAVR (24.0% vs. 4.8%, p < 0.001) and there were no differences in nonstructural valve deterioration (57.8% vs. 54.0%), bioprosthetic valve failure (6.7% vs. 7.5%) or endocarditis (5.9% vs. 5.8%).[74] At eight years of follow-up, Jørgensen

(2021) found no significant difference between TAVI and SAVR in the composite outcome of mortality, stroke, or MI.[82]

Toff (2022) published one-year results from an investigator-initiated, publicly funded, pragmatic RCT in the United Kingdom (UK TAVI) that compared clinical outcomes for 913 patients aged ≥80 years, or aged ≥70 years with low-to-intermediate surgical risk, with severe, symptomatic aortic stenosis randomized to TAVI or SAVR.[81] For the primary outcome (all-cause mortality at one year), TAVI was noninferior to SAVR (4.6% vs. 6.6%, adjusted absolute risk difference, -2.0%, one-sided 97.5% CI -∞ to 1.2%, p<0.001) based on a prespecified margin of 5%. The adjusted hazard ratio for death from any cause was 0.69 (95% CI 0.38 to 1.26, p=0.23). No significant differences in cardiovascular deaths or strokes (fatal or nonfatal) were found between groups. While TAVI was associated with significantly shorter hospital stay and fewer major bleeding events, it was also associated with more vascular complications (p<0.001), conduction disturbances requiring pacemaker implantation (p=0.01), and mild or moderate aortic regurgitation (p<0.001). Trial follow-up is planned for five years.

Including Intermediate-Risk Only

Reardon (2017) published two-year results from an RCT (SURTAVI trial) that compared clinical outcomes for 1,746 patients at intermediate surgical risk randomized to TAVR or SAVR.[76] For the primary outcome (composite death at two years), an improvement was observed in the TAVR-treated group, compared with surgery (12.6% of TAVR patients vs. 14.0% of SAVR patients [95% credible interval -5.2% to 2.3%], posterior probability >0.999). Rates of death, MI, and disabling stroke were comparable between groups, as were secondary outcomes that included echocardiographic measurement of aortic valve gradient and paravalvular regurgitation (data reported in the supplemental material). More patients were assigned to the CoreValve bioprosthesis (n=724) than received Evolut R bioprosthesis (n=137), which might have affected the results; also, a considerable number of patients withdrew consent before surgery, resulting in an as-treated population of 1660. Finally, the authors acknowledged a gap in knowledge of how baseline characteristics of patients who received surgery differed from those who did not. The authors noted the low 30-day surgical mortality ratio (0.38, observed-to-expected) and the similarity of this rate between groups (2.2% of the TAVR patients vs. 1.7% of surgical patients).

Leon (2016) reported on results of a multicenter noninferiority RCT (PARTNER 2A) comparing TAVI with the Edwards SAPIEN XT valve system in patients with severe aortic stenosis who were at intermediate risk for open surgery, stratified by access route (transfemoral or transthoracic).[68] Eligible patients had degenerative aortic valve stenosis, with NYHA functional class II or higher, and were in STS PROM score of 4 or greater (or <4 if determined by a heart team to have an “intermediate-risk patient profile with important comorbidities not represented in the STS Risk Calculator algorithm.”) The trial used a noninferiority design, with a primary composite endpoint of death from any cause or disabling stroke (score of ≥2 on the modified Rankin Scale) at two years and a noninferiority margin of 1.2 (i.e., noninferiority was considered met if upper bound of two-sided CI for the RR for the primary outcome was <1.2). A total of 2032 patients were randomized to TAVI (n=1,011) or surgical repair (n=1,021), with 1,550 considered suitable for transfemoral placement (76.3%) and 482 (23.7%) requiring transthoracic access. At baseline, the mean STS Risk Score was 5.8%; 81.3% had a score between 4% and 8%. The primary outcome results and select additional results of the trial are summarized in Table 5. Also, similar to other TAVI trials, the frequency and severity of paravalvular regurgitation was higher after TAVI than in surgical repair. The presence of

paravalvular regurgitation was associated with all-cause mortality during follow-up (HR for moderate or severe paravalvular regurgitation vs. none or trace 2.85, 95% CI 1.57 to 5.21, p<0.001). The five-year outcomes from the PARTNER 2A study revealed no significant difference in the incidence of death from any cause or disabling stroke between the TAVI and surgical repair groups (47.9% vs. 43.4%, HR 1.09, 95% CI 0.95 to 1.25, p=0.21).[83] Overall, more patients in the TAVI group had at least mild paravalvular aortic regurgitation (33.3% vs. 6.3%), experienced repeat hospitalizations (33.3% vs. 25.2%), and underwent aortic valve reinterventions (3.2% vs. 0.8%). Improvement in health status at five years was similar between the groups.

Including Low-Risk Only

Popma (2019) reported results of prespecified, interim analyses of the multinational Evolut Low Risk Trial, a noninferiority trial conducted from 2016 to 2018 comparing TAVR (n=734) to SAVR (n=734) in patients who had severe aortic stenosis and were at low surgical risk (STS-PROM ≤3%).[77] Patients with bicuspid aortic valves were excluded. Patients assigned to TAVR were treated with one of three Medtronic self-expanding, supra-annular bioprostheses (CoreValve, Evolut R, or Evolut PRO). Preliminary analyses were performed when 850 patients had reached 12-month follow-up. Long-term follow-up is scheduled to continue for 10 years. The primary outcome was a composite of death or disabling stroke at 24 months performed using Bayesian methods. At the time of the preliminary analysis, 149 patients had reached the 24 months visit. The 24-month estimated incidence of the primary outcome was 5.3% in the TAVR group and 6.7% in the SAVR group (risk difference -1.4%, 95% Bayesian credible interval −4.9 to 2.1, posterior probability of noninferiority >0.999). Several 30-day outcomes were also reported. The incidence at 30 days of disabling stroke (0.5% vs. 1.7%), bleeding complications (2.4% vs. 7.5%), AKI (0.9% vs. 2.8%), and atrial fibrillation (7.7% vs. 35.4%) were lower in TAVR compared to SAVR. The incidence at 30 days of moderate or severe aortic regurgitation (3.5% vs. 0.5%) and pacemaker implantation (17.4% vs. 6.1%) was higher in TAVR compared to SAVR. There was not a statistically significant difference in the KCCQ overall summary score at 30 days (88.7±14.2 in the TAVR group vs. 78.6±18.9 in the SAVR group). Forrest (2022) published two-year outcomes.[78] Follow-up data was available for 97.7% in the TAVI group and 92.3% in the SAVR group. The Kaplan-Meier estimate of all-cause mortality or disabling stroke at two years was 4.3% and 6.3% in the TAVI and SAVR groups, respectively (p=0.084). The number of patients requiring new permanent pacemaker implantation was significantly higher with TAVI (23.8% vs. 7.0%). Similar results were found at three years follow-up.

Mack (2019) reported results of the multinational PARTNER 3 trial randomizing patients with severe aortic stenosis and low surgical risk to either TAVR with the SAPIEN (n=503) or SAVR (n=497) in 2016 to 2017.[79] Patients bicuspid aortic valves were excluded. The primary outcome was a composite of death, stroke, or rehospitalization at one year. Follow-up is designed to continue for at least 10 years. Primary analyses were performed and reported in the as-treated population (n=496 in the TAVR, n=454 in SAVR) but sensitivity analyses of the primary outcome performed in the intention-to-treat population with multiple imputations for missing data were reportedly consistent with the primary analysis. The number of participants that did not receive the assigned treatment was higher in the SAVR group (7 vs. 43). The most common reported reason was refusal to undergo surgery or the choosing to undergo surgery at a non-trial site. The estimated incidence of the primary outcome at one year was significantly lower in TAVR versus SAVR (8.5% vs. 15.1%, risk difference -6.6%, 95% CI −10.8 to −2.5, p<0.001 for noninferiority). All components of the composite (death, stroke, and

hospitalization) individually favored TAVR at 30 days and one year. At 30 days, the rate of stroke (0.6% vs. 2.4%, HR 0.25 (95% CI 0.07 to 0.88), p=0.02) and new-onset atrial fibrillation (5.0% vs. 39.5%, HR 0.10 (95% CI 0.06 to 0.16) p<0.001) was lower in TAVR than SAVR and index hospitalization time was shorter (three days vs. seven days, p<0.001). There were no significant differences at 30 days in major vascular complications, new permanent pacemaker insertions, or moderate or severe paravalvular regurgitation. The incidence of mild paravalvular regurgitation at one year was higher with TAVR (29.4% vs. 2.1%). In an analysis specific to the echocardiographic findings of the PARTNER 3 trial, Pibarot (2020) reported that the percentage of moderate or severe aortic regurgitation was low and not statistically different between the TAVR and SAVR groups at 30 days (0.8% vs. 0.2%, p=0.38); mild aortic regurgitation occurred more frequently after TAVR than SAVR (28.8% vs. 4.2%, p<0.001).[84] Mean transvalvular gradient (13.7 ±5.6 vs. 11.6 ±5.0 mmHg, p=0.12) and aortic valve area (1.72 ±0.37 vs. 1.76 ±0.42 cm^2, p=0.12) were similar between groups at one year. In another analysis specific to atrial fibrillation (n=781), Shahim (2021) found lower early postoperative atrial fibrillation in patients following TAVI compared with SAVR (19.5% vs. 36.6%, p<0.0001).[85] At two-year follow-up, Leon (2021) reported continued improvement of the composite primary endpoint with TAVI versus SAVR (11.5% vs. 17.4%, HR 0.63, 95% CI 0.45 to 0.88, p=0.007); however, there was no significant difference in death or stroke between TAVI and SAVR.[80]

Study limitations

The purpose of the study limitation tables (see Tables 6 and 7) is to display notable limitations identified in each study. This information is synthesized as a summary of the body of evidence following the tables and provides the conclusions on the sufficiency of evidence supporting the position statement.

Table 6. Study Relevance Limitations

Section Summary: TAVI Outcomes in Patients at Intermediate- or Low-Risk for Open Surgery

Intermediate-Risk

Most participants in five RCTs were intermediate risk, and two RCTs included only intermediate surgical risk patients. The primary outcomes were generally a composite of death and stroke; most RCTs were noninferiority studies. The rates of the primary outcome were noninferior for TAVI compared with SAVR and numerically lower, although not statistically significantly lower in three of the five RCTs including the two RCTs exclusively enrolling intermediate risk patients. The rates of adverse events differed between groups, with bleeding, cardiogenic shock, and AKI higher in patients randomized to open surgery and permanent pacemaker requirement higher in patients randomized to TAVI. Subgroup analyses of meta-analyses and the transthoracic arm of the Leon RCT suggested that the benefit of TAVI may be limited to patients who are candidates for transfemoral access. Two-year follow-up results were published for NOTION, PARTNER 2A, CoreValve U.S. Pivotal, and SURTAVI trials, but reported outcomes did not include rates of reoperation. A number of recently completed meta-analyses evaluated mortality for TAVR versus SAVR at the 30-day mark. Mortality rates were found to be comparable between the two procedures.

Low-Risk

The NOTION and UK TAVI trials were predominantly low surgical risk patients; the Evolut Low Risk Trial and PARTNER 3 were only low-risk patients. The STACCATO trial also included some patients at low surgical risk. In the NOTION trial, the risk of the composite outcome of death from any cause, stroke, or MI at one year was numerically but not statistically significantly lower in the TAVR group compared to SAVR and after five years of follow-up,

there were still no significant differences between TAVR and SAVR in the incidence of the composite outcome (38.0% vs. 36.3%, p=0.86) or any of the components of the composite. Six-year follow-up from NOTION showed less structural valve deterioration in TAVR than SAVR. In the publicly sponsored UK TAVI trial, TAVI was noninferior to SAVR with respect to all-cause mortality at one year. In the Evolut Low Risk Trial, TAVR was noninferior to SAVR with respect to the composite outcome of death or disabling stroke at 24 months. At 30 days, TAVR was associated with a lower incidence of disabling stroke, acute kidney injury, bleeding events, and atrial fibrillation but with a higher incidence of aortic regurgitation and permanent pacemaker use. In the PARTNER 3 trial, the rate of the composite of death, stroke, or rehospitalization at one year was significantly lower with TAVR than SAVR. At 30 days, TAVR was associated with a lower rate of stroke, death or stroke composite, new-onset atrial fibrillation, and shorter index hospitalization. There were no significant between-group differences in major vascular complications or new permanent pacemaker insertions at 30 days. The age of participants in the low-risk RCTs was markedly lower than that in previous TAVR trials and therefore life expectancy is longer. Extended follow-up will be needed to address the long-term advantages and disadvantages of TAVR versus SAVR and valve durability. Both of the low-risk RCTs have planned follow-up of 10 years and both excluded patients with bicuspid aortic valves.

The ongoing NOTION 2 Trial (NCT02825134) includes only patients ≤75-years-old and does not exclude patients with bicuspid aortic valves. Data collection of the primary outcome was scheduled for completion in 2021.

TAVI OUTCOMES FOR "VALVE-IN-VALVE" APPROACH

Clinical Context and Therapy Purpose

The purpose of transcatheter aortic "valve-in-valve" implantation is to provide a treatment option that is an alternative to or an improvement on existing therapies, such as surgical aortic valve repair and medical management, in patients with valve dysfunction and aortic stenosis or regurgitation after aortic valve repair.

Systematic Reviews

Aedma (2022) conducted an umbrella or meta-meta-analysis evaluating the efficacy and safety of valve-in-valve (ViV) TAVI compared to redo-surgical aortic valve replacement (redo-SAVR).[86] Nine analyses were included for review. ViV TAVI was associated with a significantly lower risk of 30-day mortality (OR 0.60, 95% CI 0.53 to 0.68, p<0.00001) and procedural mortality (OR 0.52, 95% CI 0.27 to 0.98, p=0.04). No significant differences in one-year mortality or hospital readmissions were identified. ViV TAVI was also associated with a lower risk several complications, including stroke (OR 0.71, 95% CI 0.59 to 0.84, p<0.001), major bleeding (OR 0.44, 95% CI 0.35 to 0.57, p<0.000001), acute kidney injury (OR 0.57, 95% CI 0.43 to 0.75, p<0.0001), and pacemaker implantation (OR 0.67, 95% CI 0.52 to 0.86, p<0.002). No association of acute myocardial infarction with ViV TAVI and redo-SAVR was found (OR 1.15, 95% CI 0.84 to 1.59, p=0.38); however, ViV TAVI was associated with a higher risk of vascular complications (OR 2.70, 95% CI 1.58 to 4.62, p<0.0003).

Raschpichler (2022) published a meta-analysis of nonrandomized studies comparing ViV TAVI with redo-SAVR.[87] A total of 15 studies with 8,881 patients were identified for analysis, which included 4,458 patients (50.2%) treated with ViV TAVI and 4,423 patients (49.8%) treated with redo-SAVR. Short-term mortality (<30 days) was 2.8% in patients undergoing ViV TAVI

compared with 5.0% in patients undergoing redo-SAVR (RR 0.55, 95% CI 0.34 to 0.91). Midterm mortality (up to five years) was not significantly different between groups (HR 1.27, 95% CI 0.72 to 2.25). The rate of acute kidney failure was lower following ViV (RR 0.54, 95% CI 0.33 to 0.88); however, prosthetic aortic valve regurgitation (RR 4.18, 95% CI 1.88 to 9.3, p=0.003) and severe patient-prosthesis mismatch (RR 3.12, 95% CI 2.35 to 4.1, p<0.001) were significantly more frequent. Additionally, the transvalvular gradient was significantly higher following ViV procedures (standard mean difference 0.44, 95% CI 0.15 to 0.72, p=0.008). There were no significant differences between groups with respect to stroke, myocardial infarction, or pacemaker implantation. The authors concluded that the early safety advantages of ViV should be weighed against a potential midterm benefit of redo-SAVR. The authors also noted that given the likely selection bias in individual studies, an adequately powered multicenter randomized trial with sufficiently long follow-up in patients with low-to-intermediate surgical risk is warranted.

A subsequent time-to-event analysis of all-cause mortality in ViV TAVI versus redo-SAVR in 10 studies conducted by Sá (2023) similarly found a short-term protective effect with ViV TAVI in the first 44 days (HR 0.67, 95% CI 0.49 to 0.93, p=0.017).[88] A HR reversal was observed after 197 days favoring redo-SAVR (HR 1.53, 95% CI 1.22 to 1.93, p<0.001). Additionally, a statistically significant association of patient-prosthesis mismatch with all-cause mortality during follow-up for ViV TAVI was identified via Cox regression modeling (p<0.001).

In 2019, the National Institute for Health and Care Excellence prepared an interventional procedure overview on safety and efficacy of valve-in-valve TAVI for aortic bioprosthetic valve dysfunction based on a rapid review of medical literature including publications through August 2018 and specialist opinion.[89] The review included three systematic reviews and meta-analysis[90-92] and eight case series (registries) totaling 4,256 patients, although the authors note that there may be some overlap of patients in the global valve-in-valve register and other registries. There are no RCTs comparing valve-in-valve TAVI with redo SAVR. The available evidence is from observational studies and registry data with follow-up ranging from one month to one year. Two systematic reviews and meta-analysis compare valve-in-valve TAVI with redo SAVR and reported similar favorable outcomes. One of the included systematic reviews of 15 studies (861 patients) reported a pooled technical success rate of 95% (95% CI 94% to 97%). Another included systematic review of six observational studies reported no statistically significant difference between valve-in-valve TAVI and redo SAVR in perioperative mortality (5% vs. 6%, RR 0.78, 95% CI 0.33 to 1.84), late mortality (median one-year follow-up, incident rate ratio 0.93, 95% CI 0.74 to 1.16), or perioperative stroke (2% vs. 3%, RR 0.73, 95% CI 0.18 to 3.02), whereas, the rate of permanent pacemaker insertion was statistically significantly lower in the valve-in-valve TAVI group (8% vs. 15%, RR 0.57, 95% CI 0.32 to 1.0) and the rate of mild or greater paravalvular regurgitation was statistically significantly higher in the valve-in-valve TAVI group (21% vs. 6%, RR 3.83, 95% CI 1.2 to 12.22). In two registries (including 365 and 227 patients), the rate of conversion to surgery or surgical reintervention within 30 days was less than 1%.

Registries

Registries not included in the systematic reviews described above will be briefly summarized if they include longer follow-up than those already summarized.

Following the National Institute for Health and Care Excellence review, three-year results from the PARTNER 2 valve-in-valve registry were published by Webb (2019).[89] The registry

included 365 patients who had valve-in-valve[91 92] procedures with a mean age of 79 (± 10) years and mean STS-PROM score of 9.1% (±4.7). The estimated incidence of all-cause mortality at three years was 32.7%. Aortic valve re-replacement was performed in 1.9% by three years. From baseline to year three, NYHA functional class improved; 90.4% of patients were in class III or IV at baseline and 14.1% were in class III or IV at three years (p<0.0001). QoL as measured by the KCCQ overall score also increased from baseline to three years (43.1 to 73.1, p < 0.`

PRACTICE GUIDELINE SUMMARY

American College of Cardiology and American Heart Association

In 2014, the American College of Cardiology and the American Heart Association published joint guidelines on the management of valvular heart disease.[93] Both groups issued a joint focused update in 2017.[94] In 2020, a new full guideline was published that replaces the 2014 revision and 2017 focused update.[95] These guidelines made the following recommendations on the timing of intervention and choice of surgical or transcatheter intervention for treatment of aortic stenosis (see Table 8).

Additionally, the guidelines state the following:

- "Treatment of severe aortic stenosis with either a transcatheter or surgical valve prosthesis should be based primarily on symptoms or reduced ventricular systolic function. Earlier intervention may be considered if indicated by results of exercise testing, biomarkers, rapid progression, or the presence of very severe stenosis."
- "Indications for TAVI are expanding as a result of multiple randomized trials of TAVI versus surgical aortic valve replacement. The choice of type of intervention for a patient with severe aortic stenosis should be a shared decision-making process that considers the lifetime risks and benefits associated with type of valve (mechanical versus bioprosthetic) and type of approach (transcatheter versus surgical)."

Table 8. Recommendations on Surgical or Transcatheter Intervention for Aortic Stenosis

Recommendation	COR	LOE
Timing of Intervention		
“In adults with severe high-gradient AS (Stage D1) and symptoms of exertional dyspnea, heart failure, angina, syncope, or presyncope by history or on exercise testing, AVR is indicated."	I	A
“In asymptomatic patients with severe AS and a left ventricular ejection fraction <50% (Stage C2), AVR is indicated."	I	B
“In asymptomatic patients with severe AS (Stage C1) who are undergoing cardiac surgery for other indications, AVR is indicated."	I	B
"In symptomatic patients with low-flow, low-gradient severe AS with reduced left ventricular ejection fraction (Stage D2), AVR is recommended."	I	B
"In symptomatic patients with low-flow, low-gradient severe AS with reduced left ventricular ejection fraction (Stage D3), AVR is recommended if AS is the most likely cause of symptoms."	I	B
“In apparently asymptomatic patients with severe AS (Stage C1) and low surgical risk, AVR is reasonable when an exercise test demonstrates decreased exercise tolerance (normalized for age and sex) or a fall in systolic blood pressure of ≥10 mmHg from baseline to peak exercise."	IIa	B

Recommendation	COR	LOE
“In asymptomatic patients with very severe AS (defined as an aortic velocity of ≥5 m/s) and low surgical risk, AVR is reasonable."	IIa	B
“In apparently asymptomatic patients with severe AS (Stage C1) and low surgical risk, AVR is reasonable when the serum B-type natriuretic peptide level is >3 times normal."	IIa	B
"In asymptomatic patients with high-gradient severe AS (Stage C1) and low surgical risk, AVR is reasonable when serial testing shows an increase in aortic velocity ≥0.3 m/s per year."	IIa	B
"In asymptomatic patients with severe high-gradient AS (Stage C1) and a progressive decrease in left ventricular ejection fraction on at least 3 serial imaging studies to <60%, AVR may be considered.	IIb	B
"In patients with moderate AS (Stage B) who are undergoing cardiac surgery for other indications, AVR may be considered.	IIb	C
Choice of SAVR Versus TAVI for Patients for Whom a Bioprosthetic AVR is Appropriate		
"For symptomatic and asymptomatic patients with severe AS and any indication for AVR who are <65 years of age or have a life expectancy >20 years, SAVR is recommended."	I	A
"For symptomatic patients with severe AS who are 65 to 80 years of age and have no anatomic contraindication to transfemoral TAVI, either SAVR or transfemoral TAVI is recommended after shared decision-making about the balance between expected patient longevity and valve durability."	I	A
"For symptomatic patients with severe AS who are >80 years of age or for younger patients with a life expectancy of <10 years and no anatomic contraindication to transfemoral TAVI, transfemoral TAVI is recommended in preference to SAVR."	I	A
"In asymptomatic patients with severe AS and a left ventricular ejection fraction <50% who are ≤80 years of age and have no anatomic contraindication to transfemoral TAVI, the decision between TAVI and SAVR should follow the same recommendations as for symptomatic patients in the 3 recommendations above."	I	B
"For asymptomatic patients with severe AS and an abnormal exercise test, very severe AS, rapid progression, or an elevated B-type natriuretic peptide, SAVR is recommended in preference to TAVI."	I	B
"For patients with an indication for AVR for whom a bioprosthetic valve is preferred but valve or vascular anatomy or other factors are not suitable for transfemoral TAVI, SAVR is recommended."	I	A
"For symptomatic patients of any age with severe AS and a high or prohibitive surgical risk, TAVI is recommended if predicted post-TAVI survival is >12 months with an acceptable quality of life."	I	A
"For symptomatic patients with severe AS for whom predicted post-TAVI or post-SAVR survival is <12 months or for whom minimal improvement in quality of life is expected, palliative care is recommended after shared decision-making, including discussion of patient preferences and values."	I	C
"In critically ill patients with severe AS, percutaneous aortic balloon dilation may be considered as a bridge to SAVR or TAVI."	IIb	C
Intervention for Prosthetic Valve Stenosis		
"In patients with symptomatic severe stenosis of a bioprosthetic or mechanical prosthetic valve, repeat surgical intervention is indicated unless surgical risk is prohibitive."	I	B
"For severely symptomatic patients with bioprosthetic aortic valve stenosis and high or prohibitive surgical risk, a transcatheter ViV procedure is reasonable when performed at a Comprehensive Valve Center."	IIa	B
"For patients with significant bioprosthetic valve stenosis attributable to suspected or documented valve thrombosis, oral anticoagulation with a VKA is reasonable."	IIa	B

Recommendation	COR	LOE
Prosthetic Valve Regurgitation		
"In patients with intractable hemolysis or HF attributable to prosthetic transvalvular or paravalvular leak, surgery is recommended unless surgical risk is high or prohibitive."	I	B
"In asymptomatic patients with severe prosthetic regurgitation and low operative risk, surgery is reasonable."	IIa	B
"In patients with prosthetic paravalvular regurgitation with the following: 1) either intractable hemolysis or NYHA class III or IV symptoms and 2) who are at high or prohibitive surgical risk and 3) have anatomic features suitable for catheter-based therapy, percutaneous repair of paravalvular leak is reasonable when performed at a Comprehensive Valve Center."	IIa	B
"For patients with severe HF symptoms caused by bioprosthetic valve regurgitation who are at high to prohibitive surgical risk, a transcatheter ViV procedure is reasonable when performed at a Comprehensive Valve Center."	IIa	B

AS: aortic stenosis; AVR: aortic valve replacement; COR: class of recommendation; LOE: level of evidence; SAVR: surgical aortic valve replacement; TAVI: transcatheter aortic valve implantation.

SUMMARY

TAVI

There is enough research to show that transcatheter aortic valve implantation (TAVI) can improve health outcomes for individuals with heart failure who have severe symptomatic aortic stenosis. For patients who are not surgical candidates due to excessive surgical risk, trial results have shown decreased mortality for the TAVI patients at one year compared with medical care, but an increased risk of stroke and vascular complications. For patients who are surgical candidates, trials have shown similar or better outcomes for TAVI compared to open surgical procedures. Therefore, TAVI may be considered medically necessary for patients that meet the policy criteria.

TAVR

There is not enough research to show that transcatheter aortic valve replacement (TAVR) can improve health outcomes for individuals with bioprosthetic valves who have valve dysfunction and aortic stenosis or regurgitation compared with open repair. Studies comparing TAVR to surgical repair and have reported similar mortality, stroke, and survival rates for the two procedures, however there is a lack of high-quality trial data. Therefore, TAVR may be considered medically necessary for high- or prohibitive-risk surgical patients but is otherwise considered investigational.

Bicuspid Aortic Valves

There is not enough research to show that transcatheter aortic valve implantation or replacement can improve health outcomes for patients for patients with bicuspid valves. Individuals with bicuspid aortic valves were excluded from the large trials that evaluated transcatheter aortic valve implantation (TAVI) and transcatheter aortic valve replacement (TAVR), due to an increased risk of complications. Further study is needed to evaluate the long-term health outcomes and identify which patients may benefit from these procedures.

Therefore, TAVI and TAVR are considered investigational for patients with bicuspid aortic valves.

Other Indications and Devices

There is not enough research to show that transcatheter aortic valve implantation or replacement can improve health outcomes for patients without heart failure symptoms and severe aortic stenosis. There is also a lack of evidence regarding non-FDA-approved devices. Therefore, these are considered investigational.

Medical Policy Manual Surgery, Policy No. 204

Ablation of Primary and Metastatic Liver Tumors

Effective: March 1, 2024

Next Review: November 2024
Last Review: January 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Ablation is a method of locoregional therapy used to treat cancerous lesions, including hepatocellular carcinoma and hepatic metastases from other primary cancers.

MEDICAL POLICY CRITERIA

Note: This policy addresses locoregional therapies, specifically, percutaneous ethanol injection, cryoablation, radiofrequency and microwave ablation for primary and metastatic liver tumors. Please see Cross References for other ablative techniques and indications.

I. Percutaneous ethanol injection, cryoablation, radiofrequency and microwave local ablative techniques may be considered **medically necessary** for treatment of liver tumors when either of the following (A. or B.) are met:

   A. In patients *not* currently awaiting liver transplantation, and one or more of the following criteria are met:

      1. Unresectable primary liver tumors [hepatocellular carcinoma] when **all** of the following criteria (a.-c.) are met:

         a. The tumor(s) is 5 cm or less in diameter; and

b. There are no more than 3 hepatic lesions; and

c. There is documentation that the tumor(s) is unresectable (e.g., due to comorbidities or an estimate of inadequate liver volume following resection).

2. Hepatic metastases from colorectal tumors, including but not limited to adenocarcinoma when **all** of the following criteria (a.-d.) are met

a. The metastatic tumor(s) is 5 cm or less in diameter; and

b. There are no more than 5 hepatic lesions; and

c. There is documentation that the tumor(s) is unresectable (e.g., due to comorbidities, or an estimate of inadequate liver volume following resection); and

d. No extrahepatic metastatic disease is present.

3. Hepatic metastases from neuroendocrine tumors when **all** of the following criteria (a.-c.) are met:

a. The disease is symptomatic; and

b. Systemic therapy has failed to control symptoms; and

c. There is documentation that the tumor(s) is unresectable (e.g., due to comorbidities or an estimate of inadequate liver volume following resection)

B. As a bridge to liver transplantation when the intent is to prevent tumor progression or decrease tumor size to achieve or maintain a patient's candidacy for liver transplant.

II. Percutaneous ethanol injection, cryoablation, radiofrequency and microwave ablation are considered **investigational** as a treatment for all other benign or malignant liver tumors that do not meet the medical necessity criteria above, including but not limited to the following:

A. More than 3 hepatocellular carcinoma tumors; more than 5 metastatic colorectal tumors in the liver; or metastatic or primary liver tumors larger than 5 cm in diameter

B. Metastases to the liver from organ tumors other than colorectal, asymptomatic neuroendocrine tumors, or neuroendocrine tumors with symptoms controlled by systemic therapy

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

NEUROENDOCRINE TUMORS

Neuroendocrine tumors are rare, slow-growing, hormone-secreting tumors that may occur in numerous locations in the body.[1] Neuroendocrine tumors include the following:

- Carcinoid Tumors

- Islet Cell Tumors (also known as Pancreatic Endocrine Tumors)
- Neuroendocrine Unknown Primary
- Adrenal Gland Tumors
- Pheochromocytoma/paraganglioma
- Poorly Differentiated (High Grade or Anaplastic)/Small Cell
- Multiple Endocrine Neoplasia, Type 1 (also known as MEN-1 syndrome or Wermer's syndrome)
- Multiple Endocrine Neoplasia, Type 2 a or b (also known as pheochromocytoma and amyloid producing medullary thyroid carcinoma, PTC syndrome, or Sipple syndrome)

Neuroendocrine tumors may also be referred to by their location (e.g., pulmonary neuroendocrine tumors; gastroenteropancreatic neuroendocrine tumors).

Some appendiceal carcinoids, also called adenocarcinoids, goblet cell carcinoids, or crypt cell carcinoids, have mixed histology, including elements of adenocarcinoma. While these biphasic tumors have both neuroendocrine and adenocarcinoma components, the National Comprehensive Cancer Network (NCCN) recommends they be managed according to colon cancer guidelines.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

1. Specific description of the tumor(s) targeted for treatment including the following:
    - Tumor type (primary vs. metastatic; primary tumor type)
    - The location of tumor(s)
    - The number and size(s) of lesion(s) being treated
2. Rationale for the determination that the patient is not a surgical candidate or the tumor is unresectable
3. Whether the goal of treatment is curative or palliative
4. Comorbidities and any contraindicated treatments (e.g., surgery; radiation therapy)
5. Prior treatments, if any, and tumor response
6. Documentation of whether this treatment is to preserve organ function
7. Include documentation of the presence or absence of extra-hepatic disease

BACKGROUND

ABLATIVE TECHNIQUES

THERMAL ABLATION

Radiofrequency Ablation

Radiofrequency ablation (RFA) is one of a number of locoregional thermal ablation therapies to treat various benign or malignant tumors. RFA kills cells (cancerous and normal) by applying a heat-generating rapidly alternating radiofrequency current through probes inserted into the tumor. The cells killed by RFA are not removed but are gradually replaced by fibrosis and scar tissue. If there is local recurrence, it occurs at the edge of this scar tissue and, in some cases, may be retreated. RFA can be performed as an open surgical procedure, laparoscopically, or percutaneously with ultrasound or computed tomography (CT) guidance. The goals of RFA may include 1) controlling local tumor growth and preventing recurrence; 2) palliating symptoms; and 3) extending survival duration for patients with certain cancerous tumors.

Reports have been published on use of RFA to treat renal cell carcinomas, breast cancer, pulmonary (including primary and metastatic lung tumors), bone, and other tumors including those that are non-cancerous (benign). Well-established local or systemic treatment alternatives are available for each of these tumor types.

Radiofrequency ablation (RFA) has been investigated as a treatment for unresectable hepatic tumors, both as primary treatment and as a bridge to liver transplant. In the latter setting, RFA is being tested to determine whether it can reduce the incidence of tumor progression in patients awaiting transplantation and thus maintain patients' candidacy for liver ablation, transhepatic arterial chemoembolization, microwave coagulation, percutaneous ethanol injection, and radioembolization (yttrium-90 microspheres).

Microwave Ablation

Microwave ablation (MWA) is a technique in which the use of microwave energy induces an ultra-high speed, 915 MHz or 2.450 MHz (2.45 GHz), alternating electric field which causes water molecule rotation and the creation of heat. This results in thermal coagulation and localized tissue necrosis. In MWA, a single microwave antenna or multiple antennas connected to a generator are inserted directly into the tumor or tissue to be ablated; energy from the antennas generates friction and heat. The local heat coagulates the tissue adjacent to the probe, resulting in a small, approximately 2 to 3 cm elliptical area (5 x 3 cm) of tissue ablation. In tumors greater than 2 cm in diameter, 2 to 3 antennas may be used simultaneously to increase the targeted area of MWA and shorten operative time. Multiple antennas may also be used simultaneously to ablate multiple tumors. Tissue ablation occurs quickly, within one minute after a pulse of energy, and multiple pulses may be delivered within a treatment session depending on the size of the tumor. The cells killed by MWA are typically not removed but are gradually replaced by fibrosis and scar tissue. If there is local recurrence, it occurs at the edges. Treatment may be repeated as needed. MWA may be used to: 1) control local tumor growth and prevent recurrence; 2) palliate symptoms; and 3) extend survival duration.

Complications from MWA are usually considered mild and may include pain and fever. Other potential complications associated with MWA include those caused by heat damage to

normal tissue adjacent to the tumor (e.g., intestinal damage during MWA of the kidney or liver), structural damage along the probe track (e.g., pneumothorax as a consequence of procedures on the lung), liver enzyme elevation, liver abscess, ascites, pleural effusion, diaphragm injury or secondary tumors if cells seed during probe removal. MWA should be avoided in pregnant patients since potential risks to the patient and/or fetus have not been established and in patients with implanted electronic devices such as implantable pacemakers that may be adversely affected by microwave power output.

MWA is an ablative technique similar to radiofrequency or cryosurgical ablation; however, MWA may have some advantages. In MWA, the heating process is active, which produces higher temperatures than the passive heating of radiofrequency ablation and should allow for more complete thermal ablation in a shorter period of time. The higher temperatures reached with MWA (over 100° C) can overcome the “heat sink” effect in which tissue cooling occurs from nearby blood flow in large vessels potentially resulting in incomplete tumor ablation. MWA does not rely on the conduction of electricity for heating, and therefore, does not have electrical current flow through patients and does not require grounding pads be used during the procedure to prevent skin burns. Unlike radiofrequency ablation, MWA does not produce electric noise, which allows ultrasound guidance to occur during the procedure without interference. Finally, MWA can be completed in less time than radiofrequency ablation since multiple antennas can be used simultaneously.

Regulatory Status

There are several devices cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process for MWA. Covidien’s (a subsidiary of Tyco Healthcare) Evident Microwave Ablation System has 510(k) clearance for soft tissue ablation, including partial or complete ablation of non-resectable liver tumors. The following devices have 510(k) clearance for MWA of (unspecified) soft tissue:

- BSD Medical Corporation’s MicroThermX® Microwave Ablation System (MTX-180);
- MicroSurgeon Microwave Soft Tissue Ablation Device;
- Angiodynamics’ Solero Microwave Tissue Ablation System;
- Surgnova Healthcare Technologies’ Microwave Ablation System;
- Microsulis Medical’s Acculis Accu2i; and
- Johnson & Johnson’s NEUWAVE Microwave Ablation System

FDA determined that these devices were substantially equivalent to existing radiofrequency and MWA devices. FDA product code: NEY.

CRYOSURGICAL ABLATION

Cryosurgical ablation (also called cryosurgery, cryotherapy, or cryoablation) kills cells (cancerous and normal) by freezing target tissues, most often by inserting a probe into the tumor through which coolant is circulated. Cryosurgery may be performed as an open surgical technique or as a closed procedure under laparoscopic or ultrasound guidance.

The goals of cryosurgery may include the following:

- Destruction or shrinkage of tumor tissue
- Controlling local tumor growth and preventing recurrence
- Palliating symptoms

- Extending survival duration for patients with certain tumors.

Potential complications associated with cryosurgery in any organ include the following:

- Hypothermic damage to normal tissue adjacent to the tumor (e.g., nerve damage)
- Structural damage along the probe track
- Secondary tumors if cancerous cells are seeded during probe removal.

Regulatory Status

There are several cryoablation devices cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process for use in open, minimally invasive or endoscopic surgical procedures in the areas of general surgery, urology, gynecology, oncology, neurology, dermatology, proctology, thoracic surgery and ear, nose and throat. Examples include:

- Cryocare® Surgical System by Endocare;
- CryoGen Cryosurgical System by Cryosurgical, Inc.;
- CryoHit® by Galil Medical;
- IceRod® CX, IcePearl® 2.1 CX and IceFORCE® 2.1 CX Cryoablation Needles by Galil Medical;
- SeedNet™ System by Galil Medical;
- Visica® System by Sanarus Medical;
- Visual-ICE® Cryoablation System by Galil;
- ERBECRYO 2® Cryosurgical Unit, ERBE USA Incorporated

PERCUTANEOUS ETHANOL INJECTION

Using a needle, percutaneous ethanol injection (PEI) delivers an injection of 95 percent ethanol directly into a tumor. Multiple treatment sessions may be performed in order to achieve tumor destruction. Prior to RFA, PEI was the most widely accepted, minimally invasive method to treat hepatocellular carcinoma. Like other local ablative techniques, PEI is most successful in small HCC tumors when resection is not an option.

LIVER (HEPATIC) TUMORS

Hepatic tumors can arise either as primary liver cancer (such as hepatocellular carcinoma, HCC) or by metastasis to the liver from other primary cancer sites. Local therapy for hepatic metastasis may be indicated when there is no extrahepatic disease, which rarely occurs for patients with primary cancers other than colorectal carcinoma or certain neuroendocrine malignancies. At present, surgical resection with adequate margins or liver transplantation constitutes the only treatments available with demonstrated curative potential. Partial liver resection, hepatectomy, is considered the gold standard. However, the majority of hepatic tumors are unresectable at diagnosis, due either to their anatomic location, size, number of lesions, or underlying liver reserve.

Locoregional therapies are proposed as a treatment for unresectable hepatic tumors, both as primary treatment, palliative treatment, and as a bridge to liver transplant. In the case of liver transplants, it is hoped that locoregional ablative techniques will reduce the incidence of tumor progression while awaiting transplantation and thus maintain a patient's candidacy for liver transplant during the wait time for a donor organ.

EVIDENCE SUMMARY

MULTIPLE ABLATIVE TECHNIQUES

Systematic Reviews

Lu (2022) performed a systematic review of ten studies, including 854 patients with histologically proven HCC who received a combination of RFA and PEI or RFA alone.[2] The results demonstrated that patients who received RFA-PEI had slight improvements in 1-year overall survival (OS) [risk ratio (RR): 1.11; 95% CI: 1.03, 1.19] 2-year OS (RR: 1.25; 95% CI: 1.12, 1.40), 3-year OS (RR: 1.42; 95% CI: 1.11, 1.83), 1-year local recurrence-free (LRF) proportion (RR: 1.2; 95% CI: 1.01, 1.42), and complete tumor necrosis (CTN) (RR: 1.32; 95% CI: 1.14, 1.53). Common complications, such as fever, were found to be significant (RR: 1.78, 95% CI: 1.13, 2.80). Despite RFA-PEI appearing to be superior for HCC patients with a compensated liver in terms of OS, current evidence contained moderate to significant heterogeneity, and it was difficult to draw a definite conclusion regarding the therapeutic management in terms of LRF and CTN.

Yu (2021) performed a meta-analysis of RCTs comparing RFA with microwave ablation for the treatment of localized, very early- or early-stage HCC.[3] Five RCTs comparing RFA (n=413) and microwave ablation (n=431) were identified. The OS between microwave ablation and RFA was not significantly different at one year (OR=0.705; 95% CI 0.382 to 1.301) or three years (OR=0.972; 95% CI 0.615 to 1.538). Similarly, there was no difference observed in recurrence-free survival between microwave ablation and RFA at one year (OR=1.167; 95% CI: 0.568 to 2.396) and three years (OR=0.981; 95% CI 0.616 to 1.562). Among the procedure-related complications evaluated, there were no statistically significant differences between the two groups.

A similar analysis was published by Gupta in 2021 that compared outcomes for very early and early HCC following RFA, MWA, or cryoablation.[4] A total of 19 studies (six RCTs and 13 observational studies) met inclusion criteria. No statistically significant differences between groups were identified for OS or local recurrence (LR).

Shin (2021) compared the efficacy of surgical resection with local ablative therapies for HCC meeting Milan criteria.[5] The analysis included seven RCTs and 18 non-randomized trials (n=5,629) that compared surgical resection with either RFA, microwave ablation, or RFA plus TACE. Four of the RCTs were judged to be at high risk of bias overall, due to either lack of reported randomization method or missing data. All non-randomized trials were classified as having a high risk for bias due to the missing data. There was no significant difference between surgical resection and RFA alone when the RCTs were analyzed; the three- and five-year OS favored surgical resection in the analysis of the non-randomized trials. A multiple treatment meta-analysis using a frequentist framework random effect model found that 5-year recurrence free survival was highest with surgical resection (hazard ratio [HR]=0.64, 95% CI 0.56 to 0.74 vs RFA), followed by RFA plus TACE (HR=0.70, 95% CI 0.53 to 0.92 vs RFA); no difference was found between microwave ablation and RFA (HR=0.93, 95% CI 0.63 to 1.37). However, the latter comparisons were limited by the number of trials evaluating RFA plus TACE (five studies) and microwave ablation (two studies).

Cui (2020) conducted a systematic review and meta-analysis of MWA compared to various treatment modalities for the treatment of hepatocellular carcinoma.[6] The analysis included four RCTs, with three comparing MWA to RFA and one comparing MWA to TACE. The

remaining 11 studies were nonrandomized trials comparing MWA to RFA (eight studies), resection (two studies), or ethanol ablation (one study). Meta-analyses were not performed for MWA versus TACE or ethanol ablation, because these comparisons were only examined in one study each. Meta-analyses of studies comparing MWA to RFA found no difference in three-year OS, five-year OS, local tumor progression at one year, progression-free survival at three years, or major complications. A meta-analysis of two nonrandomized studies comparing MWA to resection found no difference in three-year OS between treatments; however, this comparison is limited by the small number of studies included and the lack of RCTs included. The reviewers concluded that MWA showed similar safety and efficacy compared with RFA, but higher quality clinical studies are needed to validate the superiority of MWA.

Gui (2020) reported a systematic review and meta-analysis of trans-arterial chemoembolization plus RFA compared to surgical resection for hepatocellular carcinoma.[7] One RCT and eight retrospective studies met inclusion criteria. According to the unadjusted pooled analysis, there was no significant difference in one-, three-, and five-year OS and one-year disease-free survival between TACE+RFA and surgical resection. There were statistically significant differences favoring surgical resection in three-year disease-free survival (odds ratio [OR] 0.78, 95% confidence interval [CI] 0.62 to 0.98, p=0.03) and five-year disease-free survival (OR 0.74, 95% CI 0.58 to 0.95, p=0.02) compared to TACE+RFA. In the propensity matched analysis, the difference in three- and five-year disease-free survival was not significant.

Han (2020) reported a systematic review comparing MWA and RFA for early stage hepatocellular carcinoma.[8] Five RCTs, one prospective cohort studies and 20 retrospective cohort studies were included, for a total of 4,396 patients. Four of the RCTs were rated as high quality and one as low quality. Of the remaining studies, 16 were rated as high quality and five as low quality. According to the meta-analysis, there were no statistically significant differences between MWA and RFA for disease progression (OR=0.877, 95% CI 0.710 to 1.084, I^2=0%, p =0.225), or survival, either overall or disease-free (hazard ratio [HR]=0.891 and 1.014, p=0.222 and 0.852, respectively). Only six studies reported the OS rates, with five reporting one-year, five reporting three-year, and three reporting five-year OS. The one-, three-, and five-year OS estimates were 88.00% (95% CI 72.30% to 100%), 47.00% (95% CI 23.50 to 70.50%), and 17.00% (95% CI 0 to 34.60%) for LITT; 95.10% (95% CI 91.20 to 99.00%), 76.83% (95% CI 67.00 to 86.60%), and 27.00% (95% CI 11.00 to 51.00%) for RFA; not reported, 66.67% (95% CI 29.40 to 103.90%), and 33.33% (95% CI 0 to 70.60%) for MWA; and 91.49% (95% CI 83.70 to 99.30%), 79.3% (95% CI 59.70 to 98.90%), and not reported for PC.

Xiang (2020) published a systematic review and pooled analysis of multiple types of magnetic resonance-guided ablation techniques for the treatment of liver tumors.[9] Thirty studies (14 on RFA, one on MWA and RFA, eight on LITT, two on percutaneous cryoablation, and one on percutaneous ethanol injection) met inclusion criteria. No quality assessment was reported. The rates of complete ablation were 95.60%, 98.86%, 77.78%, 47.92%, and 85.71% in patients who underwent RFA, MWA, LITT, PC, and PEI, respectively.

Glassberg (2019) performed a systematic review and meta-analysis comparing MWA and RFA for the treatment of liver cancer.[10] A total of 28 RCTs and observational studies met inclusion criteria. The overall quality of the studies was rated as acceptable and most studies had low or unclear risk of bias across most domains. The meta-analysis indicated that local tumor progression was significantly reduced in patients treated with MWA as compared to RFA,

whether the analysis included all studies (30% reduction, risk ratio [RR]=0.70, p=0.02) or RCTs only (45% reduction, RR=0.55, p=0.007). No other efficacy or safety outcomes were found to be significantly different between groups.

Di Martino (2019) compared local ablative therapies for resectable colorectal liver metastases in a systematic review and meta-analysis.[11] Therapies evaluated included RFA, MWA, cryoablation and electroporation. A total of 20 studies with 860 patients met inclusion criteria. Surgical resection was superior to local ablative therapies with respect to disease-free survival, tumor progression, and overall survival. Compared to surgical resection, RFA reduced one-year disease-free survival (RR 0.83, 95% CI 0.71 to 0.98), three-year disease-free survival (RR 0.5, 95% CI 0.33 to 0.76), five-year DFS (RR 0.53, 95% CI 0.28 to 0.98) and five-year OS (RR 0.76, 95% CI 0.58 to 0.98).

A meta-analysis by Meijerink (2018) compared RFA and MWA to systemic chemotherapy and to partial hepatectomy (PH) for the treatment of colorectal liver metastases.[12] Forty-eight articles were identified, most of which were observational studies and case series, although two RCTs and eight systematic reviews were included. The authors found 18 observational studies of very low quality that looked at RFA alone compared to PH alone or PH plus RFA. For OS, their analysis concluded that PH alone was superior to RFA alone (HR=1.78; 95% CI 1.35 to 2.33). The meta-analysis for 30-day mortality comparing RFA alone to PH alone showed no difference between the two interventions (RR=0.64; 95% CI 0.21 to 1.95). DFS was higher for PH alone over RFA alone (HR=1.49; 95% CI 1.23 to 1.81), as well as for local progression-free survival (HR=5.36; 95% CI 1.64 to 17.52). However, complication rates were lower for RFA alone than for PH alone (risk ratio=0.47; 95% CI 0.28 to 0.78). One limitation of this review is that the included observational studies were all confounded by indication because RFA was only performed on unresectable lesions. Observational studies are also at increased risk for publication bias.

Majumdar (2017) published a Cochrane review and network meta-analysis of the management of early and very early-stage HCC.[13] Reviewers included 14 RCTs (total n=2533 patients) of nonsurgical treatments compared with each other, sham, or no intervention in patients with unresectable HCC. The quality of the evidence was rated as low or very low for all outcomes. Follow-up ranged from 6 to 37 months. Compared with RFA, mortality was higher for percutaneous acetic acid injection (HR=1.8; 95% CI 1.1 to 2.8; one trial; n=125) and PEI (HR=1.49; 95% CI 1.2 to 1.9; five trials; n=882). No trials reported health-related quality of life.

In 2016, Lan published a network meta-analysis comparing different interventional treatments for early stage HCC.[14] A total of 21 RCTs were included that compared transhepatic arterial chemoembolization (TACE), RFA, percutaneous ethanol injection (PEI), and hepatic resection, or combinations of treatments. These studies were all rated at a low-to-moderate risk of bias, with lack of blinding being the most substantial limitation. The primary outcome measures were overall survival (OS) at one, three, and five years posttreatment. The treatments and combinations of treatments were rank-ordered by results on OS. At each time point, the combination of RFA plus TACE was the number one ranked treatment. The combination of RFA plus TACE ranked second highest at one and three years, and was third highest at five years, with hepatic resection ranked second at five years. RFA alone was ranked as the fourth highest treatment at one year and the fifth highest treatment at three and five years.

In 2016, Facciorusso reported results from a systematic review and meta-analysis of one RCT and six retrospective studies (n=774) comparing RFA and MWA for the treatment of

unresectable hepatocellular carcinoma (HCC).[15] The authors found a non-significant trend of higher complete response rates in the patients treated with MWA (OR=1.12, 95% CI 0.67 to1.88, p = 0.67). Overall local recurrence was similar between the two treatment groups (OR 1.01, 95% CI 0.53 to 1.87, p=0.98) but MWA outperformed RFA in cases of larger nodules (OR 0.46, 95% CI 0.24 to 0.89, p=0.02). Three-year survival was higher after RFA without statistically significant difference (OR 0.95, 95% CI 0.58 to 1.57, p=0.85). Major complications were more frequent, although not significantly, in MWA patients (OR 1.63, 95% CI 0.88 to 3.03, p=0.12).

In a 2013 Cochrane review, Weis reviewed studies on RFA for HCC versus other interventions.[16] Moderate-quality evidence demonstrated hepatic resection had superior survival outcomes compared with RFA; however, resection might have greater rates of complications and longer hospital stays. Other systematic reviews and meta-analyses have also found superior survival with hepatic resection but higher rates of complications than RFA.[17-20] This finding reinforces the use of RFA only for unresectable HCC. The Cochrane review also reported finding moderate quality evidence demonstrating superior survival with RFA over PEI.[16] Evidence on RFA versus acetic acid injection, microwave ablation, or laser ablation was insufficient to draw conclusions.[16]

RADIOFREQUENCY ABLATION

RFA AS A PRIMARY TREATMENT OF HEPATOCELLULAR CANCER

Systematic Reviews

Jia (2021) performed a meta-analysis to compare clinical efficacy between RFA and surgical resection in patients with HCC meeting Milan criteria.[21] The analysis only included RCTs, accounting for eight trials (n=1,177). There were no significant differences found between RFA and surgical resection in OS and disease-free survival (DFS) rates. In a subgroup analysis stratifying by tumor size, there was still no significant differences between the two therapies for both tumors ≤4 cm and >4 cm. Limitations of the analysis include inclusion of clinical trials with small sample sizes and a lack of double blinding as it is not feasible.

Pan (2020) reported a systematic review comparing stereotactic body radiotherapy and RFA for hepatocellular carcinoma.[22] No RCTs and 10 retrospective studies (n=2,732 patients) met inclusion criteria. Over half of the studies were giving a medium score for quality because of inconsistent comparability. According to the meta-analysis, SBRT had significantly higher one- and three-year local control (OR 0.42, 95% CI 0.24 to 0.74, p=0.003; and OR 0.54, 95% CI 0.37 to 0.80, p=0.002, respectively) and significantly shorter one- and two-year OS (OR 1.52, 95% CI 1.21 to 1.90, p=0.0003; and OR 1.66, 95% CI 1.38 to 2.01, p<0.00001, respectively). When used as a bridge to treatment, no significant differences were identified between groups in transplant rate or post-transplant pathological necrosis rate (OR 0.57, 95% CI 0.32 to 1.03, p=0.060; and OR 0.49, 95% CI 0.13 to 1.82, p=0.290, respectively).

Jin (2020) performed a systematic review of RCTs comparing laparoscopic hepatectomy and RFA for HCC.[23] Seven RCTs met inclusion criteria. The studies were at unclear risk of bias for allocation concealment and blinding (participants, personnel, and outcome assessment) and low risk of reporting and attrition bias. Pooling of the five studies that reported duration of surgery showed that the RFA group had significantly shorter duration than the hepatectomy group (MD=−99.04; 95% CI −131.26 to −66.82; p<0.001; I^2=95%). Four studies reported the incidence of cancer recurrence, and pooled data from these RCTs indicated a higher rate of

recurrence in the RFA group (OR=2.68; 95% CI 1.72 to 4.18; p<0.001; I^2=23%). The pooled data from the four RCTs that reported on estimated bleeding volume during surgery and duration of hospital stay showed that the RFA group had significantly lower volume (MD=−241.97; 95% CI −386.93 to −97.02; p< 0.001; I^2=97%) and shorter duration (MD=−3.4; 95% CI −5.22 to −1.57; p<0.001; I^2=94%) than the hepatectomy group. Pooling of the three studies that reported the incidence of blood transfusion during surgery indicated significantly lower incidence in the RFA group (OR=0.08; 95% CI 0.02 to 0.37; p=0.001; I^2=0%).

Li (2019) performed a systematic review and meta-analysis to compare the effectiveness of laparoscopic hepatectomy and RFA.[24] A total of 10 studies met inclusion criteria. This included 1,570 HCC patients treated with laparoscopic hepatectomy or RFA. The pooled five-year OS rate was significantly higher in the hepatectomy group (OR=0.53, 95% CI=0.40, 0.69, p<0.001) analyzed as a whole and in a subgroup analysis of small HCCs (OR=0.47, 95% CI=0.33, 0.66, p<0.001). The hepatectomy group also had better one- and three-year disease-free survival rate and a lower recurrence rate, but additionally a higher complication rate (OR=0.64, 95% CI 0.46 to 0.89, p=0.008).

Si (2019) reported results of a systematic review and meta-analysis of minimally invasive liver surgery compared to RFA for the treatment of small HCC nodules.[25] A total of six studies met inclusion criteria, including 313 RFA-treated and 284 surgically treated patients. Three-year OS rates were significantly higher in the surgically treated patients (OR 0.55; 95% CI 0.36 to 0.84), as were three-year disease-free survival rates (OR 0.63; 95% CI 0.41 to 0.98). RFA-treated patients experienced significantly higher rates of local intrahepatic recurrence (OR 2.24; 95% CI 1.47 to 3.42), lower incidence of postoperative complications (OR 0.34; 95% CI 0.22 to 0.53), and shorter operation (OR - 145.31, 95% CI - 200.24 to - 90.38) and hospitalization (OR - 4.02,95% CI - 4.94 to - 3.10) durations.

Another systematic review comparing surgery to RFA, this one of early HCC, was reported by Tan (2019).[26] A total of 11 studies met inclusion criteria. These included 1,691 patients undergoing hepatic resection or RFA. The hepatic resection group had statistically significantly higher three- and five-year OS, as well as three-year disease-free survival. This group also had a lower local recurrence rate that did not reach statistical significance. Patients undergoing laparoscopic radiofrequency ablation had higher three- and five-year OS than other minimally invasive ablation techniques.

In 2012, Xu reported on a meta-analysis of 13 studies that compared RFA with surgical resection for early HCC.[27] Only two studies were RCTs. Surgical resection was done in 1233 patients and RFA was used in 1302 patients. Surgical resection patients had significantly longer OS rates at one, three, and five years than RFA patients (OR 0.60; 95% CI 0.42 to 0.86, OR=0.49; 95% CI 0.36 to 0.65; OR=0.60; 95% CI 0.43 to 0.84), respectively. When only HCC tumors of 3 cm or less were analyzed, resection still had significantly better OS than RFA at one, three, and five years. Recurrence rates were also significantly lower in the surgical resection group at one, three, and five years than in the RFA group (OR=1.48; 95% CI 1.05 to 2.08; OR=1.76; 95% CI 1.49 to 2.08; OR=1.68; 95% CI 1.21 to 2.34; all respectively). Local recurrence rates did not differ significantly between procedures. Complication rates were higher with resection than with RFA (OR=6.25; 95% CI 3.12 to 12.52; p=0.000), but, in a subanalysis of HCC 3 cm or less, complication rates were significantly lower with resection than RFA.

Randomized Controlled Trials

No randomized trials published after the above systematic reviews were identified.

Nonrandomized Studies

A large body of case series, meta-analyses, and retrospective evidence has been published on RFA as a treatment of unresectable primary liver tumors.[28-34] These articles reported disease-free survival rates consistent with those reported in the randomized controlled trials.

RFA AS A PRIMARY TREATMENT OF INTRAHEPATIC CHOLANGIOCARCINOMAS

Cholangiocarcinomas are tumors that originate in the bile duct epithelium; 90% are adenocarcinomas. Intrahepatic cholangiocarcinomas (ICC) are located within the hepatic parenchyma. They may also be referred to as peripheral cholangiocarcinomas. Extrahepatic cholangiocarcinomas (ECC) are more common than intrahepatic cholangiocarcinoma and are located within the extrahepatic bile duct. Complete resection with negative margin is potential curative, though recurrence is common and most cases are unresectable due to advanced disease when diagnosed. For unresectable or metastatic cholangiocarcinomas at any location, the primary treatment may include chemotherapy, treatment within a clinical trial, or best supportive care. RFA and other locoregional therapies may be an option. Biliary drainage with biliary stenting may be warranted for unresectable or metastatic extrahepatic disease. Liver transplantation is potentially curative in carefully selected patients with lymph node negative, nondisseminated locally advanced hilar cholangiocarcinomas and otherwise normal biliary and hepatic function or underlying liver disease precluding surgery.

A number of small (n<20) retrospective analyses and case series have been published for ablation of ICC.[35-43] These studies consistently reported high technical effectiveness with early tumor necrosis, and a low rate of major adverse effects.

RFA AS A PRIMARY TREATMENT OF LIVER METASTASES OF COLORECTAL AND NEUROENDOCRINE ORIGIN

Colon Cancer

More than half of patients with colorectal cancer (CRC) will develop liver metastases, generally with a poor prognosis.[44] A median survival of 21 months has been observed in patients with a single CRC liver metastasis; those with several unilobar lesions have median survival of 15 months; and those with disseminated metastases have median survival of less than one year. A number of first-line systemic chemotherapy regimens have been used to treat metastatic CRC, with a two-year survival rate of 25% for those treated with 5-fluorouracil (5-FU) or 5-FU plus leucovorin.[44] With the introduction of newer agents (e.g., irinotecan, oxaliplatin) and targeted drugs (e.g., cetuximab, bevacizumab), two-year survival rates have increased to between 30% and 39%, with marked improvement in OS. Because the liver is often the only site of metastases from CRC, however, locoregional therapies have been investigated. Surgical resection is considered the criterion standard for treatment of CRC liver metastases, with five-year actuarial survival rates that historically range from 28% to 38%, but may reach 58% in appropriately selected, resectable patients without widely disseminated disease.[45, 46] However, only 10% to 25% of patients with CRC metastases are eligible for surgical resection because of the extent and location of the lesions within the liver or because of the presence of comorbid conditions or disseminated disease. Unresectable cases or those for whom surgery is contraindicated typically are treated with systemic chemotherapy, with poor results and considerable adverse effects.

Alternatively, RFA has been proposed to treat metastatic CRC in the liver. Early clinical experience with RFA comprised case series to establish feasibility, safety, tolerability, and local therapeutic efficacy in short-term follow-up. A 2006 literature review encompassing six case series (total n=446 patients) showed that RFA of unresectable CRC metastases was associated with one-, two-, and three-year survival rates that ranged from 87% to 99%, 69% to 77%, and 37% to 58%, respectively.[45] While these results suggested RFA may have clinical benefit in this setting, a primary caveat is the definition of the term “unresectable” in the different series and that different surgeons may have different opinions on this issue. Further, differences in lesion size, number, distribution, prior treatments, RFA technology, and physician experience may affect results, making it difficult to compare results of different studies.

Systematic Reviews

Hao (2020) reported a systematic review and meta-analysis of RFA versus liver resection for solitary colorectal liver metastases.[47] A total of 10 studies met inclusion criteria. Study quality was not assessed. Significant interstudy heterogeneity was identified. Statistically significant differences were identified in the meta-analysis for one-year PFS (RR 0.77 95% CI 0.630 to 0.940, p=0.009), three-year OS (RR 0.860, 95% CI 0.760 to 0.980, p=0.021, and five-year OS (RR 0.66, 95% CI 0.52 to 0.85, p=0.001), with superior outcomes in the resection group. There was significantly lower incidence of postoperative complication in the RFA group (RR 0.340, 95% CI 0.230 to 0.510, p=0.000). The subgroup analysis identified the following variables as contributing to the heterogeneity: publication year, geographic location, tumor size, adjuvant chemotherapy, and synchronous metastases.

A 2017 systematic review with meta-analyses by van Amerongen compared the RFA to surgery as a curative treatment for patients with colorectal liver metastases.[48] Authors found that all studies included had risk of patient selection bias.

A 2012 systematic review by Cirocchi analyzed 17 nonrandomized studies and a meeting abstract of an RCT on RFA for CRC liver metastases.[49] The RCT reported PFS was significantly higher in 60 patients receiving RFA plus chemotherapy than in 59 patients receiving only chemotherapy. The RCT did not report OS. This Cochrane review found different types of vulnerability in all reviewed studies. Of main concern was the imbalance in patient characteristics across studies reviewed, as well as heterogeneity in the interventions, comparisons, and outcomes. Therefore, the reviewers concluded the evidence was insufficient to recommend RFA for CRC liver metastasis. In a 2014 Health Technology Assessment, Loveman also found insufficient evidence to draw conclusions on the clinical effectiveness of ablative therapies, including RFA, for liver metastases.[50]

In 2012, Weng reported a meta-analysis comparing RFA with liver resection for the treatment of CRC liver metastases.[51] One prospective study and 12 retrospective studies were included in the analysis. OS at three and five years was significantly longer in liver resection than in RFA (relative risk [RR], 1.377; 95% CI 1.246 to 1.522; RR=1.474; 95% CI 1.284 to 1.692, respectively). DFS was also significantly longer in liver resection than RFA at three and five years (RR=1.735; 95% CI 1.483 to 2.029; RR=2.227; 95% CI 1.823 to 2.720, respectively). While postoperative morbidity with liver resection was significantly higher than with RFA (RR=2.495; 95% CI 1.881 to 3.308), mortality did not differ significantly between treatments. Liver resection also performed significantly better than RFA when data were analyzed in three subgroups: tumors less than 3 cm, solitary tumor, and open or laparoscopic approach.

However, hospital stays were significantly shorter (9.2 days vs 3.9 days, p<0.01) and rates of complications lower (18.3% vs 3.9%, p<0.01) with RFA than liver resection. Interpretation of the meta-analysis is limited by the retrospective nature of most studies.

Randomized Controlled Trials

In 2012 and 2017, Ruers published the results of a multicenter RCT that compared RFA plus systemic treatment with systemic treatment alone for unresectable colorectal liver metastases.[52, 53] This RCT, originally designed as a phase 3 study, was completed as a phase 2 study due to slow accrual (n=119 patients). To be included in the trial, patients had to have nonresectable liver metastases with fewer than 10 nodes and without extrahepatic disease. In the experimental arm, RFA, with or without additional resection, was given in combination with systemic therapy. The primary end point was a 30-month survival higher than 38% in the experimental arm with intention-to-treat analysis. At three years, OS did not differ significantly between groups. However, there was a significant improvement in progression-free survival (HR=0.74; 95% CI 0.42 to 0.95; p=0.025), which corresponded to a difference in progression-free survival at three years from 10.6% in the systemic therapy arm to 27.6% in the combined treatment arm. At a median follow-up of 9.7 years, 39 (65%) of 60 patients in the combined treatment arm had died compared with 53 (89.8%) of 59 in the systemic treatment arm (HR=0.58; 95% CI 0.38 to 0.88; p=0.01).

Nonrandomized Studies

Nonrandomized studies in which RFA was compared to resection or systemic chemotherapy in patients with localized CRC metastases and no evidence of additional metastatic disease have been conducted. Tago reported a retrospective analysis in 2021 of CRC patients with liver metastases who underwent RFA (n=26), resection (n=92), or chemotherapy (n=29).[54] Median OS was 44.9, 49.5, and 11.6 months in the RFA, resection, and chemotherapy groups, respectively, with statistically significant differences between RFA and resection (p=0.027), and RFA and chemotherapy (p=0.003). Five-year OS was not significantly different between RFA and resection (p=0.508).

In 2016, Hof compared outcomes from RFA or hepatic resection in patients with hepatic metastases from CRC.[55] There were 431 patients included from an institutional database. All patients underwent locoregional treatment for hepatic metastases from CRC. Initial treatment was either hepatic resection (n=261), open RFA (n=26), percutaneous RFA (n=75), or a combination of resection plus RFA (n=69). Mean follow-up was 38.6 months. The overall recurrence rate was 83.5% (152/182) in patients treated with RFA compared to 66.6% (201/302) in patients treated with hepatic resection (p<0.001). The five-year OS estimate by Kaplan-Meier analysis was 51.9% for RFA and 53.0% for hepatic resection (p=0.98).

Abdalla examined recurrence and survival rates for clinically similar patients treated with hepatic resection only (n=190), resection plus RFA (n=101), RFA only (n=57, open laparotomy by hepatobiliary surgeon), and systemic chemotherapy alone (n=70).[56] In the key relevant comparison, RFA versus chemotherapy in chemotherapy-naive patients with nonresectable CRC metastases (median, one lesion per patient; range, 1 to 8; median tumor size, 2.5 cm), OS at four years was 22% in the RFA group and 10% in the chemotherapy group (p=0.005). Median survival was estimated at 25 months in the RFA group and 17 months in the chemotherapy group (p not reported). Recurrence at a median follow-up of 21 months was 44% in the RFA group and 11% in the resection-only group (p<0.001), although the proportion

of patients with distant recurrence as a component of failure was similar (41% resection vs 40% RFA, p=*NS*).

In a second trial, a consecutive series of well-defined, previously untreated patients (n=201) without extrahepatic disease underwent laparotomy to determine therapeutic approach.[57] Three groups were identified: those amenable to hepatic resection (n=117); those for whom resection plus local ablation were indicated (RFA, n=27; cryoablation, n=18); and those deemed unresectable and unsuitable for local ablation (n=39) who received systemic chemotherapy. Median OS was 61 months (95% CI 41 to 81 months) in resected patients (median, one tumor per patient; range, 1 to 9; median diameter, 3.8 cm), 31 months (95% CI 20 to 42 months) in locally ablated patients (median, four tumors per patient; range, 1-19; median diameter, 3 cm per lesion), and 26 months (95% CI 17 to 35 months) in the chemotherapy patients (median, four tumors per patient; range, 1 to 17; median diameter, 4 cm per lesion; p=*NS*, ablated vs chemotherapy). Results from two validated quality-of-life instruments (EuroQol-5D, EORTC QLQ C-30) showed that patients treated by local ablation returned to baseline values within three months, whereas those treated with chemotherapy remained significantly lower (ie, worse quality of life) than baseline over 12 months posttreatment ($p<0.05$).

In 2011, Van Tilborg reported long-term results in 100 patients with unresectable colorectal liver metastases who underwent a total of 126 RFA sessions (237 lesions).[58] Lesion size ranged from 0.2 to 8.3 cm (mean 2.4 cm). Mean follow-up time was 29 months (range, 6-93 months). Major complications (including abscess, hemorrhage, grounding pad burns, and diaphragm perforation) occurred in eight patients. Factors that determined the success of the procedure included lesion size and the number and location of the lesions. Local tumor site recurrence was 5.6% for tumors less than 3 cm, 19.5% for tumors 3 to 5 cm, and 41.2% for those greater than 5 cm. Centrally located lesions recurred more often than peripheral, at 21.4% versus 6.5%, respectively (p=0.009). Mean survival time from the time of RFA was 56 months (95% CI 45 to 67 months).

Neuroendocrine Cancer

Unlike the above liver tumors, the treatment benefit for RFA of neuroendocrine metastases in the liver is related to symptom control rather than survival or local recurrence. Therefore, patient selection and outcome measures in related studies focused on the level of symptoms rather than lesion size, number, and location. The primary treatment of symptomatic neuroendocrine tumor (NET) metastases is chemotherapy.

Systematic Reviews

Most reports of RFA treatment for neuroendocrine liver metastases include small numbers of patients or subsets of patients in reports of more than one ablative method or very small subsets of larger case series of patients with various diagnoses. A systematic review of RFA as treatment for unresectable metastases from neuroendocrine tumors was published in 2015.[59] Seven unique studies (total n=301 patients) included in the review, all were retrospective case series from a single institution. The most common tumor type was carcinoid (59%), followed by nonfunctional pancreatic tumors (21%) and functional pancreatic tumors (13%). There were two periprocedural deaths (rate, 0.7%), and the overall rate of complications was 10% (including hemorrhage, abscess, viscus perforation, bile leak, biliopleural fistula, transient liver insufficiency, pneumothorax, grounding pad burn, urinary retention, pneumonia, pleural effusion). Improvement in symptoms was reported in 92%

(117/127) of symptomatic patients, with a median duration of symptom relief ranging from 14 to 27 months. There was a high degree of variability in the length of follow-up and surveillance used for follow-up, and a wide range of local recurrence rates, from less than 5% to 50%. The reported five-year survival rates ranged from 57% to 80%.

Randomized Controlled Trials

No randomized controlled trials of RFA as a treatment for neuroendocrine metastases in the liver were identified.

Nonrandomized Studies

Fairweather (2017) compared OS in patients with neuroendocrine liver metastases (N=649) from a large prospective database.[60] Primary treatment modalities included: systemic therapy (n=316), chemoembolization (n=130), observation (n=117), surgical resection (n=58), and RFA (n=28). The most favorable 10-year OS estimates were achieved with surgical resection (70%), followed by RFA (55%), systemic therapy (31%), chemoembolization (28%), and observation (20%).

Berber (2008) analyzed a large series of liver tumors treated with RFA.[61] Of 1,032 tumors in the study, 295 were neuroendocrine tumor metastases. The mean number of lesions treated was 5.6 (range, 1 to 16) and mean lesion size was 2.3 cm (range, 0.5 to 10.0 cm). Local recurrence rates were lower in patients with neuroendocrine tumors than in patients with other tumor types: neuroendocrine tumors (19/295 [6%]), colorectal metastases (161/480 [24%]), non–colorectal, non–neuroendocrine metastases (28/126 [22%]), and HCC (23/131 [18%]). In patients with neuroendocrine tumors, 58% of the recurrences were evident at one year and 100% at two years versus 83% at one year and 97% at two years for colorectal metastases. Eight neuroendocrine tumors were eligible for repeat RFA; seven were retreated, and one was not. Symptom control and survival were not reported.

Mazzaglia reported on a series gathered over 10 years for 63 patients with neuroendocrine metastases who were treated with 80 sessions of LRFA.[62] Tumor types were 36 carcinoid, 18 pancreatic islet cell, and nine medullary thyroid cancer. Indications for study enrollment were liver metastases from neuroendocrine tumors, enlarging liver lesions, worsening of symptoms, and/or failure to respond to other treatment modalities and predominance of disease in the liver; patients with additional minor extrahepatic disease were not excluded. RFA was performed 1.6 years (range, 0.1 to 7.8 years) after diagnosis of liver metastases. Fourteen patients had repeat sessions for disease progression. The mean number of lesions treated at the first RFA session was six and the mean tumor size was 2.3 cm. One week after surgery, 92% of patients had at least partial symptom relief and 70% had complete relief. Symptom control lasted 11 months. Median survival times were 11 years postdiagnosis of the primary tumor, 5.5 years postdiagnosis of the neuroendocrine hepatic metastases, and 3.9 years after the first RFA treatment.

Elias reported on 16 patients who underwent a one-step procedure comprising a combination of hepatectomy and RFA for treatment of gastroenteropancreatic endocrine tumors.[63] A mean of 15 liver tumors per patient were surgically removed, and a mean of 12 were ablated using RFA. Three-year survival and DFS rates were similar to those observed in the authors' preliminary series of 47 patients who had hepatectomy with a median of seven liver tumors per patient. Venkatesan reported on six patients treated for pheochromocytoma metastases.[64]

Complete ablation was achieved in six of seven metastases. Mean follow-up was 12.3 months (range, 2.5 to 28 months).

RFA AS A PRIMARY TREATMENT OF UNRESECTABLE LIVER METASTASES OF OTHER ORIGIN

Breast Cancer

A number of case series have reported on use of RFA to treat breast cancer liver metastases. In 2014, Veltri analyzed 45 women treated with RFA for 87 breast cancer liver metastases (mean size, 23 mm).[65] Complete ablation was seen on initial follow-up in 90% of tumors, but tumor recurrence occurred in 19.7% within eight months. RFA did not impact OS, which at one year was 90% and at three years was 44%.

In a retrospective review, Meloni assessed local control and intermediate- and long-term survival in 52 patients.[66] Inclusion criteria were fewer than five tumors, maximum tumor diameter of 5 cm, and disease confined to the liver or stable with medical therapy. Complete tumor necrosis was achieved in 97% of tumors. Median time to follow-up from diagnosis of liver metastasis and from RFA was 37.2 and 19.1 months, respectively. Local tumor progression occurred in 25% of patients, and new intrahepatic metastases developed in 53%. Median OS, from the time of first liver metastasis diagnosis, was 42 months, and five-year survival was 32%. Patients with tumors 2.5 cm in diameter or larger had worse prognoses than those with smaller tumors. The authors concluded that these survival rates were comparable to those reported in the literature for surgery or laser ablation. In another series of 43 breast cancer patients with 111 liver metastases, technical success (tumor ablation) was achieved in 107 (96%) metastases.[67] During follow-up, local tumor progression was observed in 15 metastases. Estimated median OS was 58.6 months. Survival was significantly lower among patients with extrahepatic disease, with the exception of skeletal metastases.

A series of 19 patients was reported by Lawes.[68] Eight patients had disease confined to the liver, with 11 also having stable extrahepatic disease. At the time of the report, seven patients, with disease confined to the liver at presentation, were alive, as were six with extrahepatic disease; median follow-up after RFA was 15 months (range, 0 to 77 months). Survival at 30 months was 41.6%. RFA failed to control hepatic disease in three patients.

Sarcoma

Jones evaluated RFA in a series of patients with sarcoma.[69] Thirteen gastrointestinal stromal tumor (GIST) patients and 12 with other histologic subtypes received RFA for metastatic disease in the liver: 12 responded to the first RFA procedure and one achieved stable disease. Two GIST patients received RFA on two occasions for separate lesions within the liver, and both responded to the second RFA procedure. Of the other subtypes, seven underwent RFA to liver lesions, five of whom responded to RFA, one progressed, and one was not assessable at the time of analysis. RFA was well-tolerated in this series of sarcoma patients. RFA may have a role in patients with GIST who have progression in a single metastasis but stable disease elsewhere. The authors advised conducting further larger studies to better define the role of this technique in this patient population.

A case series of 66 patients who underwent hepatic resection (n=35), resection and RFA (n=18), or RFA alone (n=13) was reported by Pawlik.[70] After a median follow-up of 35.8 months, 44 patients had recurrence (intrahepatic only, n=16; extrahepatic only, n=11; both,

n=17). The one-, three-, and five-year OS rates were 91.5%, 65.4%, and 27.1%, respectively. The authors recommended that patients with metastatic disease who can be rendered surgically free of disease be considered for potential hepatic resection.

RFA AS A TREATMENT OF UNRESECTABLE HCC TUMORS IN THE TRANSPLANT SETTING

The goal of RFA prior to transplantation is to maintain a patient's eligibility for liver transplant by either downsizing a large tumor or by preventing progression of a smaller tumor. The literature related to locoregional therapy for HCC in the transplant setting can be divided into three objectives:

- Prevention of tumor progression while on the waiting list
- Downgrading HCC prior to transplantation
- To reduce risk of post-transplantation tumor recurrence in patients with T3 tumors

Assessment of the effects of pre-transplantation RFA on these objectives would, ideally, include clinical trials that compare the recurrence-free survival of patients who received pretransplant locoregional therapies with those who did not and to study recurrence-free survival in patients who received locoregional therapies to downsize larger tumor(s) or to prevent progression of smaller tumor(s) in order to meet transplant waiting list criteria.

The current published evidence is limited to case series and retrospective reviews which are considered unreliable due to methodologic limitations such as lack of randomization and lack of a control group for comparison.[71-80] In addition to these limitations, current studies targeted only a subset of candidates for liver transplant to treat HCC. Because only patients with adequate liver reserves were offered treatment, it cannot be determined whether any reported increase in recurrence-free survival was related to the pretransplant locoregional therapy or liver reserve status. It is unknown whether patients with adequate liver reserves have improved outcomes regardless of pretransplant management.

United Network for Organ Sharing policy

The United Network for Organ Sharing (UNOS) recognizes pretransplant locoregional therapies including RFA as a component of patient management during the waiting period for a donor liver.[81] In allocating donor organs, UNOS sought to balance risk of death on the waiting list against risk of recurrence after transplant. For HCC, part of this balance included tumor size and number of nodules as follows:

T1: 1 nodule 1.9 cm or smaller
T2: 1 nodule between 2.0–5.0 cm, or 2 or 3 nodules each smaller than 3.0 cm
T3: 1 nodule larger than 5.0 cm, or 2 or 3 nodules with at least 1 larger than 3.0 cm

Patients with T1 lesions were considered at low risk of death on the waiting list, while those with T3 lesions were considered at high risk of post-transplant recurrence. Patients with T2 tumors were considered to have an increased risk of dying while on the waiting list compared with T1 lesions, and an acceptable risk of post-transplant tumor recurrence. Therefore, the UNOS criteria prioritized T2 HCC. In addition, patients could be removed from the waiting list if they were determined to be unsuitable for transplantation based on progression of HCC. Thus these criteria provide incentives to use locoregional therapies to maintain T2 classification.

The UNOS allocation system provides incentives to use locoregional therapies in two different settings:

To downsize T3 tumors to T2 status to meet the UNOS criteria for additional allocation points; or to prevent progress of T2 tumors while on the waiting list to maintain the UNOS allocation points.

These two indications are discussed further here. It should be noted that the UNOS policy addresses the role of locoregional therapy in the pretransplant setting as follows:

> Organ Procurement and Transplant Network (OPTN) Class 5T (Treated) nodules are defined as any OPTN Class 5 or biopsy-proven HCC lesion that was automatically approved upon initial application or extension and has subsequently undergone loco-regional treatment. OPTN Class 5T nodules qualify for continued priority points predicated on the pre-treatment classification of the nodule(s) and are defined as:
>
> - Past loco-regional treatment for HCC (OPTN class 5 lesion or biopsy proven prior to ablation).
> - Evidence of persistent/recurrent HCC such as nodular or crescentic extra-zonal or intra-zonal enhancing tissue on late arterial imaging (relative to hepatic parenchyma) may be present.

OPTN guidelines also indicate “candidates whose tumors have been ablated after previously meeting the criteria for additional MELD/PELD points (OPTN Class 5T) will continue to receive additional MELD/PELD points (equivalent to a 10-percentage point increase in candidate mortality) every 3 months without RRB review, even if the estimated size of residual viable tumor falls below stage T2 criteria.”

Candidates with HCC not meeting transplant criteria, “including those with downsized tumors whose original or presenting tumor was greater than a stage T2, must be referred to the applicable RRB [Regional Review Board] for prospective review in order to receive additional priority.”[81]

ADVERSE EVENTS

Complication rates for RFA of liver tumors are reported in approximately 7% of patients, as compared with that of open liver resection which may be as high as 22%.[82]

Specific complications reported in the literature to date include the following:[58, 61, 82-85]

1. Hemorrhage
2. Liver Abscess
3. Liver infarction
4. Liver failure
5. Cutaneous burn
6. Diaphragm perforation
7. Bowel perforation
8. Seeding of the needle tract with cancer cells
9. Hydrothorax or hemothorax requiring drainage
10. Bile duct injury
11. Death

MWA AS A TREATMENT OF HEPATOCELLULAR CARCINOMA

Systematic Reviews

Dou (2022) conducted a systematic review and meta-analysis that compared the safety and efficacy of MWA compared to RFA in patients with HCC.[86] The analysis included 28 cohort studies and 5 RCTs. Overall, there was no significant difference in disease-free survival, OS, or major complications between the two groups. In the cohort studies, MWA had a lower local tumor progression rate than RFA (OR, 0.78; 95% CI, 0.64 to 0.96; p=.02). The authors concluded that there were various differences in the included studies (e.g., equipment used, operator experience) and that more high-quality RCTs are needed to draw a definitive conclusion on MWA and RFA in this patient population.

Glassberg (2019) conducted a systematic review of MWA compared to resection in patients with HCC or metastatic liver cancer. One RCT (Xu 2015)[87] was included; the other studies (n=15) were observational (2 prospective, 13 retrospective).[88] Patients who received MWA had significantly higher risk of LTR compared to those who received resection (RR=3.04; p<0.001). At one year, overall survival did not differ between MWA and resection, but three- and five-year overall survival was significantly higher in patients who had received resection. Overall complications and major complications were lower with MWA compared to resection. Additionally, operative time, intraoperative blood loss, and hospital length of stay were significantly lower with MWA. Some studies included patients that were nonresectable in the MWA treatment arm, but due to limited reporting and patient preference affecting which treatment was performed, the reviewers were not able to calculate the number of patients who were nonresectable or to conduct subgroup analyses by resectable vs unresectable tumors. Microwave ablation was typically selected for patients with smaller and/or deeper tumors, more comorbidities, and a preference for a less invasive procedure. The reviewers concluded that MWA can be an effective and safe alternative to HR in patients or tumors that are not amenable to resection, but more studies are needed to determine the target population that would benefit most from MWA.

In 2017, Zhang reported results from a systematic review and meta-analysis comparing hepatic resection with microwave ablation as a treatment of hepatocellular carcinoma.[89] Nine studies with follow-up time of three years or greater were included overall, totalling 1,480 participants. For overall survival (seven reports), studies were not found to have statistical bias, and overall heterogeneity amongst studies was not significant (I^2 =0.0%, p=0.749), however, heterogeneity amongst studies included for meta-analysis of disease-free survival (five reports) was significant (I^2 =71.1%, p=0.008). No difference was found comparing MWA to resection for OS and DFS (HR =0.98, 95% CI 0.76 to 1.26, p=0.878, and HR =1.16, 95% CI 0.79 to 1.71, p=0.442, respectively). Meta-analysis demonstrated that MWA was associated with shorter operation time (standardized mean difference [SMD] −1.37, 95% CI −1.92 to −0.81, p=0.000), less amount of blood loss in operation (SWD −1.19, 95% CI −1.76 to −0.61, p=0.000), and less complications (OR 0.22, 95% CI 0.12 to 0.40, p=0.000) than resection. The authors concluded that MWA may be superior given there were no differences identified in OS and DFS, but demonstrated fewer complications and improved intraoperative outcomes.

In 2011, Bertot conducted a systematic review evaluating mortality and complication rates of ablation techniques for primary and secondary liver tumors.[90] This review included two studies using MWA totaling 1,185 patients.[91, 92] The pooled mortality rate for MWA was 0.23% (95%

CI 0.0 to 0.58%). Major complication rates were 4.6% for MWA (calculated by using a random effects model since there was significant heterogeneity). The authors concluded that percutaneous ablation techniques, including MWA, are safe and have acceptable complication rates for the treatment of liver tumors.

In 2009, Ong conducted a systematic review of studies on MWA for primary and secondary liver tumors.[93] Based on the results from 25 clinical studies, the authors concluded that MWA was an effective and safe technique for liver tumor ablation with low complication rates and survival rates comparable to hepatic resection. However, rates of local recurrence after MWA were noted to be higher than hepatic resection. In most studies of MWA, hepatocellular carcinoma recurrence rates were approximately 10% but were also noted to be as high as 50%, which the authors indicated could be addressed with further ablation. Survival rates in the studies on MWA for hepatocellular carcinoma were as high as 92% at three years and 72% at five years, which was noted to be comparable to radiofrequency ablation (RFA) and percutaneous ethanol injections. Pain and fever were the most frequently reported complications, but complications increased when there were more tumors, larger tumors, and more microwave antennas used. The authors concluded that MWA may be a promising option for the treatment of HCC tumors but should be reserved for patients not amenable to hepatic resection. The authors also noted further randomized clinical trials are warranted to compare MWA to other ablation procedures.

Randomized Controlled Trials

Zaitoun (2021) compared the safety and efficacy of combination therapy with TACE and MWA (n=89) compared to TACE (n=84) or MWA (n=92) only in patients with solitary HCC lesions measuring between 3 to 5 cm.[94] TACE was performed first, followed by MWA after 15 days. Mean tumor size was 3.6 cm, 3.9 cm, and 3.7 cm in the TACE, MWA, and combination groups, respectively (p=0.053). Complete response at one month was achieved by 86.5% of patients who received combination therapy compared with 54.8% of patients treated with TACE and 56.5% of patients treated with MWA. Patients treated with combination therapy had a significantly lower recurrence rate at 12 months (p=0.0001) and a significantly higher OS rate at three years (69.6%; p=0.02). Post-procedural minor adverse events (e.g., nausea, vomiting, abdominal pain, and low-grade fever) were reported in 24.7%, 47.6%, and 38% of patients in the combined, TACE, and MWA groups, respectively. Severe hepatic dysfunction was observed in one patient in the combined group and three patients in the TACE group. Tumor seeding was reported in two patients in the MWA group. A decrease in alpha-fetoprotein (AFP) concentration was observed in 75%, 63%, and 48% of patients who underwent combined therapy, MWA, or TACE, respectively.

Chong (2020) conducted an RCT comparing MWA to RFA in 93 patients with HCC (up to 3 lesions of 5 cm or smaller).[95] Mean tumor size was 3.1 cm in the MWA group and 2.8 cm in the RFA group. The primary outcome of this study was the rate of complete ablation at one month, which did not differ significantly for MWA (95.7%) versus RFA (97.8%; p>0.99). Rates of OS up to five years and rates of disease-free survival up to three years were similar between groups. However, the sample size calculations were based on rates of complete ablation at one month, so the study may not have been adequately powered to detect differences in OS or disease-free survival.

Fang (2019) randomized hepatic carcinoma patients to receive conventional surgical excision (n=47) or ultrasound-guided microwave ablation (n=47).[96] Statistically significant differences

(p<0.05) between groups were reported for duration of operation (shorter for MWA), quantities of intraoperative bleeding and blood transfusions (lower for surgical excision), effective rate of treatment (higher for MWA), occurrence rate of complications (lower for MWA). In addition significantly higher albumin and total bilirubin and lower alanine aminotransferase and aspartate transaminase were reported for the MWA group (p<0.05).

Older RCTs are included in the SRs above.

Nonrandomized Studies

In addition to the studies noted above, a number of nonrandomized studies have been published on the use of MWA in patients with hepatocellular carcinoma. Several examples are cited, below. The results of these studies should be interpreted with caution due to the following limitations:

- Results from small sample sizes (n<100), limit the ability to rule out the role of chance as an explanation of study findings.[97-104]
- Results from studies with short-term follow-up (<one year) are not adequate to determine the durability of the treatment effect.[97, 105, 106]
- A lack of comparison group, without which it is not possible to account for the many types of bias that can affect study outcomes.[91, 92, 103-112]

Given the limitations noted above, nonrandomized studies do not provide reliable data to demonstrate the efficacy of MWA treatment in patients with HCC.

MWA AS A TREATMENT OF HEPATIC METASTASIS

Systematic Reviews

Mimmo (2022) conducted a systematic review of MWA for colorectal liver metastases.[113] Twelve studies (N=741) were included, and 395 patients were treated with MWA versus conventional surgical procedure (n=346). The mean follow-up duration was 20.5 months. Pooled data analysis showed mean recurrence free rates for MWA at one, three, and five years were 65.1%, 44.6%, and 34.3%, respectively. Mean OS rates for MWA at one, three, and five years were 86.7%, 59.6%, and 44.8%, respectively. Mean local recurrence rates for MWA at 3, 6, and 12 months were 96.3%, 89.6%, and 83.7%, respectively.

A 2014 Health Technology Assessment[50] and a 2013 Cochrane review[114] also identified only one RCT on ablation for liver metastasis, Shibata.[115] The reviewers found insufficient evidence to determine any benefits of MWA for liver metastasis over surgical resection.

In 2013, Vogl reviewed evidence regarding RFA, laser-induced thermotherapy (LITT) and MWA treatment of breast cancer liver metastasis.[116] Local tumor response, progression and survival rates were evaluated. Authors reported positive response rates of 63 % to 97 % in RF-ablated lesions, 98.2 % in LITT-treated lesions and 34.5-62.5 % in MWA lesions. Median survival was 10.9-60 months with RFA, 51-54 months with LITT and 41.8 months with MWA. Five-year survival rates were 27-30 %, 35 % and 29 %, respectively. Local tumour progression ranged from 13.5 % to 58 % using RFA, 2.9 % with LITT and 9.6 % with MWA. The authors called for additional, large RCTs to further explore the benefits of ablation therapies.

In the Ong review described above[93], local recurrence rates for liver metastases after treatment with MWA averaged approximately 15% but varied between 0 and 50% in the seven studies reviewed that addressed liver metastases. As noted above, Ong concluded MWA may be a promising treatment option for the treatment of liver tumors but should be reserved for patients not amenable to hepatic resection.

In 2011, Pathak also conducted a systematic review of ablation techniques for colorectal liver metastases, which included 13 studies on MWA, totaling 406 patients with a minimum of 1-year follow-up.[117] Mean survival rates were 73%, 30% and 16% and ranged from 40–91.4%, 0–57% and 14–32% at one-, three-, and five-years' follow-up, all respectively. Minor and major complication rates were considered acceptable and ranged from 6.7–90.5% and 0–19%, respectively. Local recurrence rates ranged from 2-14%. The authors acknowledged limitations in the available studies but concluded survival rates for MWA are more favorable than for palliative chemotherapy alone.

Randomized Controlled Trials

Only one RCT comparing the use of MWA for hepatic metastases to the gold standard of surgical resection was identified. In 2000, Shibata reported on a trial of 30 patients with hepatic metastases from colorectal cancer randomly assigned without stratification to treatment with either MWA after laparotomy (n=14) or hepatectomy (n=16).[115] The study began with 40 patients, but 10 patients were excluded because the researchers discovered intraoperatively that these patients did not meet study criteria due to having extensive metastasis or equal to or greater than 10 tumors. The treatment groups of MWA vs. hepatectomy were not significantly different in age (mean age 61 in both groups) number of tumors (mean 4.1 vs. 3.0, respectively) or tumor size (mean 27 mm vs. 34 mm, respectively). The authors reported no significant differences in survival rates following MWA or hepatectomy (27 months vs. 25 months, respectively) and mean disease-free survival (11.3 vs. 13.3 months, respectively). However, intraoperative blood loss was significantly lower and no blood transfusions were required in the MWA group whereas six patients in the hepatectomy group required blood transfusions. Complications in the microwave group consisted of one hepatic abscess and one bile duct fistula. In the hepatectomy group, complications were one intestinal obstruction, one bile duct fistula and one wound infection.

Nonrandomized Studies

Several nonrandomized trials regarding MWA treatment in patients with liver metastases were identified; however, these studies were limited by a lack of comparison group,[118-120] short-term follow-up[118, 119] and small sample size.[118, 120].

CRYOSURGICAL ABLATION

CRYOSURGICAL ABLATION AS A TREATMENT OF HEPATOCELLULAR CARCINOMA

The evidence regarding cryoablation as a treatment for hepatocellular carcinoma (HCC) remains controversial. However, use of cryotherapy for HCC became a standard of care and published research increased through the late 1990's and early 2000's. Awad published a systematic Cochrane Review in 2009, noting that the literature consisted of two prospective cohort studies and two retrospective cohort studies.[121] Overall, the Review concluded that the evidence is not sufficient to evaluate potential harms and benefits; large well-designed

randomized clinical trials (RCTs) are feasible and necessary to define the role of cryotherapy in the treatment of HCC.

A 2023 meta-analysis by Kim compared the benefits and harms of locoregional treatments for HCC in patients who had early HCCs of <4 cm with no extrahepatic spread of portal invasion [122]. While this study included 19 trials, the only cryoablation study included was the one included below by Wang (2015). Overall, cryoablation had similar overall survival, progression-free survival, and local progression-free survival scores as radiofrequency ablation. Further research is needed with additional participants to examine the effect of cryoablation on patient health outcomes compared to standard care.

Since the 2009 Cochrane Systematic Review, Wang (2015) reported results from one RCT comparing the safety and efficacy of cryotherapy vs RFA.[1] One hundred eighty participants were randomized to each group, with no significant differences found at baseline between the arms, with the exception of number of tumors – 10.56% of the cryo group participants had two tumors at enrollment, compared to 5% in the RFA group. Participants were followed for five years, and there were no differences in local recurrence, new recurrence, overall survival, or tumor-free survival. At the end of follow-up, 52 patients (28.9%) in the CRYO group and 55 patients (30.6%) in the RFA group died. The causes of death included HCC progression in 44 (24.4%), hepatic failure in five (2.8%), and variceal bleeding in three (1.7%) in the CRYO group, and HCC progression in 47 (26.1%), hepatic failure in four (2.2%), variceal bleeding in two (1.1%), and refractory ascites-induced renal failure in two (1.1%) in the RFA group. Overall, the authors concluded that patients with Child-Pugh class A-B cirrhosis and HCC lesions less than or equal to 4cm and no more than two lesions in total, percutaneous cryoablation and RFA are equally safe and effective ablation treatments. For HCC 3.1 to 4.0 cm, cryoablation was associated with a lower rate of local tumor progression than RFA.

CRYOSURGICAL ABLATION AS A TREATMENT OF LIVER METASTASES

A 2019 Cochrane SR was published by Bala evaluation the use of cryotherapy for the treatment of liver metastases.[123] The selection criteria included RCTs assessing effects of cryotherapy and its comparators for liver metastases. One RCT was identified. It compared cryotherapy with conventional surgery for patients with liver metastases from the following primary sites: colon and rectum (66.6%), stomach (7.3%), breast (6.5%), skin (4.9%), ovaries (4.1%), uterus (3.3%), kidney (3.3%), intestines (1.6%), pancreas (1.6%), and unknown (0.8%). The SR authors were not able to calculate the risk of bias of the randomization process, allocation concealment, presence of blinding, incomplete outcome data, or selective outcome reporting bias due to insufficient reporting by the RCT authors. Follow-up was five months to 10 years. The trial reported mortality at 10 years (81% vs. 92% for cryotherapy vs. conventional therapy) and the SR authors calculated the relative risk (RR=0.88, 95% CI 0.77 to 1.02). The evidence regarding mortality was rated as low-certainty. The SR authors also calculated chance of recurrence in the liver, which was 86% in the cryotherapy group and 95% in the conventional surgery group (RR 0.90, 95% CI 0.80 to 1.01; low-certainty evidence). The SR authors concluded that the evidence is limited and they cannot determine whether cryotherapy is beneficial or harmful compared to conventional surgery.

PERCUTANEOUS ETHANOL INJECTION

Like RFA, percutaneous ethanol injection (PEI) is most often considered a treatment option for patients with small HCC lesions who are not resection candidates. RFA and PEI are the most commonly performed ablation therapies.

Weis (2015) published a Cochrane Systematic Review that evaluated the harms and benefits of percutaneous ethanol injection (PEI) and percutaneous acetic acid injection (PAI) in adults with early HCC defined by Milam criteria, i.e., one cancer nodule up to 5 cm in diameter or up to three cancer nodules up to 3 cm in diameter compared with no intervention, sham intervention, each other, other percutaneous interventions, or surgery.[124] One randomized trial compared PEI versus surgery; we included 76 participants in the analyses. There was no significant difference in the overall survival (HR 1.57; 95% CI 0.53 to 4.61) and recurrence-free survival (HR 1.35; 95% CI 0.69 to 2.63). No serious adverse events were reported in the PEI group while three postoperative deaths occurred in the surgery group. Given the data on PEI were available for only one RCT, the authors concluded there is insufficient evidence to determine whether PEI versus surgery was more effective for early HCC.

In a number of RCT's, the safety and efficacy of RFA and PEI have been investigated in the treatment of Child-Pugh class A patients with early stage HCC tumors.[125-131] Complication rates were relatively low for both methods.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)

The NCCN guidelines for hepatocellular carcinoma cancers (v.2.2023) recommend ablation be considered in patients who are not candidates for transplant, surgical curative treatments, or as part of a strategy to bridge patients for other curative therapies (category 2A).[132] In addition, they state that "ablation alone may be curative in treating tumors ≤ 3 cm. In well-selected patients with small, properly located tumors, ablation should be considered as definitive treatment in the context of a multidisciplinary review. Lesions 3 to 5 cm may be treated to prolong survival using arterially directed therapies, or with combination of an arterially directed therapy and ablation as long as the tumor is accessible for ablation. Unresectable/inoperable lesions greater than 5 cm should be considered for treatment using arterially directed therapy, systemic therapy, or RT. (category 2A).

The NCCN guidelines for rectal (v.6.2023) and colon (v.2.2022) cancer metastatic to the liver state that "Ablative techniques may be considered alone or in conjunction with resection. All original sites of disease need to be amenable to ablation or resection."[133, 134] (category 2A).

The NCCN guidelines for neuroendocrine and adrenal tumors (v.1.2023) recommend ablation be considered as a primary therapy in locally advanced/metastatic disease. The recommendations state that "percutaneous thermal ablation, often using microwave energy (radiofrequency and cryoablation are also acceptable), can be considered for oligometastatic liver disease, generally up to 4 lesions each smaller than 3 cm. Feasibility considerations include safe percutaneous imaging-guided approach to the target lesions, and proximity to vessels, bile ducts, or adjacent non-target structures that may require hydro- or aero-dissection for displacement [category 2B]."[135]

AMERICAN COLLEGE OF RADIOLOGY (ACR)

The 2014 ACR Appropriateness Criteria® for metastatic rectal cancer states that RFA "yields excellent local control of small (<3 cm) CRC liver metastases."[136]

The 2011 ACR Appropriateness Criteria® considered RFA by percutaneous, open, or laparoscopic methods effective for treatment of small (≤5 cm) HCC tumors.[137] While ablative

therapy is most effective for these small HCCs, moderate success has also been described with tumors ≤7 cm. With larger tumor number and/or size, “the operator may want to focus on arterial-based therapies and adjuvant or neoadjuvant therapy.” The 2016 guidelines were consistent with the previous recommendations.[138]

AMERICAN ASSOCIATION FOR THE STUDY OF LIVER DISEASES

The American Association for the Study of Liver Diseases (2018) published a guideline on the treatment of hepatocellular carcinoma.[139] For adults with Child-Pugh class cirrhosis and resectable T1 or T2 hepatocellular carcinoma (HCC), the guideline suggests using resection over radiofrequency ablation (RFA; moderate quality/certainty of evidence; conditional strength of recommendation). Technical remarks in the guideline note that "Stage T1 and T2 HCC include a wide range of tumor sizes from <1 cm to 5 cm, and the effectiveness of available therapies depend in large part on the size, number, and location of the tumors. Whereas smaller, single tumors (<2.5 cm) that are favorably located may be equally well treated by either resection or ablation, tumors larger than 2.5-3 cm, multifocal, or near major vascular or biliary structures may have limited ablative options." Additionally, the guideline highlighted that "randomized trials performed to date comparing RFA to resection have been performed primarily in East Asian patients, in whom there is a higher etiologic prevalence of HBV [hepatitis B virus] (including noncirrhotic HBV–associated HCC) and a lower prevalence of other liver diseases such as NAFLD [non-alcoholic fatty liver disease] or HCV [hepatitis C virus] compared with Western patients. The impact of these demographic differences on oncologic outcomes of different therapies is unknown."

SUMMARY

For primary tumors of the liver, and hepatic metastases from colorectal tumors or neuroendocrine tumors, there is limited research regarding locoregional ablative therapies; however, treatment options are limited in this population. Clinical practice guidelines based on research recommend ablative therapies in carefully selected patients. Therefore, percutaneous ethanol injection, cryoablation, radiofrequency and microwave ablation may be considered medically necessary when policy criteria are met.

Due to a lack of research and clinical practice guidelines, percutaneous ethanol injection, cryoablation, radiofrequency and microwave ablation are considered investigational when the policy criteria are not met.

Implantable Peripheral Nerve Stimulation and Peripheral Subcutaneous Field Stimulation

Effective: January 1, 2024

Next Review: April 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Implantable peripheral nerve stimulation (PNS) for chronic pain of *peripheral nerve origin* is a type of neuromodulation therapy that involves the subcutaneous implantation of electrodes near or on a peripheral nerve that is *considered to be the origin of pain*. Peripheral subcutaneous field stimulation (PSFS) is a modification of PNS in which electrodes are implanted subcutaneously within the area of maximal pain with the intent of stimulating the nerves, cutaneous afferents, or the dermatomal distribution of the nerves communicating the pain. These procedures differ from other forms of electrical stimulation because the origin of pain is from a peripheral nerve or nerve field and the electrical impulses are delivered to the nerve or nerve field versus surrounding tissues or the spine.

MEDICAL POLICY CRITERIA

Note: This policy only addresses implantable peripheral nerve stimulation (PNS) and peripheral subcutaneous field stimulation (PSFS) (e.g., StimRouter®, SPRINT®) for chronic pain of peripheral nerve origin. Please refer to the Cross References below for other specific neuromodulation or stimulation therapies.

Implantable peripheral nerve stimulation (PNS) and peripheral subcutaneous field

stimulation (PSFS) for pain of peripheral nerve origin is considered **investigational** for all indications, including but not limited to chronic, postoperative, and post-traumatic pain.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Peripheral nerve stimulation (PNS) systems vary from other electrical stimulation therapies.

- Transcutaneous electrical nerve stimulation (TENS) delivers impulses across the skin to alleviate pain. PNS is similar to TENS, except PNS requires electrodes to be inserted under the skin and targets a nerve considered to be the origin of the pain.
- Percutaneous neuromodulation therapy (PNT) is an electrical stimulation therapy in which fine filament electrodes are temporarily placed in the tissues near the area causing pain. PNS is similar to PNT, except PNS requires electrodes to be inserted under the skin and targets a nerve considered to be the origin of the pain.
- Occipital nerve stimulation (ONS) is related to PNS in that a subcutaneous electrode delivers stimulation to the occipital nerve in an attempt to prevent migraines and other headaches in patients who have not responded to medications.

BACKGROUND

Implantable peripheral nerve stimulation (PNS) is a type of neuromodulation that delivers electrical impulses *directly to a nerve*.

Implantable PNS therapies have been around since the 1960s.[1] There are several implantable PNS neuromodulation therapies that use electrical stimulation for pain.[2] Examples include, but are not limited to: occipital nerve stimulation (ONS) and spinal cord stimulation (SCS).The StimRouter®, an implantable PNS system, is being marketed specifically for chronic pain *of peripheral nerve origin* i.e. upper/lower limb pain, entrapment syndromes, intercostal neuralgias and other peripheral injuries or diseases.[3] Although SCS addresses pain in the truck and limbs, the electrodes for SCS deliver electrical stimulation to the spine versus directly to the peripheral nerve pain site like the StimRouter®.[4] The SPRINT® Peripheral Nerve Stimulation System (SPR Therapeutics, Inc) has been cleared for marketing for symptomatic relief of chronic pain, post-surgical, and post-traumatic pain of the back and extremities.[5]

PNS systems include a neurostimulator (pulse generator), leads (thin wires with electrodes), a controller (device that allows the patient to control the device), and a programmer that allows a medical professional to make adjustments to the settings of the pulse generator. The leads are subcutaneously positioned and connected to the generator but the electrodes are not permanently implanted as in spinal cord stimulation. For example, the SPRINT® Peripheral

Nerve Stimulation System is indicated for up to 60 days. A trial of PNS is indicated prior to permanent implantation of the generator. If the trial is successful (defined has >50% response rate in pain reduction), the generator is permanently implanted in the chest, abdomen or buttocks.

Peripheral subcutaneous field stimulation (PSFS) is a modification of peripheral nerve stimulation. In peripheral subcutaneous field stimulation, leads are placed subcutaneously within the area of maximal pain. The objective of peripheral subcutaneous field stimulation is to stimulate the region of affected nerves, cutaneous afferents, or the dermatomal distribution of the nerves, which then converge back on the spinal cord. Combination spinal cord stimulation plus peripheral subcutaneous field stimulation is also being evaluated.

REGULATORY STATUS

In July 2018, the SPRINT® Peripheral Nerve Stimulation System (SPR Therapeutics, Inc) was cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process (K181422).[5] The SPRINT® PNS System is not intended to treat pain in the craniofacial region. The Bioness StimRouter® Neuromodulation System received FDA 510(k) approval in February 2015,[6] October 2019,[7] and March of 2020.[8] The StimRouter® is not intended to treat pain in the craniofacial region

In March of 2016, the StimQ Peripheral Nerve Stimulator (PNS) System received FDA 510(k) approval.[9] The StimQ PNS System is not intended to treat pain in the craniofacial region.

No device has been approved specifically for peripheral subcutaneous field stimulation (PSFS) by the U.S. Food and Drug Administration (FDA). PSFS is an off-label use of spinal cord stimulation devices or peripheral nerve stimulation devices (e.g. the SPRINT® PNS System) that have been FDA approved for the treatment of pain.

EVIDENCE SUMMARY

The principal outcomes associated with treatment of pain due to any cause may include: relief of pain, improved functional level, and return to work. Relief of pain can be a subjective outcome associated with a placebo effect. Therefore, data from adequately powered, blinded, randomized controlled trials (RCT) are required to control for the placebo effect and determine if an implanted peripheral nerve stimulation (PNS) system f provides a significant advantage over placebo.

Treatment with an implanted PNS system must also be evaluated in general groups of patients against the existing standard of care for the condition being treated. For example, in patients with pain symptoms, treatment with an implanted PNS system should be compared to other forms of conservative therapy such as rest, non-steroidal anti-inflammatory medications, physical therapy, or steroid injection.

IMPLANTED PERIPHERAL NERVE STIMULATION

Systematic Reviews

Ni (2021) published a systematic review with meta-analysis of 13 studies (N=221) in which PNS was evaluated for the treatment of trigeminal neuropathic pain (TNP).[10] Eleven of the 13 studies examined effects of peripheral neuromodulation for TNP. Intractable facial pain of at least six months duration was an inclusion criterion for all included studies, with the exception

of one study which evaluated temporary PNS for the treatment of TNP caused by herpes zoster ophthalmicus. Ten of 13 (76.9%) studies reported response rates (pain reduction over 50%) as the clinical measurement during follow-up and visual analog scale (VAS) scores were available pre- and post-treatment in eight studies (N=110). The overall estimated response rate was 60.2% (95% CI: 41.9–76.1%, I^2 = 70.733%, p < 0.0001) and the mean pain scores were significantly lower at follow-up compared to baseline (standard difference 2.363; 95% CI: 1.408–3.319, I^2 = 85.723%, p < 0.0001). Sub-analysis was conducted to evaluate outcomes by target site of stimulation. In the three studies targeting the Gasserian ganglion as the stimulation target for facial pain, the overall response rate was 29.3% (95% CI: 19.2–41.8%, I^2 = 0, p = 0.635) and in studies using peripheral branch stimulation, 77.6% of patients reported over 50% pain relief (p < 0.0001). Study quality review revealed most studies did not provide sufficient information to evaluate adequate blinding of outcomes assessment, and for none of the included studies was adequate information on sample size justification, power description, or variance and effect estimates provided. Improper location of electrodes, infection, and electrode defects were the most commonly reported complications. The authors conclude that "randomized, controlled, prospective studies are needed to further compare the clinical efficiency of PNS with other conventional treatments for TNP."

Randomized Controlled Trials

Ilfeld (2021) published the results of a randomized controlled pilot study of PNS for the treatment of acute postoperative pain.[11] In this study, an electrical lead was percutaneously implanted preoperatively to target the sciatic nerve for major foot/ankle surgery (e.g., hallux valgus correction), the femoral nerve for anterior cruciate ligament reconstruction, or the brachial plexus for rotator cuff repair, followed by a single injection of long-acting local anesthetic along the same nerve/plexus. Postoperatively, participants were randomized to 14 days of either electrical stimulation (n = 32) or sham stimulation (n = 34). Coprimary outcome measures were cumulative opioid consumption and mean average daily pain scores on a 0 to 10 Numeric Rating Scale within the first seven postoperative days. The authors found opioid use in the active stimulation group was a median (interquartile range) of 5 mg (0 to 30) and 48 mg (25 to 90) in the sham treatment group (ratio of geometric means, 0.20 [97.5% CI, 0.07 to 0.57]; p < 0.001). The average pain intensity in the active stimulation group was (mean ± SD) 1.1 ± 1.1 and 3.1 ± 1.7 in the sham group (difference, −1.8 [97.5% CI, −2.6 to −0.9]; p < 0.001). This pilot study is severely limited by the short follow-up time of seven days, precluding evaluation of mid- or longer-term safety and effectiveness of the intervention. A larger, longer-term randomized controlled trial is anticipated.

In an industry-sponsored randomized controlled trial (RCT) published by Gilmore (2019), 28 lower-extremity amputees with postamputation pain were randomized to PNS or placebo for four weeks.[12] A significantly greater proportion of subjects receiving peripheral nerve stimulation (PNS) (n=7/12, 58%, p=0.037) demonstrated ≥50% reductions in average postamputation pain up to four weeks compared with subjects receiving placebo (n=2/14, 14%). In addition, a significantly greater proportion of PNS subjects reported ≥50% reductions in pain and pain interference after eight weeks of therapy compared with subjects receiving placebo, however the partial crossover design of this study prevents evaluation of placebo effects beyond four weeks. Twelve-month follow-up is ongoing. Overall, the study is limited by a small sample size which limits generalizability.

The results of an RCT of PNS compared to usual care (UC) for hemiplegic shoulder pain was published by Wilson (2016).[13] The study included 25 participants (12 PNS and 12 UC).

Although pain reduction with PNS treatment group was reported as significantly greater than the UC group, the per-protocol analysis of 21 participants showed significant reductions in pain in both groups and no significant slope difference between groups during the study. In addition, no significant group differences were observed for secondary outcome measures including pain interference, physical functioning, and global success rates. The authors concluded that additional RCTs are needed to determine treatment effectiveness.

Deer (2015) published a multicenter, randomized, double-blinded, partial crossover study addressing the safety and efficacy of the StimRouter® neuromodulation system for 94 patients with chronic pain of peripheral nerve origin (upper or lower extremity or trunk).[14] The patients were assigned to the StimRouter® group (n=45) or the control group (n=49). Efficacy was evaluated for three months and safety for one year. Primary outcomes included pain relief and safety. At three months the StimRouter® group reported 27.2% pain reduction vs. the control group 2.3%. Fifty-one percent of patients did not follow-up at one year. No serious adverse events were reported related to the device. A significant limitation of the study is the small sample size and large loss to follow-up.

Nonrandomized Studies

Warner (2020) published a retrospective case series of 72 patients who had undergone PNS implantation for treatment of various indications including occipital neuralgia (47%) and lower-extremity neuropathies (17%).[15] Six-month outcomes were assessed by numerical rating scale pain scores, opioid utilization, and self-reported functioning. Infection and device-related complications were also assessed. PNS implantation was associated with reductions in pain scores ($p<0.001$) and opioid utilization ($p<0.001$). Postoperative surgical site infection was found in ten percent of patients leading to device removal in five patients. No comparison to standard of care was provided.

A retrospective chart review including data from 240 patients implanted with a PNS, 165 of whom were being treated for complex regional pain syndrome, was published by Chmiela in 2020.[16] Median length of follow-up was 74 months. Pain scores at 12-month follow-up were decreased by an estimated 1.87 points (95% CI: [1.29, 2.46], paired t-test $p<0.001$). The percentage of patients on chronic opioid therapy decreased over 12 months from 62% to 41%. Of the 126 patients who reported changes in functional status, 64 (51%) reported improvement, 27 (21%) reported worsening, and 35 (28%) did not report any meaningful change. Excluding end-of-life battery replacements, surgical revision was needed in 56 (34%) of patients. Thirteen patients (8%) underwent implantation of a second PNS due to symptomatic expansion outside of the original region and device explant was performed in 32 (19%) of patients.

A multi-center, prospective case series published by Oswald (2019) evaluated outcomes in 39 patients implanted with the StimRouter™ on various isolated mononeuropathies.[17] The authors report 78% of the participants noted an improvement in pain, 72% noted improvement in activity, and 89% experienced a greater than 50% reduction in opioid consumption. This was not a controlled trial and no information comparing these outcomes to outcomes achieved through standard of care was provided. Future RCTs addressing these limitations are required.

Ilfeld (2017) published a review evaluating the safety of lead types in clinical studies of percutaneous neurostimulation of the peripheral nervous system.[18] Forty-three studies were included and of these both coiled (n = 21) and noncoiled (n = 25) leads were studied. The infection rates were estimated to be 0.03 (95% CI 0.01 to 0.13) infections per 1,000 indwelling

days for coiled leads and 0.83 (95% CI 0.16 to 4.33) infections per 1,000 indwelling days for noncoiled leads. No information is provided in the publication regarding clinical outcomes other than infection rates and no control group is evaluated.

Deer and Rosenfeld (2010) published the results of a single-center open-label study in which eight patients with carpal tunnel syndrome were evaluated for pain relief from the StimRouter™.[19] Pain evaluation occurred before implant, during implant and after explant. The authors concluded the StimRouter™ was effective and safe for pain reduction from carpal tunnel syndrome, but the study had methodological limitations including a small sample size and no mention of follow-up after the StimRouter™ was explanted after five days of treatment.

Numerous additional case series and case studies been published on PNS for the treatment of conditions including complex regional pain syndrome,[20] chronic shoulder pain,[21] chronic low back pain,[22] peripheral neuralgia,[23] oncologic pain,[24] and trigeminal pain.[25] Case studies and small case series generally are not considered in evidence reviews as they do not provide sufficient sample sizes or comparison groups to determine the added benefit of the technology on health outcomes over standard of care for any patient population.

PERIPHERAL SUBCUTANEOUS FIELD STIMULATION

Systematic Review

Sarica (2022) published the results of a systematic review with meta-analysis of studies reporting pain outcomes (visual analogue scale [VAS]) in patients treated with peripheral nerve field stimulation for facial pain, with a focus on trigeminal nerve pain.[26] Data from eleven observational, single-site cohort studies (N=109) were included in the review, five of which were prospective. Nine studies included cohorts of mixed diagnoses, and the most common diagnoses were persistent idiopathic facial pain (PIFP; n = 26) and trigeminal neuropathic pain (TNP; n = 25), followed by postherpetic neuralgia (PHN; n = 19), symptomatic trigeminal neuralgia (STN; n = 14), trigeminal neuralgia type 2 (TN2; n = 12) and type 1 (TN1; n = 8), and trigeminal deafferentation pain (TDP; n = 5). The number of patients included in each study ranged from 7 to 19. Common previously trialed interventions included nerve blocks (56%, 37/66), microvascular decompression (MVD; 25%, 16/65), percutaneous gasserian ganglion procedures (PGPs; 18%, 10/57), and stereotactic radiosurgery (SRS; 7%, 4/57). Nine trials included pre-implantation trial of temporary lead placement, one trial used adhesive electrodes and one used nerve block injections. The mean study follow-up period ranged from one month to 63.7 months. Analysis of individual patient data available for 62 patients from eight studies found mean improvement in VAS pain score at last follow-up to be 6.3 (95% CI 5.5–7.1, paired t-test, $p < 0.001$), with 79% (49/62) having a postoperative pain score < 5. A total of 51 complications occurred across 105 implantation surgeries in 44 patients (49% per procedure). The rate of complications requiring a surgical intervention was 32% per procedure (range 0%–82% across studies). The most frequent complications that required surgical management were skin erosions (n = 13) and infection (n = 10). The risk of bias of the included studies ranged from 4 to 6 out of a possible 6 stars when assessed using the Newcastle-Ottawa Scale and statistical heterogeneity was considerable ($I2 = 79\%$) across all studies. Although evidence of publication bias was not found (Egger's test, $p = 0.20$), significant small-study effects were found; 4 of the 11 studies fell outside of the 95% CI of the effect summary estimate for pain reduction outcome. The considerable heterogeneity across studies with respect to follow-up periods, rating scales used, patient selection/trial methods, stimulation parameters and preoperative conditions, as well as small sample sizes and lack of

controlled/comparator groups are limitations to the available evidence regarding peripheral nerve field stimulation for the treatment of facial pain.

A systematic review (SR) by Hofmeister (2020) evaluating the effectiveness of neurostimulation technologies for the management of chronic pain included one study on peripheral subcutaneous field stimulation (PSFS).[27] This study (Eldabe 2018) is discussed below.[28]

Randomized Controlled Trials

Albright-Trainer (2022) conducted a randomized controlled feasibility trial of PNS for the management of post-amputation pain.[29] Sixteen U.S. veterans undergoing major lower limb amputation at a single center received up to 60 days of PNS with the SPRINT system and standard medical therapy (n=8) or standard medical therapy alone (n=8). Standard medical therapy was defined as routine use of opioid and non-opioid pain medications, injections, physical rehabilitative therapies or complementary and alternative therapies. Responders were defined as participants with a at least a 50% reduction in average residual and phantom limb pain over time as assessed by the Brief Pain Inventory-Short Form (BPI-SF), with greater than 50% improvement considered substantial. At 12 weeks of follow-up, the PNS group experienced a 76% and 100% reduction in average phantom and residual limb pain from baseline compared to 58% and 75% in the control group, respectively. Additionally, only 20% of patients in the PNS group were taking opioids at 12 weeks compared to 38% in the control group. No patients in the PNS group required hospital readmission within 30 days compared to 25% requiring readmission in the control group. Follow up analysis through 12 months is ongoing. No serious study-related adverse events were reported. Follow-up at 12 weeks was missing for three individuals in the PNS group and one individual in the control group. The authors concluded that larger studies are warranted to reproduce the encouraging results of their feasibility study and to elucidate optimal timing of PNS therapy, evaluate surgical indications, and optimize patient selection.

Ilfeld (2021) published the results of a randomized, sham-controlled, pilot study of PNS for the treatment of postoperative pain in individuals receiving foot, ankle, knee, or shoulder surgery. Subjects were randomized to 14 days of electrical PNS stimulation (n=32) or sham stimulation (n=34). The dual primary outcomes were cumulative opioid consumption and mean daily pain scores within the first 7 postoperative days. Both outcomes met superiority thresholds with median opioid consumption of 5 mg versus 48 mg (estimated ratio of geometric means, 0.20; 97.5% CI, 0.07 to 0.57; p<.001) and average pain intensity of 1.1 versus 3.1 (difference in means, -1.8; 97.5% CI, -2.6 to -0.9; p<.001) as assessed by the Brief Pain Inventory-Short Form (BPI-SF) in treatment and sham groups, respectively. Differences in average pain, worst pain, and pain as assessed by the Defense and Veterans Pain Rating Scale were not significantly different between groups following completion of the treatment period on postoperative days 15 and 30.

Van Gorp (2019) published the 12-month follow-up of a multicenter RCT of patients with chronic low back pain in failed back surgery syndrome (FBSS) treated with spinal cord stimulation (SCS) alone and SCS with peripheral subcutaneous nerve field stimulation (PSFS).[28] Although the initial RCT randomized patients to treatment (SCS with PSFS) or control (SCS alone),[30] after the three-month study period, all patients in both groups received optimal SCS with PSFS during the open follow-up for the duration of the subsequent nine months. Thus, for the analysis of the follow-up data, both groups were combined and data from

all patients at 12 months (n=50) were compared to their own baseline values. Back pain, measured on a 100-mm visual analog scale (VAS), significantly decreased by 30.0 mm (95% CI: 237.7/222.4]; p<0.001), and leg pain decreased by 43.7 mm (95% CI: [251.5/236.2]; p<0.001). The authors also reported significant improvements across the 50 participants on secondary outcome measures including physical functioning, disability, pain, social functioning, anxiety, and medication indices. While this prospective, multicenter study provides valuable data on the efficacy of the simultaneous use of SCS and PSFS in a homogeneous, highly selected group of FBSS patients, the data do not permit conclusions regarding the added benefit of PSFS over SCS alone or the added benefit of this technology in other clinical populations. Additional long-term RCTs evaluating the added benefit of PSFS on health outcomes are needed.

Eldabe (2018) published a multi-site (21 sites) RCT comparing the effectiveness of subcutaneous peripheral nerve (field) stimulation (SQS) plus optimized medical management (SQS + OMM arm) compared to optimized medical management alone (OMM arm) in patients with back pain due to failed back surgery syndrome (FBSS).[31] Those in the SQS arm were implanted with a neurostimulator and up to two subcutaneous percutaneous cylindrical leads in the area of pain. Patients were evaluated pre-randomization and at one, three, six, and nine months post-randomization. The primary endpoint was the proportion of subjects with a ≥50% reduction in back pain intensity ("responder") from baseline to nine months. A total of 33.9% (19/56, missing: n = 20 [36%]) of subjects in the SQS + OMM arm and 1.7% (1/60, missing: n = 24 [40%]) in the OMM arm were responders at month nine (p < 0.0001). Although these results suggest that the addition of SQS to OMM is more effective than OMM alone in relieving low back pain at up to nine months in this study population, due to the slow rate of recruitment, the study was terminated early. Additional appropriately powered RCTs with longer-term follow-up are needed.

One small randomized double-blind crossover trial was published by McRoberts in 2013, however, this study did not include a control group or a comparison group of alternative treatment modalities.[32] The aim of this two-phase study was "to obtain preliminary estimates of the safety and efficacy of PSFS therapy using equipment originally designed for spinal cord stimulation." In the first phase of the study, patients (n=32) were initially randomized to one of the four stimulation groups, minimal, subthreshold, low frequency, and standard stimulation. Participants then rotated through all four stimulation groups in four to eight-day intervals. Both the investigator and patient were blinded to the group assigned. Two patients exited the study during phase I due to device/procedure-related adverse effects. "Responders" (n=24), defined as patients in any of the three active stimulation groups reporting $\geq$ 50% pain reduction, progressed to the second phase of permanent system implant (n=23). One responder did not receive permanent implantation due to non-device/procedure-related adverse effects.

Patients were followed for 52 weeks during which time reported mean visual analog scale (VAS), present pain index, and total scores on the Short Form McGill Pain Questionnaire were significantly improved from baseline at all follow-up visits (p<0.001). Excellent or good pain relief was reported in 16 (69.5%) patients at the 52-week follow-up visit. Opioid use decreased in 10 (43%) patients, remained stable in 8 (35%) patients, and increased in 5 (22%) patients. The most common adverse events were diminished or loss of therapy (n=10) and lead migration (n=7). Four patients had their systems explanted prior to completion of the study.

This study had a number of significant limitations that precluded conclusions, including but not limited to the small number of patients and the lack of an appropriate control group. Because

this study did not include a control group, the methodologic strength of these results is similar to that of an uncontrolled study. Further data are needed from well-designed RCTs which include large sample sizes and an appropriate control group for comparison.

NONRANDOMIZED TRIALS

Kloimstein (2014) reported on a prospective study of 118 patients treated with PSFS for chronic low back pain.[33] Before patients were implanted with the permanent PSFS system, a trial of stimulation was given for at least seven days. The permanent stimulation system was implanted in 105 patients. Significant improvements occurred at one, three, and six months' follow-up after implantation in the average pain VAS, Oswestry Disability Questionnaire, Becks Depression Inventory, and the Short Form-12 health survey. Significant reductions in opioid, nonsteroidal anti-inflammatory and anti-convulsant medications also occurred.

Verrills (2014) reported on PSFS for chronic headache conditions.[34] After a trial stimulation period, 60 patients underwent permanent implantation of the PSFS system and were followed for an average of 12.9 ± 9.4 months (range, 3-42 months). Ten patients required revision of the implant system. Significant reductions in pain were reported ($p \leq 0.001$). Additionally, use of analgesics or prophylactic medications was reduced in 83% of patients and disability and depression improved.

Verrills (2011) reported on a series of 100 patients treated PSFS for chronic neuropathic pain. Indications included chronic pain in occipital/craniofacial (n=40), lumbosacral (n=44), thoracic (n=8), groin/pelvis (n=5), or abdominal (n=3) regions.[35] Selection criteria included a clearly defined, discrete focal area of pain with a neuropathic component or combined somatic neuropathic pain component with characteristics of burning and increased sensitivity, and failure to respond to other conservative treatments including medications, psychological therapies, physical therapies, surgery, and pain management programs. Outcomes were assessed at a mean of 8.1 months after implantation (range, 1-23 months) with a combination of numerical pain scores, patient answered questionnaires, and patient medical histories. For the entire cohort, pain decreased from 7.4 at baseline to 4.2 at follow-up. About 34% of patients had at least a 75% improvement in pain scores and 69% improved by at least 50%. Analgesic use decreased in 40% of patients following PSFS. Adverse events were reported in 14% of patients, including unpleasant sensations, lead erosions and lead or battery migration.

Sator-Katzenschlager (2010) reported a retrospective multicenter study of the use of PSFS.[36] A total of 111 patients with chronic pain were treated, including 29 patients with low back pain, 37 with failed back surgery syndrome, 15 with cervical neck pain, and 12 patients with postherpetic neuralgia. The median duration of chronic pain was 13 years and the median number of previous surgeries was 2.7. For permanent implantation of the leads, patients had to have achieved at least 50% improvement in pain on a numerical rating scale during the trial period. After permanent implantation, pain intensity decreased in 102 patients (92%). Mean pain intensity decreased from 8.2 at baseline to 4.0 at follow-up with a reduction in consumption for analgesics and antidepressants. Lead dislocation or fracture occurred in 20 patients (18%).

PRACTICE GUIDELINE SUMMARY

AMERICAN SOCIETY OF PAIN AND NEUROSCIENCE

In 2022, the American Society of Pain and Neuroscience published consensus clinical guidelines for the use of implantable peripheral nerve stimulation in the treatment of chronic pain based on a review of the literature through March 2021. [37] Recommendations for best practices are listed below:

Head and Neck:

- Stimulation of occipital nerves may be offered to patients with chronic migraine headache when conservative treatment have failed. The average effect size for relief of migraine symptoms is modest to moderate. Level of Evidence (LOE) I. Degree of Recommendation (DOR) B.
- There is presently insufficient evidence to recommend stimulation of supraorbital and infraorbital nerves for neuropathic craniofacial pain LOE: II-3 DOR: C

Upper Extremities:

- PNS may offer modest and short-term pain relief, improved physical function, and better quality of life for chronic hemiplegic shoulder pain. LOE: I DOR: B
- PNS for mononeuropathies of the upper extremity may be offered following a positive diagnostic ultrasound-guided nerve block of the targeted nerve and is associated with modest to moderate pain relief. LOE: II-2 DOR: B

Low Back and Trunk

- Subcutaneous peripheral field stimulation combined with optimal medication management may offer moderate improvement in pain intensity for failed back surgery syndrome compared to optimal medication management alone. LOE: I DOR: B
- There is evidence that peripheral nerve stimulation (PNS) of medial branch nerves may improve pain intensity, physical function, and pain interference in patients with axial, mechanical low back pain. LOE: II-2 DOR: B
- There is limited evidence that PNS alleviates pain in neuropathic pain syndrome involving the trunk and back, including radiculopathy and post-herpetic neuralgia. LOE: III DOR: C

Lower Extremities:

- PNS may be considered for lower extremity neuropathic pain following failure of conservative treatment options and is associated with modest pain relief. LOE: I DOR: B
- PNS may be considered for lower extremity post-amputation pain following failure of conservative treatment options and is associated with modest to moderate pain relief. LOE:I DOR:B

Complex regional pain syndrome (CRPS)

- As a less-invasive modality compared to spinal cord stimulator (SCS) therapy, PNS may be offered to patients with CRPS Type I/II or peripheral causalgia, and may be associated with modest improvement in pain intensity and functional outcomes. However, high-quality evidence is limited and other neuromodulation interventions such as dorsal root ganglion SCS are recommended. LOE: III DOR: C

Other Considerations:

- PNS carries a low-to-intermediate risk for bleeding complications and depends on the proximity of the targeted nerve to critical vessels and invasiveness of PNS implantation. LOE: III DOR: I

The National Institute for Health and Care Excellence issued guidance in 2013 on peripheral subcutaneous field stimulation for chronic low back pain.[38] The guidance stated: “Current evidence on the efficacy of peripheral nerve-field stimulation (PNFS) for chronic low back pain is limited in both quantity and quality, and duration of follow-up is limited. Evidence on safety is also limited and there is a risk of complications from any implanted device. Therefore, this procedure should only be used with special arrangements for clinical governance, consent and audit or research.”

SUMMARY

There is not enough research to show that implantable peripheral nerve stimulation (PNS) or peripheral subcutaneous field stimulation (PSFS) improves health outcomes for any indication, including for the treatment of chronic, postoperative, or post-traumatic pain of peripheral nerve origin. Therefore, the use of an implantable PNS system including peripheral subcutaneous field stimulation (PSFS) for treatment of pain of peripheral nerve origin is considered investigational including but not limited to the treatment of chronic pain, post-operative, or post-traumatic pain.

Balloon Dilation of the Eustachian Tube

Effective: July 1, 2023

Next Review: March 2024
Last Review: May 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Balloon dilation of the Eustachian tube is a tuboplasty procedure intended to improve the patency of the cartilaginous Eustachian tube. During the procedure, a saline-filled balloon catheter is introduced into the Eustachian tube through the nose using a minimally invasive transnasal endoscopic method. Pressure is maintained for approximately two minutes after which the balloon is emptied and removed. The procedure is usually performed under general anesthesia.

MEDICAL POLICY CRITERIA

I. Balloon dilation of the eustachian tube for treatment of chronic obstructive eustachian tube dysfunction may be considered **medically necessary** when all of the following Criteria are met (A. – E.):

A. Patient is 18 years and older;

B. Patient has chronic signs and symptoms of obstructive eustachian tube dysfunction that impairs function and meets all of the following Criteria (1. – 4.):

1. The patient does not have patulous eustachian tube dysfunction or another contraindication (See Policy Guidelines); and

2. Symptoms have occurred for at least 12 months including but not limited to aural fullness, aural pressure, otalgia, or hearing loss; and

3. The patient does not have other causes of aural fullness such as temporomandibular joint disorders, extrinsic obstruction of the eustachian tube, superior semicircular canal dehiscence, and endolymphatic hydrops; and

4. Symptoms are continuous rather than episodic (e.g., symptoms occur only in response to baro-challenge such as pressure changes while flying); and

C. The patient has undergone a comprehensive diagnostic assessment documenting all of the following findings:

1. Abnormal tympanogram (Type B or C); and

2. Abnormal tympanic membrane (retracted membrane, effusion, perforation, or any other abnormality identified on exam); and

D. Failure to respond to appropriate medical management of co-occurring conditions, including 4-6 weeks of a nasal steroid spray if indicated. Co-occurring conditions include but are not limited to allergic rhinitis, rhinosinusitis, and laryngopharyngeal reflux; and

E. If the patient had a history of tympanostomy tube placement, symptoms of obstructive eustachian tube dysfunction should have improved while tubes were patent.

II. Balloon dilation of the eustachian tube is considered **not medically necessary** when Criterion I. is not met.

III. Balloon dilation of the eustachian tube is considered **investigational** for repeat balloon dilation of the eustachian tube and all other indications.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Contraindications to Balloon Dilation of the Eustachian Tube

The following patients should not be considered for balloon dilation of the eustachian tube:

- Patients with patulous eustachian tube dysfunction
  - A diagnosis of patulous ETD is suggested by symptoms of autophony of voice, audible respirations, pulsatile tinnitus, and/or aural fullness.
- Patients with extrinsic reversible or irreversible causes of eustachian tube dysfunction including but not limited to:
  - craniofacial syndromes, including cleft palate spectrum
  - neoplasms causing extrinsic obstruction of the eustachian tube
  - history of radiation therapy to the nasopharynx
  - enlarged adenoid pads
  - nasopharyngeal mass
  - neuromuscular disorders that lead to hypotonia/ineffective eustachian tube dynamic opening

    - systemic mucosal or autoimmune inflammatory disease affecting the mucosa of the nasopharynx and eustachian tube (e.g. Samter's triad, Wegener's disease, mucosal pemphigus) that is ongoing/active (i.e. not in remission)
- Patients with aural fullness but normal exam and tympanogram
- Patients with chronic and severe atelectatic ears

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes including length of time signs and specific symptoms of obstructive eustachian tube dysfunction have been present and have impaired function.
- Indication for the requested service.
- Documentation patulous eustachian tube dysfunction and other contraindications to the procedure have been ruled out.
- Diagnostic findings documenting abnormal tympanogram and an abnormal tympanic membrane.
- Documentation of failure of medical management for any co-occurring conditions and specify length of time it was trialed.
- If there is a history of tympanostomy tube placement, provide documentation that symptoms of obstructive eustachian tube dysfunction improved while tubes were patent.

BACKGROUND

EUSTACHIAN TUBE FUNCTION

The Eustachian tube (ET) connects the middle ear space to the nasopharynx. It is approximately 36 mm long in adults. The ET ventilates the middle ear space to equalize pressure across the tympanic membrane, clears mucociliary secretions, and protects the middle ear from infection and reflux of nasopharyngeal contents.[1] The tube opens during swallowing or yawning.

Eustachian tube dysfunction (ETD) occurs when the functional valve of the ET fails to open and/or close properly. This failure may be due to inflammation or anatomic abnormalities. ET dilatory dysfunction (ETDD) is most commonly caused by inflammation including rhinosinusitis and allergic rhinitis. ETDD can cause symptoms such as muffled hearing, ear fullness, tinnitus, and vertigo.[2] Chronic ETDD can lead to hearing loss, otitis media, tympanic membrane perforation, and cholesteatomas.

EPIDEMIOLOGY OF ETD

The epidemiology of ETD, including incidence and prevalence of the disorder and associated symptoms in the community, primary care, and referral populations, is not well-characterized.

Data are also lacking to describe the natural history of the disorder and impact on patient functioning.

DIAGNOSIS AND OUTCOME MEASURES

There are no comprehensive guidelines regarding the diagnosis of ETD. Schilder (2015) published a consensus statement from an international group of scientists and physicians with expertise in Eustachian tube disorders, prompted by a Health Technology Assessment from the UK National Institute of Health and Research stating that an important limitation with available evidence for treatments of ETD is a lack of consensus on the definition and diagnosis.[1] The meeting was funded by Acclarent, a manufacturer of a dilation technology. The following summarize relevant 2015 consensus statements from the group.

- There is no universally accepted set of patient-reported symptom scores, functional tests, or scoring systems to diagnose ETD.
- Diagnosis of ETDD should consider patient-reported symptoms along with evidence of negative pressure in the middle ear assessed by clinical assessment.
- Transient ETD is ETD with symptoms and signs lasting less than 3 months while chronic ETD is ETD with symptoms and signs lasting for more than 3 months.
- Future clinical trials should include outcomes related to patient-reported symptoms, otoscopy, tympanometry, and pure-tone audiometry, and outcomes should be assessed at baseline, in the short term (6 weeks to 3 months) and in the long term (6-12 months).
- The 7-item Eustachian Tube Dysfunction Questionnaire (ETDQ-7) is the only patient-reported outcome scale to have undergone initial validation studies.

Tympanometry is a frequently used outcome measure in ETD. Tympanometry measures the mobility of the tympanic membrane and graphically displays results in tympanograms. Tympanograms are classified by the height and location of the tympanometric peak. They are classified into three general patterns: type A indicates normal middle ear and ET function; type B indicates poor tympanic membrane mobility (“flat” tympanogram); and type C indicates the presence of negative middle ear pressure.[3]

The ETDQ-7 is used to assess ETD-related symptoms such as pressure, pain, “clogged” ears, and muffled hearing over the previous month. The 7 items are rated by patients on a 7-level scale from 1 (no problem) to 7 (severe problem). The overall score is reported as a mean item score with a range from 1.0 to 7.0. ETDQ-7 has been shown to be a valid and reliable symptom score for use in adults with ETD with overall score of 2.1 or higher having high accuracy to detect the presence of ETD.[4]

Other important outcomes for evaluating a treatment for ETD are hearing outcomes, otitis media, clearance of middle ear effusion, tympanic membrane retraction, and quality of life. Another important consideration is the need for additional treatment, e.g., additional surgical procedures (including reintervention).

TREATMENT OF ETDD

Medical management of ETDD is directed by the underlying etiology: treatment of viral or bacterial rhinosinusitis; systemic decongestants, antihistamines, or nasal steroid sprays for

allergic rhinitis; behavioral modifications and/or proton pump inhibitors for laryngopharyngeal reflux; and treatment of mass lesions. Although topical nasal steroids are commonly used for ETDD, triamcinolone acetonide failed to show benefit in patients ages six and older presenting with otitis media with effusion and/or negative middle ear pressure in a randomized, placebo-controlled, double-blind trial published in 2011.[5]

Patients who continue to have symptoms following medical management may be treated with surgery. Available surgical management includes myringotomy with placement of tympanostomy tubes or eustachian tuboplasty. There is limited evidence supporting use of these surgical techniques.[6] Norman (2014) reported that eustachian tuboplasty (other than balloon dilation) has been evaluated in seven case series and was associated with improvement in symptoms in 36% to 92% of patients with low rates (13%-36%) of conversion to type A tympanogram (which is normal). Myringotomy and tympanostomy have been evaluated in two case series and were associated with symptom alleviation in a subgroup of patients.[6]

REGULATORY STATUS

In December 2015, the AERA® (Acclarent) was granted a de novo 510(k) classification by the U.S. Food and Drug Administration (FDA) (class II, FDA product code: PNZ).[7] The new classification applies to this device and substantially equivalent devices of this generic type. The device was cleared for marketing by FDA through the 510(k) process (K163509) in January 2018.The AERA® is cleared for dilating the Eustachian tube in patients ages 22 and older with persistent ETD.

In April 2017, the XprESS™ ENT Dilation System (Entellus Medical, Plymouth, MN) was cleared for marketing by FDA through the 510(k) process (K163509).[8] FDA determined that this device was substantially equivalent to existing devices for use in Eustachian tube dysfunction. The predicate devices are XprESS™ Multi-Sinus Dilation System and AERA® Eustachian Tube Balloon Dilation System.

EVIDENCE SUMMARY

SCIENTIFIC EVIDENCE

Evaluating the safety and effectiveness of balloon dilation of the Eustachian tube requires randomized comparisons with standard treatments. These comparisons are necessary to determine whether the benefits of balloon dilation of the Eustachian tube outweigh any risks and whether they offer advantages over conventional methods with respect to increasing quality of life and decreasing long-term morbidity and mortality, or secondary outcomes such as improved Eustachian tube function. The evidence summary below is focused on systematic reviews and randomized controlled trials (RCTs).

Systematic Reviews

Aboueisha (2022) conducted a systematic review of balloon dilation for eustachian tube (BDET) dysfunction in pediatric populations which included seven studies and 408 participants with a mean age of 9.9 years.[9] The primary outcomes of interest were changes in tympanograms and air-bone gap. Type B tympanograms decreased after BDET from 64.2% (95%CI 53.3, 73.8) to 16.1% (95%CI 8.5, 28.4). Air-bone gap (ABG) decreased after BDET from a mean of 25.3 dB (95%CI 18.9, 31.6) to 10.2 dB (95%CI 8.9, 11.5). The pooled estimate

of adverse events after BDET was 5.1% (95%CI 3.2, 8.1), the majority being self-limited epistaxis with no major adverse events reported. This review is limited by the lack of high quality studies including randomized, comparative trials. Additional comparative trials are needed to establish the efficacy of BDET in pediatric populations.

Froehlich (2020) conducted a systematic review and meta-analysis of balloon dilation for eustachian tube dysfunction.[10] Twelve studies were included in the meta-analysis, including three RCTs, five prospective observational studies, and four case series. One RCT (Liang 2016) that compared balloon dilation to tympanic paracentesis reported tympanometry and otoscopy scores but not symptoms. The other two RCTs compared balloon dilation plus medical management to medical management alone and used the ETDQ-7 to measure symptoms. Pooled analyses showed improvements in subjective and objective measures including ETDQ-7 scores, tympanograms, otoscopy exams, and ability to perform a Valsalva maneuver. Improvements appeared to be maintained in studies with longer-term follow up (3-12 months). Case series included in these reviews consistently reported that patients experienced improvement when comparing symptoms before and after balloon dilation. The studies varied in the type of medical management used to treat eustachian tube dysfunction before and after balloon dilation.

The results of two additional systematic reviews and meta-analyses for adults with ETD who were treated with balloon dilation are discussed here. Huisman (2018)[11] provided pooled results for 15 case series (n=1,155) while Hwang (2016)[12] provided qualitative summaries only, for nine case series (n=474). Most selected case series provided follow-up of less than a year. All case series reported that patients experienced improvement when comparing symptoms before and after balloon dilation. The selected studies differed with respect to other treatments for ETD used before and after balloon dilation. In Huisman (2018), revisions due to failure of the first ET balloon dilation procedure were reported in three of the 15 studies (n=714); 122 revisions were reported. Huisman (2018) also reported studies had methodological limitations including risk of bias and high heterogeneity and that high quality RCTs are needed.

Jufas (2016) published a SR that evaluated balloon dilation, with a transtympanic approach for Eustachian tube dysfunction (ETD).[13] Three limited case series were included. The authors concluded there was a high risk of bias and safety and efficacy outcomes were conflicting.

Randrup (2015) published a SR evaluating balloon eustachian tuboplasty for ETD.[14] The authors evaluated nine case series and health outcomes for 443 patients. All case series were poor quality and had a high risk of bias.

Randomized Controlled Trials

Krogshede (2022) published a randomized controlled trial with six months of follow up evaluating 24 patients.[15] Of the 13 subjects randomized to the treatment group, nine showed normalization from retraction or serous otitis media in addition to showing improved tympanometry. There were no differences in audiometric findings or in Eustachian Tube Dysfunction Questionnaire-7 scores between the two groups. The authors concluded that the treatment is safe and effective for adult patients with mild chronic Eustachian tube dysfunction.

Meyer (2018) published the results of a one-year-follow-up-inclusive, prospective, multi-center RCT of balloon dilation as a treatment for persistent eustachian tube dysfunction (ETD) and compared the intervention to continued medical therapy (control).[16] Inclusion criteria required

patients be diagnosed with medically refractory, persistent ETD. Participants were randomly assigned (1:1) to intervention or control; however, control participants were offered the intervention after six weeks if their symptoms remained. The outcomes measured include primary efficacy endpoint using Eustachian Tube Dysfunction Questionnaire (ETDQ-7) scores and the rate of complications. The trial involved 60 randomized participants (31 intervention, 29 control). Mean (SD) change in overall ETDQ-7 score at six weeks was 2.9 (1.4) for balloon dilation compared with 0.6 (1.0) for control: balloon dilation was superior to control ($p<0.0001$). No complications were reported in either study arm. Among participants with abnormal baseline assessments, improvements in tympanogram type ($p < 0.006$) and tympanic membrane position ($p<0.001$) were significantly better for balloon dilation than control. Improvements in the ETDQ-7 scores were maintained through 12 months after balloon dilation. Limitations of this RCT are its small sample size and the inability to blind the participants to their treatment.

Cutler (2019) reported longer-term follow-up data on a subset of patients from the treatment arm of the RCT reported by Meyer.[17] Of 58 patients from the original study who were eligible for the extension study, 47 were enrolled in the follow up study. The mean follow-up time was 29.4 months post-procedure. Changes from baseline at the end of the longer-term follow-up period were similar to improvements observed at one year on outcome measures including the ETDQ-7, normalized tympanogram, ability to perform the Valsalva maneuver, and patient satisfaction. One patient underwent a revision ET dilation after 362 days, performed concurrently with balloon dilation for recurrent sinus disease. No other surgeries or adverse events were reported.

Poe (2017) published a randomized trial (n=323) comparing balloon dilation of the eustachian tube (BDET) with ET balloon catheter (ETBC) plus medical management versus medical management alone. Participants were 22 years or older, had persistent patient-reported symptoms of ETD (ETDQ-7; mean item score, ≥2.1), abnormal tympanometry (type B or type C), and failed medical management including either a minimum of four weeks of daily use of any intranasal steroid spray or a minimum of one course of an oral steroid.[18] The balloon catheter used in the trial was a custom-designed ET balloon catheter (Acclarent). The RCT results are also described in the AERA (Acclarent) de novo summary from the Food and Drug Administration.[7]

The investigators in this study were required to perform three successful ETBC procedures in nonrandomized “lead-in” patients who were then followed for durability and safety outcomes. Randomization and analyses were performed at the person-level regardless of whether the patient had unilateral or bilateral ETD. The primary efficacy outcome (normalization of tympanometry) was assessed by both site investigators and a blinded, independent evaluator; discrepancies were resolved by a second independent evaluator. For bilaterally treated patients, both ears had to be rated as normalized for that patient to be considered normalized for the primary outcome. Patients completed follow-up visits at 2, 6, 12, 24, and 52 weeks but data from the 52-week visit have not been reported. Patients in the medical management arm were allowed to receive BDET after the six-week visit. Trial enrollment was stopped early after the second preplanned look when the prespecified O’Brien-Fleming stopping boundary for the primary outcome was crossed.

At baseline, the mean ETDQ-7 score was 4.7, 43% of patients had allergic rhinitis, and 61% of patients had at least one prior ear tube surgery. By the second interim analysis, 162 patients had been assigned to ETBC and 141 were included in analysis; 80 had been assigned to

medical management and 72 were included in analysis. Patients were included in analysis if they received the study treatment for which they were randomized and had 6-week follow-up data. Approximately 52% of ETBC patients experienced tympanogram normalization at 6 weeks compared with 14% of medical management patients (p<.001). The publication reported that sensitivity analysis was performed to test the robustness of results for the impact of missing data in the analysis cohort versus an intention-to-treat cohort, but the method of sensitivity analyses was not described. It was noted that there was a significant treatment by site interaction. Two sites had a higher percentage of tympanogram normalization for MM subjects than for ETBC subjects while the remaining sites had higher normalization for ETBC. The pre-specified secondary efficacy outcome (percentage with minimal clinically important difference change of 0.5 points on ETDQ-7) was not reported in the publication but was reported in the FDA summary. The minimal clinically important difference change in ETDQ-7 scores was observed for 91% of ETBC patients at 6 weeks compared with 45% of medical management patients (p not reported). Fifty-six percent of ETBC patients had an ETDQ-7 mean item score of less than 2.1 at six weeks compared with about 9% of medical management patients (p<0.001). See the summary of results in table 1 below.

Comparative analyses were not possible after six weeks because 82% of medical management patients elected to ETBC after 6 weeks. Durability of the effect is supported by analysis of tympanogram normalization in 170 patients with week 24 data (98 randomized to ETBC and 74 from the lead-in); 62% of those randomized to ETBC and 58% of lead-in patients demonstrated tympanogram normalization at 24 weeks. Data from 52 weeks have not been reported.

This trial had methodological limitations, including the inability to blind patients, the exclusion of patients who did not received the assigned treatment, and the premature ending of the study. In addition, there were relevance gaps that prevented the RCT from providing enough evidence to guide treatment for ETDD. These included but are not limited to:

- Patients continued nasal steroids and other medications prescribed prior to the study
- Hearing outcomes were not reported
- Short-term follow-up prevented evaluation of long-term outcomes.

Table 1. Summary of Key RCT Results

Study (Year)	Normalization of Tympanometry (% of patients)	ETDQ-7 Symptom Scores <2.1 (% of patients)[a]	Change in Mean ETDQ-7 Score (SD)	Change in Mucosal Inflammation	Positive modified Valsalva Maneuver (% ears)	SAEs (no. of events)
Poe (2017)[18]						
N	211	208		NR	NR	NR
BDET plus MM	52%	56%		+22%	33%	4
MM	14%	9%		-5%	3%	1
Tx effect	RR=NR	RR=NR		NR	NR	NR
p	<0.001	<0.001				
Meyer (2018)[16]						
N			28			
BDET plus MM			-2.9 (1.4)			
N			27			
MM			-0.6 (1.0)			

Study (Year)	Normalization of Tympanometry (% of patients)	ETDQ-7 Symptom Scores <2.1 (% of patients)[a]	Change in Mean ETDQ-7 Score (SD)	Change in Mucosal Inflammation	Positive modified Valsalva Maneuver (% ears)	SAEs (no. of events)
p			<0.0001			

BDET: balloon dilation of the Eustachian tube; BL: baseline; ETDQ-7: 7-item Eustachian Tube Dysfunction Questionnaire; MM: medical management; NR: not reported; RR: relative risk; SAE: serious adverse event; Tx: treatment.
[a] The prespecified secondary outcome was the proportion of subjects achieving an improvement of at least a minimal clinically important difference of 0.5 points; it was not reported.

Adverse events were only briefly described in the publication but are more fully described in the Food and Drug Administration summary.[7] Two-hundred ninety-nine patients who were treated with ETBC were included in the safety analysis (80 lead-in patients, 149 patients randomized ETBC, 70 patients randomized to medical management who received ETBC). There were 16 nonserious device or procedure-related adverse events in 13 patients—most commonly, epistaxis and ETD. Two patients had three potentially device-related adverse events: mucosal tear, worsened ETD, and conductive hearing loss. The potentially device- or procedure-related adverse events were mild or moderate in severity and resolved without sequelae. Five serious adverse events were reported (four events in the BDET group, one event in the MM group); all were thought to be unrelated to device, procedure, or medication.

A 12-month follow-up on the treatment group was published by Anand (2019), which reported that the overall number of patient with normalized tympanograms and ETDQ-7 scores at one year were comparable to those reported after six weeks (71/128 vs. 73/143 and 71/124 vs. 79/142, respectively).[19] Results in the control group were not assessed.

Nonrandomized Studies

Satmis (2018) published a retrospective cohort study of 42 consecutive adult patients with chronic dilatory eustachian tube dysfunction. Patients in a tertiary referral hospital setting who received transnasal balloon dilation of the Eustachian tube were evaluated. Objective outcome measures included the ETDQ-7 score, bone conduction threshold, and tympanic membrane and middle ear conditions, which were pre and postoperatively collected. Mean ETDQ-7 scores improved from 4.28 to 3.09 and from 4.10 to 2.96 postoperatively at one and three months, respectively. There was a 62.0% improvement in tympanic membrane and middle ear condition. No serious procedure related complications were reported.

PRACTICE GUIDELINE SUMMARY

NATIONAL INSTITUTE FOR HEALTH AND CARE EXCELLENCE (NICE)

In 2019, The National Institute for Health and Care Excellence (NICE) published updated guidance on balloon dilation of the eustachian tube.[20] The guidance was based on a rapid review of the evidence and stated: "Evidence on the safety and efficacy of balloon dilation for eustachian tube dysfunction is adequate to support the use of this procedure provided that standard arrangements are in place for clinical governance, consent and audit." NICE standard arrangements recommendations mean that there is enough evidence for doctors to consider the procedure as an option. The guidance also noted:

- The procedure was not effective in all patients, and there was little evidence on the benefit of repeat procedures.

- The procedure is only indicated for chronic eustachian tube dysfunction refractory to medical treatment.

AMERICAN ACADEMY OF OTOLARYNGOLOGY-HEAD AND NECK SURGERY FOUNDATION

In 2019, The American Academy of Otolaryngology published a clinical consensus statement on balloon dilation of the eustachian tube.[21] The target population was defined as adults ages 18 years or older who are candidates for BDET because of obstructive eustachian tube dysfunction (ETD) in 1 or both ears for 3 months or longer that significantly affects quality of life or functional health status. The expert panel concluded:

- BDET is an option for treatment of patients with obstructive ETD.
- The diagnosis of obstructive ETD should not be made without a comprehensive and multifaceted assessment, including otoscopy, audiometry, and nasal endoscopy.
- BDET is contraindicated for patients diagnosed as having a patulous ETD
- Further study will be needed to refine patient selection and outcome assessment.

The authors emphasized the importance of identifying other potentially treatable causes of ETD, including allergic rhinitis, rhinosinusitis, and laryngopharyngeal reflux, and noted that medical management of these disorders is indicated prior to offering BDET. They also noted that potential risks of BDET that are relevant to patient counseling include bleeding, scarring, infection, development of patulous ETD, and/or the need for additional procedures.

SUMMARY

There is enough research to show that balloon dilation of the Eustachian tube improves health outcomes in patients with chronic signs and symptoms under certain circumstances. Additionally, clinical practice guidelines recommend the use of balloon dilation of the Eustachian tube for select patients. Therefore, the use of balloon dilation of the Eustachian tube may be considered medically necessary for the treatment of Eustachian tube dysfunction when policy criteria are met.

Due to not showing positive health outcomes for patients who do meet patient selection criteria, the use of balloon dilation for the treatment of Eustachian tube dysfunction is considered not medically necessary when policy criteria are not met.

There is not enough research to show that balloon dilation of the Eustachian tube improves health outcomes for people with any other indication or for repeat balloon dilation procedures. Therefore, balloon dilation of the Eustachian tube is considered investigational for the treatment for any other indication or repeat balloon dilation procedures.

Transurethral Water Vapor Thermal Therapy and Transurethral Water Jet Ablation (Aquablation) of the Prostate

Effective: April 1, 2024

Next Review: December 2024
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Transurethral water vapor thermal therapy and transurethral waterjet ablation are surgical alternatives to transurethral resection of the prostate (TURP) for the treatment of benign prostatic hyperplasia.

MEDICAL POLICY CRITERIA

I. Transurethral water vapor thermal therapy may be considered **medically necessary** for the treatment of benign prostatic hyperplasia (BPH) when all of the following criteria are met (A. – D.):

   A. Moderate to severe symptomatic BPH (See Policy Guidelines); and

   B. Patient is at least 50 years of age; and

   C. Prostate volume is 30 cc to 80 cc by ultrasound or other radiologic assessment; and

   D. A trial of conservative medical therapy (defined as one month of an alpha blocker, 3 months of a 5-alphareductase inhibitor, or 3 months of an

anticholinergic) for BPH has been unsuccessful, is contraindicated, or is not tolerated (See Policy Guidelines).

II. Transurethral waterjet ablation (e.g., Aquablation) may be considered **medically necessary** for the treatment of benign prostatic hyperplasia (BPH) when all of the following criteria are met (A. – C.):

A. Moderate to severe BPH (See Policy Guidelines); and

B. Prostate volume is 30cc to 150cc by ultrasound or other radiologic assessment; and

C. A trial of conservative medical therapy (defined as one month of an alpha blocker, 3 months of a 5-alphareductase inhibitor, or 3 months of an anticholinergic) for BPH has been unsuccessful, is contraindicated, or is not tolerated (See Policy Guidelines).

III. Transurethral water vapor thermal therapy of the prostate and transurethral waterjet ablation are considered **investigational** when the above criteria are not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

BENIGN PROSTATIC HYPERPLASIA SEVERITY

The American Urological Association Symptom Index (AUA-SI) is a validated clinical tool for measuring severity of benign prostatic hyperplasia (BPH).[1] BPH severity is reported as mild (AUA-SI score of 0 to 7), moderate (8 to 19), and severe (20 to 35). The IPSS is the same as the AUA-SI but includes an additional question regarding impact of symptoms on quality of life.

CONSERVATIVE MEDICAL THERAPY

The medications listed in Table 1 may be used for conservative treatment of BPH.

Table 1. Medications for conservative treatment of BPH

Class	Common Examples
Alpha-1-receptor antagonists	Alfuzosin (Uroxatral, Xatral), doxazosin (Cardura), tamsulosin (Flomax), and terazosin (Hytrin)
5-alphareductase inhibitors	Finasteride, dutasteride
Anticholinergics	Fesoterodine (Toviaz), tolterodine (Detrol, Detrol LA), oxybutynin (Ditropan, Ditropan XL), darifenacin (Enablex), solifenacin (Vesicare), trospium (Sanctura, Sanctura XR)

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below must be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Conservative treatment provided, if any

    - If options for more conservative management are relatively or absolutely contraindicated, those contraindications should be specified.
    - If options for more conservative management previously have been tried and have been ineffective or not tolerated, clinical information regarding those previous treatments should be provided.
- Relevant imaging (ultrasound, etc) reports documenting prostate volume.

BACKGROUND

Benign prostatic hyperplasia (BPH) is a diagnosis that describes the enlargement of the prostate often associated with a group of obstructive symptoms, termed lower urinary tract symptoms (LUTS). These symptoms include decreased force of stream, hesitancy, straining, incomplete bladder emptying, and nocturia. The enlargement is caused by the proliferation of epithelial and smooth muscle cells in the transition zone of the prostate. Proliferation generally increases with age, and the initiation of BPH likely begins by the age of 30.[2] According to a multinational survey, 90% of men ages 50-80 experience BPH, although only 11% of men in the study received medical treatment.[3]

Standard management of BPH includes watchful waiting (active surveillance) in patients not bothered by their symptoms, medical management, surgery, and a number of new minimally invasive therapies. Surgical treatments include transurethral resection of the prostate (TURP), transurethral waterjet ablation (also referred to as robotic waterjet treatment [RWT] or Aquablation), transurethral vaporization, holmium laser enucleation or resection of the prostate, prostatic artery embolization, and prostatectomy. Minimally invasive therapies include transurethral needle ablation of the prostate (TUNA) and transurethral microwave thermotherapy (TUMT), as well as transurethral water vapor thermal therapy.

Transurethral water vapor thermal therapy is a process by which water vapor is created outside of the body and delivered to the prostate with a needle. The treatment is repeated in multiple locations within the prostate. During the procedure, saline irrigation cools and protects the surface of the urethra. The heat from the vapor disrupts cell membranes in the prostate, which leads to cell death and necrosis.

Aquablation cuts tissue by using a pressurized jet of fluid delivered to the prostatic urethra. The American Urological Association does not consider Aquablation to be a minimally invasive treatment because general anesthesia is required.[4]

REGULATORY STATUS

In 2015, the U.S. Food and Drug Administration (FDA) approved the Rezūm™ System (NxThera, Inc., acquired by Boston Scientific in 2018) under the 510(k) process for use in relieving symptoms and obstructions, and reducing prostate tissue associated with BPH. It is indicated for men > 50 years of age with a prostate volume >30cm3 and <80cm3. The Rezum System is also indicated for the treatment of prostate with hyperplasia of the central zone and/or a median lobe.

In April 2017, the Aquabeam® System (Procept Robotics Corporation) was cleared for marketing by the FDA through the 513(f)(2) (de novo) classification process (DEN170024). The device is intended for the resection and removal of prostate tissue in males suffering from LUTS due to benign prostatic hyperplasia.

EVIDENCE SUMMARY

The primary beneficial outcomes of interest are symptom reduction, measured in various ways, including the International Prostate Symptom Score (IPSS), the benign prostatic impact index (BPHII), and the maximum urinary flow rate (Qmax). Evaluating the safety and effectiveness of transurethral water vapor thermal therapy and Aquablation requires randomized comparisons with standard care. These comparisons are necessary to determine whether the benefits of implantable cardiac monitors outweigh any risks and whether they offer advantages over conventional methods with respect to increasing quality of life and decreasing symptoms.

TRANSURETHRAL WATER VAPOR THERMAL THERAPY

Systematic Reviews

Chughtai (2022) published a systematic review and meta-analysis of treatment options for men with moderate-to-severe lower urinary tract symptoms (LUTS) due to benign prostatic hyperplasia (BPH).[5] This study examined the long-term cost-effectiveness of generic combination therapy (CT), prostatic urethral lift (PUL), water vapor thermal therapy (WVTT), photoselective vaporization of the prostate (PVP), and transurethral resection of the prostate (TURP) for the treatment of BPH. The study found that IPSS improvement was highest in TURP and PVP, followed by WVTT. Compared to the other minimally invasive therapies WVTT had the highest quality-adjusted life years (QALY). However, QALYs from WVTT were lower than QALYs from the surgical therapies TURP and PVP.

Another systematic review by Tzeng (2022) reviewed all clinical trials investigating prostatic urethral lift (PUL), water vapor thermal therapy (WVTT), and temporary implantable nitinol device (TIND), with emphasis on clinical efficacy and complications.[6] Eighteen articles were included in this study, Evidence consisted of few randomized controlled trials, and multiple single-arm prospective and retrospective studies. Among the emerging technologies introduced to treat BPE, the in-office PUL, WVTT, and TIND systems are valuable additions to the current surgical options. WVTT demonstrate acceptable outcomes in terms of functional improvement, retreatment, and complications.

A similar Cochrane network meta-analysis by Franco (2022) included randomized controlled trials assessing the following treatments: convective radiofrequency water vapor thermal therapy (WVTT; or Rezūm); prostatic arterial embolization (PAE); prostatic urethral lift (PUL; or Urolift); temporary implantable nitinol device (TIND); and transurethral microwave thermotherapy (TUMT) compared to transurethral resection of the prostate (TURP) or sham surgery.[7] This study reported that PUL and PAE had the highest likelihood of being the most efficacious for urinary symptoms and quality of life, TUMT for major adverse events, WVTT and TIND for erectile function and PUL for ejaculatory function.

Babar (2022) published a systematic review to evaluate the latest efficacy and safety profile of Rezum in patients with LUTS secondary to BPH. [8] Randomized and nonrandomized studies that evaluated urinary outcomes and/or adverse events were deemed eligible. Nineteen studies (N = 1942), published in 25 articles, were included. The study reported an

improvement in the International Prostate Symptom Score (IPSS), quality of life (QoL), and maximum urinary flow rate (Qmax) as early as 1 month postoperatively and remained durable for up to 5 years.

A Cochrane systematic review (SR) was reported by Kang in 2020.[9] The search was limited to parallel-group randomized controlled trials (RCTs), cluster-RCTs, and non-randomized observational prospective studies with concurrent comparison groups, in which men with BPH underwent convective radiofrequency water vapor thermal therapy, another active therapy, or a sham procedure. Only the RCT described below met inclusion criteria. The authors concluded that both urologic symptom scores and quality of life appear to be improved by water vapor thermal therapy, but they were very uncertain about major adverse events and that study limitations and imprecision led to a downgrade of evidence, which ranged from moderate to very low.

Randomized Controlled Trials

A single RCT was identified, with results published in multiple publications through five years of follow-up on a subset of participants.[10-15] The trial began with a three month randomized phase followed by an uncontrolled, open-label crossover phase. One-hundred and ninety-seven men experiencing lower urinary tract symptoms associated with benign prostatic hyperplasia were randomized 2:1. The active treatment group received water vapor ablation therapy with the Rezūm® System and the control group underwent a control procedure including rigid cystoscopy with simulated active treatment sounds. After three months, 53 of 61 control subjects who met criteria elected to participate in a crossover active treatment study. The International Prostate Symptom Score (IPSS) was 10.8 (standard deviation [SD] = 6.5) and 17.5 (SD = 7.6) in the active therapy and sham groups, respectively ($p<0.0001$) at three months post-treatment. The peak flow-rate (Qmax) increased significantly more in the treatment group at three months, to 16.1 (SD ±7.3), compared with 10.8 (SD = 4) in the sham group ($p<0.0001$). Quality of life, as measured by the IPSS-QOL question, was statistically significantly better in the treatment group (2.3; SD = 1.4) than in the sham group (3.5; SD = 1.5; $p<0.0001$).

In the patients that crossed over to the treatment group after unblinding at three months, improvements in IPSS, IPSS-QOL, and Qmax were all reported to be statistically significant compared to baseline values at 3, 6, 12, 24, 36, and 48 months ($p<0.0001$). Sexual function scores (IIEF-EF and MSHQ function) remained unchanged at two years, but declined at four years (-7.6% change, $p=0.0333$ and -14.2% change, $p=0.0038$, respectively).

Adverse events reported include one treated patient each who experienced nausea, vomiting, and de-novo urinary retention. In addition, among active treatment patients, 17% reported dysuria, 15% reported hematuria, 7% reported urinary frequency, and 7% reported hematospermia. Over five years, the surgical retreatment rate was 4.4% and the medication retreatment rate was 11.1%.

At four years, 45 subjects were excluded from the analysis. Of these, seven were excluded due to use of BPH medication. Additionally, further surgical intervention was performed in six patients. Fifty percent of patients had data included for five-year outcomes. This study is limited by duration of follow-up, with no control group present after three months of follow-up, and a lack of comparison to alternative treatments. Additionally, there was a high loss to follow-up, with data available for the primary outcome at four years from 90 of 197 patients.

Nonrandomized Studies

Garden (2021) published a retrospective analysis of Rezūm outcomes in men with prostates ≥ 80 cc (large prostate group; n=36) versus < 80 cc (small prostate group; n=168).[16] For individuals with large prostates, there were significant improvements in Qmax and post-void residual volume (PVR) postoperatively (p=0.039 and p=0.009, respectively), but no changes in AUA-Symptom Score (AUA-SS) or Sexual Health Inventory for Men (SHIM) were reported (p=0.29 and p=0.825, respectively). For men with prostates < 80 cc, the study reported improved PVR (89.51 to 62.72, p=0.027) and AUA-SS (16.59 to 11.21, p=0.003), but not in Qmax (9.47 to 10.90, p=0.187). Passing trial void (large prostate 94.44%, small prostate 93.45%), postoperative UTI (large prostate 19.44%, small prostate 10.12%), ED visits (large prostate 22.22%, small prostate 17.86%), readmissions (large prostate 8.33%, small prostate 4.76%), and retreatment (large prostate 8.33%, small prostate 4.76%) were not significantly different between groups. Mean days to foley removal (large prostate 9, small prostate 5.71, p=0.003) and urosepsis rates (large prostate 5.56%, small prostate 0.00%, p=0.002) were significantly different between groups. No Clavien grade ≥III complications were reported.

Bole (2020) reported a retrospective analysis of Rezūm for large prostates.[17] A total of 182 patients were identified as having undergone Rezūm, 25.8% of whom had prostate volume over 80cc. In this group, mean prostate volume was 119 cc and 55.3% were catheter dependent. AUA-SS improved from 22 pre-treatment to 13.4 following Rezūm (p=0.04). The improvement in peak flow rate was also statistically significant (7.7 to 12.7 mL/second; p=0.002).

Alegorides (2020) reported outcomes of 62 men with BPH treated with convective radiofrequency water vapor thermal therapy.[18] The IPSS decreased significantly from baseline at six months post-treatment, and the decrease persisted at one year (12-point decrease, p<0.001). Also at one year, the QoL score decreased by 3.2 points (p<0.001), the Qmax improved by 6mL/s (p<0.001), and there was a 2.1% rate of surgical retreatment. No serious side effects (>Clavien II) and no cases of de novo erectile dysfunction were reported.

McVary (2020) reported on a retrospective case series of water vapor thermal therapy for nonneurogenic complete urinary retention associated with BPH.[19] A total of 38 men with complete urinary retention and catheter-dependence were treated with water vapor thermal therapy using the Rezūm™ System. Of the 37 men available for follow-up, 26 voided spontaneously and were catheter free at a median of 26 days (range 4 to 65) following the procedure. Median follow-up for the catheter-free patients was 15.8 months. Adverse events included dysuria (n=5), gross hematuria (n=4), and UTIs in patients with indwelling catheters (n=2).

Mollengard (2018) published a retrospective review of 129 patients with BPH who underwent Rezūm. Minimum follow-up was four months. IPSS, and Qmax improved from baseline at the 91-180 day follow-up (18.3 to 6.9 and 10.5 to 16.8 mL/s, respectively; p<0.001). PVR also significantly improved over that time span (108.0 to 73.1, p=0.005). The most commonly reported adverse events were urinary tract infections (17%) and transient urinary retention (14%).

Darson (2017) reported the results of a case series of 131 patients treated with transurethral convective radiofrequency water-vapor thermal therapy with LUTS associated with BPH.[20] Not all values were reported for all patients at all time-points. Statistical significance of changes from baseline was determined using a longitudinal general estimation-equation model using an

exchangeable working correlation structure, which takes into account the correlation within a subject over time. IPSS at baseline, three to six months, and 12 months was 19.9 (SD = 6.7), 9.8 (SD = 6.9), and 10.1 (SD = 7.2). The three to six- and 12-month values were significantly lower than baseline (p<0.001). Qmax values at baseline, three to six, and 12 months were 8.7 (SD = 4.7), 11.6 (SD = 7.7), and 10 (SD = 5). The three- to six-month value was significantly different from baseline, but the 12-month value was not (p=0.04 and p=0.4, respectively). Improvement in IPSS-QOL scores from baseline to three-month follow-up was statistically significant, from 4.3 (SD = 1.2) to 2.3 (SD = 1.5; p<0.0001), and this statistically significant improvement was maintained at the 12-month follow-up. Urinary frequency, urgency, frequency and urgency, hematuria and nocturia were reported in less or equal to 4% of patients.

Dixon (2015 and 2016) reported the results of a case series in two publications.[21, 22] A total of 65 men at or above the age of 45 experiencing LUTS secondary to BPH received convective radiofrequency thermal therapy. Results were gathered as self-administered questionnaires as well as measurements taken at scheduled follow-up visits over the following two years. Not all values were reported for all patients at all time-points. Statistical differences were calculated using a paired Student's *t*-test for each measure. IPSS at one, three, 12, and 24 months was 14.8 (SD = 8.4), 8.3 (SD = 5.8), 9.2 (SD = 6.5), and 9.6 (SD = 6.5), respectively. All values were significantly improved compared to baseline (21.7 SD = 5.5; p<0.001). Qmax at one, three, 12, and 24 months was 9.9 (SD = 3.9), 12.8, 12.7 (SD = 6.3), and 12 (SD = 6.2). These values were also values were significantly improved compared to baseline (7.9 SD ± 3.2; p<0.001 except 24 months, where p=0.001). Improvement in IPSS-QOL scores from baseline to each time point reported were statistically significant (p<0.001). Adverse events reported were hematuria (14%), UTIs (20%), dysuria (22%), and urinary urgency (20%). All were mild to moderate transient events and 75% were reported within the first 30 days.

Section Summary

The evidence regarding transurethral water vapor thermal therapy of the prostate for the treatment of BPH includes systematic reviews, one RCT, two case series, and a non-randomized studies. These studies report clinically significant improvements in several measures of urinary symptoms and quality of life. Limitations of the published evidence include limited comparative follow-up and lack of studies with no industry associations. Despite the limitations, water vapor thermal therapy appears to improve urologic symptom scores and quality of life.

AQUABLATION

SYSTEMATIC REVIEWS

Van Kollenburg (2023) conducted a systematic review and meta-analysis of 10 RCTs in order to compare treatments for LUTS to each other and to TURP.[23] The treatments included Aquablation, prostatic urethral lift, prostatic artery embolization, convective water vapor thermal treatment and temporary implantable nitinol device (TIND). The review found that overall aquablation was most comparable to TURP. Of the treatment alternatives to TURP Aquablation was associated with the greatest improvement in Qmax at both 3- and 12-months follow-up (mean difference 0.80; 95%CI:-4.25, 5.88). However, TURP improved Qmax scores better than the other treatments. Aquablation was also comparable to TURP for post void residual improvement. There were no significant differences between TURP and the other

treatments for IPSS or Quality of Life scores. Overall adverse events were more likely with TURP, but Aquablation was associated with a two times higher incidence of urine retention compared to the other treatments. The authors note the available evidence from RCTs is heterogeneous and of low certainty, but concluded that Aquablation is the most effective of the alternative therapies for LUTS included in the review.

Randomized Controlled Trials

Aquablation for treatment of BPH has been assessed in one RCT, known as WATER (Waterjet Ablation Therapy for Endoscopic Resection of Prostate Tissue; NCT02505919).[24] WATER was a noninferiority trial comparing Aquablation with TURP in 181 participants at 17 sites in four countries. Participants were men ages 45 to 80 years with moderate-to-severe LUTS, defined as IPSS 10 score greater than or equal to 12, and prostate size between 30 and 80 cc. There were 65 participants in the Aquablation group and 116 in the TURP group. The primary efficacy endpoint was the difference between groups in the change in IPSS at six months, and the primary safety end point was the development of Clavien-Dindo persistent grade 1, or 2 or higher operative complications at three months. Primary endpoint results were reported by Gilling in 2018,[24] 12-month results in Gilling (2019),[25] and three-year results in Gilling (2020).[26] Additionally, a synthesis of the trial results up to 12 months was reported in a Cochrane systematic review conducted by Hwang (2019).[27]

WATER trial results at 12 months, as summarized in the Cochrane review, are shown in Table 1. The reviewers assessed the certainty of the evidence for each outcome using the GRADE approach.[27] The reviewers concluded that up to 12 months, Aquablation likely results in a similar improvement in urologic symptom scores to TURP and may result in similar quality of life when compared to TURP. They also concluded that Aquablation may result in little to no difference in major adverse events, but considered the evidence for this finding very low certainty due to study limitations and imprecision of estimates.

Table 1. WATER Trial Results at 12 months (Adapted from Hwang [2019])

Outcome at 12 months	N Analyzed	Mean Difference (95% CI)	Certainty of the Evidence (Reason for downgrading)
IPSS	174	-0.6 (-2.51 to 2.39)	Moderate (study limitations)
IPSS QoL	174	0.27 (-0.024 to 0.78)	Low (imprecision)
Major adverse events	181	15 fewer per 1000 (-64 to 116) RR 0.84 (0.31 to 2.26)	Very low (high risk of performance bias, unclear risk of reporting bias, wide confidence interval crosses assumed threshold of minimal clinically important difference)
Retreatment	181	10 more per 1000 (13 fewer to 228 more) RR 1.68 (0.18 to 15.83)	Very low (imprecision and high risk of performance and attrition bias)
Erectile function	64	2.31 (-0.63 to 5.25)	Very low (imprecision and high risk of performance and attrition bias)
Ejaculatory function	121	2.57 (0.6 to 4.53)	Very low (imprecision: confidence interval crosses assumed threshold of minimal clinically important difference, high risk of performance and attrition bias)

Source: adapted from Hwang (2019). RR: relative risk; WATER: Waterjet Ablation Therapy for Endoscopic Resection of Prostate Tissue

On the primary efficacy outcome, Aquablation was noninferior to TURP. At six months, mean IPSS decreased from baseline by 16.9 points for Aquablation and 15.1 points for TURP (mean difference 1.8 points; p<0.0001 for noninferiority and p=0.1347 for superiority). The primary safety endpoint rate was lower in the Aquablation group compared to the TURP group (26% vs 42%, p=0.0149). The rate of grade 2 and greater events was similar in the two groups (20% for Aquablation and 23% for TURP; p=0.3038).

Gilling (2020) reported WATER trial results at three years (Table 2).[26] Improvements in symptoms and quality of life were maintained through three years in both treatment groups, and the rate of serious adverse events did not differ between groups any time point.

Table 2. WATER Trial Results at 3 Years

Treatment	Mean IPSS reduction at 3 years	Mean % reduction in IPSS at 3 years	Improvement at least 5 points from baseline at 3 years	IPSS QoL improvement at 3 years	Qmax (mL/s)	Retreatment Rate at 3 years	Serious Adverse Events Subjects (%)
Aquablation	14.4 (6.8)	64%	78%	3.2 (1.8)	11.6	5/116 (4.3%)	0 to 3 months: 7 (6.0%) 3 months to 1 year: 5 (4.3%) 1 to 2 years: 8 (6.9%) 2 to 3 years: 4 (3.4%)
TURP	13.9 (8.6)	61%	82%	3.2 (1.7)	8.2	1/65 (1.5%)	0 to 3 months:04 (6.2%) 3 months to 1 year: 5 (7.7%) 1 to 2 years: 2 (3.1%) 2 to 3 years: 1 (1.5%)
Difference	0.6 (-3.3 to 2.2)	3%	4%	0	3.3 (-0.5 to 7.1)	2.8%	
p-value	0.6848	NS	NS	0.7845	0.0848	0.4219	NS at any time point

Oumedjbeur (2023) published five-year outcomes of the WATER trial in the subgroup of men with prostate volumes 50-80mL.[28] The differences in IPSS scores in which Aquablation showed greater improvement than TURP were maintained at five years (P=0.020); however, the improvement in Qmax and QoL seen at three years did not remain consistent. There was no change in ejaculatory function with Aquablation at five years, but TURP was associated with a decline in MSHQ-EjD scores at all follow-up time points (p= 0.0095). Aquablation was associated with a lower rate of medical and surgical retreatment for LUTS than TURP at 5

years (3.2% vs. 17.6%). The occurrence of serious adverse events was not significantly different between the two treatments (p>0.05). The authors concluded that Aquablation is superior to TURP for prostates 50-80mL. The study was limited by a significant difference in prostate size at baseline, however a sensitivity analysis found no change in IPSS measures when controlling for baseline prostate size.

There were limitations of the WATER trial in outcomes, blinding, and selective reporting. Adverse events occurring after one year were not adjudicated by the clinical events committee. Although patients and outcome assessors were blinded, baseline evaluation and study surgeons were not blinded. Additionally, secondary outcomes were not prespecified.

WATER II was a prospective clinical trial that investigated whether Aquablation is effective for people with larger prostate volumes than were included in the WATER trial. WATER II enrolled 101 men from 16 study sites who had prostate volumes of 80 to 150mL. Bhojani (2023) published 5-year outcomes from the WATER II trial, reporting on 60 subjects who completed their 60-month visit.[29] Study attrition was directly linked to the COVID-19 pandemic for about half of the participants who were not available at five years. Study outcomes included IPSS scores, which showed significant improvement at 5-years compared to baseline (p< 0.001). There was also significant improvement in mean Qmax, which increased from 8.6 to 17.1 mL/s at five years (p<0.001) However, six (6%) of patients were prescribed medication for BPH and an additional 3% had surgical retreatment for LUTS. The majority of these interventions occurred in the initial three years after Aquablation, suggesting stabilization may have occurred. Limitations include the single-arm design of the study.

Nonrandomized studies

Several nonrandomized, single-arm studies have been performed, primarily with small sample sizes and short follow-up. Outcomes from prospective studies with over 100 participants and 12 months or longer follow-up are displayed in Table 3.

Table 3. Nonrandomized Studies of Aquablation.

Study	Study Design	n	Mean prostate volume (range) mL	Follow-up	Urinary/QOL outcomes	Ejaculatory/Sexual function	Adverse Events
Bach (2020) [30]	prospective, multicenter, single-arm, open-label, international clinical trial	178	59.3 (20–148)	12 months	IPSS (21.6 at baseline to 6.5 at 12 months) and Qmax (10 cc/s at baseline to 20.8 cc/s at 12 months) significantly at 12 months (p<0.0001 for both)	No significant change from baseline in any MSHQ measure except Male Sexual Health Questionnaire bother score at 12 months (p=0.0025).	36 Clavien-Dindo grade 2 or higher events. Primarily injection and bleeding
Desai (2020) [31]	prospective case series	101	107 (80-150)	2 years	Mean IPSS (23.2 at baseline to 5.8 at 2 years, p<0.0001) and IPSS quality of life (4.6 at baseline to	Not reported	29% within 1 month

Study	Study Design	n	Mean prostate volume (range) mL	Follow-up	Urinary/QOL outcomes	Ejaculatory/Sexual function	Adverse Events
					1.1 at 2 years, p<0.0001) improved significantly at the two-year follow-up		

PRACTICE GUIDELINE SUMMARY

American Urological Association

The American Urological Association (AUA) published an evidence-based clinical practice guideline "Management of Benign Prostatic Hyperplasia/ Lower Urinary Tract Symptoms: AUA Guideline," which includes the following recommendations:[32]

- WVTT [water vapor thermal therapy] should be considered as a treatment option for patients with LUTS/BPH provided prostate volume 30-80cc. (Moderate Recommendation; Evidence Level: Grade C)
- WVTT may be offered as a treatment option to eligible patients who desire preservation of erectile and ejaculatory function. (Conditional Recommendation; Evidence Level: Grade C)
- Robotic waterjet treatment (RWT) may be offered as a treatment option to patients with LUTS/BPH provided prostate volume 30-80cc. (Conditional Recommendation; Evidence Level: Grade C)

A conditional recommendation is described as:

- Balance between Benefits & Risks/Burdens unclear
- Alternative strategies may be equally reasonable
- Better evidence likely to change confidence

SUMMARY

It appears that transurethral water vapor thermal therapy and transurethral waterjet ablation (Aquablation) of the prostate improve urinary symptoms for some people with benign prostatic hyperplasia. In addition, clinical practice guidelines based on evidence recommend transurethral water vapor thermal therapy and transurethral waterjet ablation of the prostate for certain individuals with benign prostatic hyperplasia. Therefore, transurethral water vapor thermal therapy and transurethral waterjet ablation of the prostate may be considered medically necessary when criteria are met. In all other situations, there is not enough evidence to show that transurethral water vapor thermal therapy or transurethral waterjet ablation of the prostate improves health outcomes. Therefore, transurethral water vapor thermal therapy and transurethral waterjet ablation of the prostate are considered investigational when criteria are not met.

Phrenic Nerve Stimulation for Central Sleep Apnea

Effective: January 1, 2024

Next Review: June 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Central sleep apnea (CSA) is characterized by repetitive cessation or decrease in both airflow and ventilatory effort during sleep. The goal of phrenic nerve stimulation treatment is to normalize sleep-related breathing patterns.

MEDICAL POLICY CRITERIA

Note: This policy only addresses phrenic nerve stimulation for *central* sleep apnea (CSA). It does not address hypoglossal nerve stimulation for *obstructive* sleep apnea (OSA). See Cross References section below.

The use of phrenic nerve stimulation for central sleep apnea is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

2. Surgeries for Snoring, Obstructive Sleep Apnea Syndrome, and Upper Airway Resistance Syndrome, Surgery, Policy No. 166
3. Hypoglossal Nerve Stimulation, Surgery, Policy No.215

BACKGROUND

CENTRAL SLEEP APNEA

Central sleep apnea (CSA) is characterized by repetitive cessation or decrease in both airflow and ventilatory effort during sleep. CSA may be idiopathic or secondary (associated with Cheyne-Stokes breathing, a medical condition, drugs, or high altitude breathing. Cheyne-Stokes breathing is common among patients with heart failure or who have had strokes, and accounts for about half of the population with CSA. CSA is less common than obstructive sleep apnea (OSA). Based on analyses of a large community-based cohort in the Sleep Heart Health Study, the estimated prevalences of CSA and OSA are 0.9% and 47.6%, respectively.[1] Risk factors for CSA include age (>65 years), male gender, history of heart failure, history of stroke, other medical conditions (acromegaly, renal failure, atrial fibrillation, low cervical tetraplegia, and primary mitochondrial diseases), and opioid use. Individuals with CSA have difficulty maintaining sleep and therefore experience excessive daytime sleepiness, poor concentration, morning headaches, and are at higher risk for accidents and injuries.

TREATMENT

The goal of treatment is to normalize sleep-related breathing patterns. Because most cases of CSA are secondary to an underlying condition, central nervous system pathology, or medication side effects, treatment of the underlying condition or removal of the medication, may improve CSA.

Treatment recommendations differ depending on the classification of CSA as either hyperventilation-related (most common, including primary CSA and those relating to heart failure or high altitude breathing) or hypoventilation-related (less common, relating to central nervous system diseases or use of nervous system suppressing drugs such as opioids).

For patients with hyperventilation-related CSA, continuous positive airway pressure (CPAP) is considered first- line therapy. Due to CPAP discomfort, patient compliance may become an issue. Supplemental oxygen during sleep may be considered for patients experiencing hypoxia during sleep or who cannot tolerate CPAP. Patients with CSA due to heart failure and with an ejection fraction >45% and who are not responding with CPAP and oxygen therapy, may consider bilevel positive airway pressure (BPAP) or adaptive servo-ventilation (ASV) as second-line therapy. BPAP devices have two pressure settings, one for inhalation and one for exhalation. ASV uses both inspiratory and expiratory pressure, and titrates the pressure to maintain adequate air movement. However, a clinical trial reported increased cardiovascular mortality with ASV in patients with CSA due to heart failure and with an ejection fraction <45%,[2] and therefore, ASV is not recommended for this group.

For patients with hypoventilation-related CSA, first-line therapy is BPAP.

Pharmacologic therapy with a respiratory stimulant may be recommended to patients with hyper- or hypoventilation CSA who do not benefit from positive airway pressure devices, though close monitoring is necessary due to the potential for adverse effects such as rapid heart rate, high blood pressure, and panic attacks.

PHRENIC NERVE STIMULATION

Currently, there is one phrenic nerve stimulation device approved by the Food and Drug Administration (FDA), the remedē System (Respicardia, Inc.). The remedē System is an

implantable device that stimulates the phrenic nerve in the chest which sends signals to the diaphragm to restore a normal breathing pattern. A cardiologist implants the battery powered device under the skin in the right or left pectoral region. The procedure is conducted using local anesthesia. The device has two leads, one to stimulate a phrenic nerve (either the left pericardiophrenic or right brachiocephalic vein) and one to sense breathing. The device runs on an algorithm that activates automatically at night when the patient is in a sleeping position, and suspends therapy when the patient sits up. Patient-specific changes in programming can be conducted externally by a programmer.

REGULATORY STATUS

In October 2017, the FDA granted approval for the remedē System (Respicardia, Inc; Minnetonka, MN) through the premarket approval application process. The approved indication is for treatment of moderate to severe central sleep apnea in adults. Product code: PSR.

EVIDENCE SUMMARY

Outcomes of interest include sleep quality metrics and quality of life measures. The Apnea-Hypopnea Index (AHI) is the number of apnea and hypopnea (events per hour of sleep, in which the apnea events last at least 10 seconds and are associated with decreased blood oxygenation. In adults, the AHI scale is: <5 AHI (normal); 5<AHI<15 (mild); 15<AHI<30 (moderate); and>30 AHI (severe). Additional sleep metrics include central apnea index (CAI, number of central apnea events per hour of sleep) and obstructive apnea index (OAI, number of obstructive apnea events per hour of sleep).

Quality of life outcomes can be measured by the Epworth Sleepiness Scale (ESS) or a Patient Global Assessment. The ESS is a short, self-administered questionnaire that asks patients how likely they are to fall asleep (0="no chance" to 3="high chance") in 8 different situations (e.g., watching TV, sitting quietly in a car, or sitting and talking to someone). The scores are added, ranging from 0 to 24, with scores over 10 indicating excessive sleepiness and recommendation to seek medical attention.

SYSTEMATIC REVIEWS

Luni (2020) reported a meta-analysis of five studies (n=204) evaluating the efficacy of transvenous neurostimulation of the phrenic nerve for central sleep apnea.[3] An analysis of the pooled data demonstrated a reduction of mean AHI in the stimulation group compared to the control group by 26.7 events/hour (95% CI -31.99 to -21.46, p 0.00), and a mean AHI difference of -22.47. Compared with the control group, the mean reduction in the oxygen desaturation index of 4% or more was decreased in the stimulation group by -24.16 events/hour (95% CI -26.20 to -22.12, p 0.00).

RANDOMIZED CONTROLLED TRIAL

Costanzo (2015) provided background and methodologic details of the remedē System Pivotal Trial.[4] The trial is a prospective, multicenter, randomized, open-label controlled trial comparing transvenous unilateral phrenic nerve stimulation with no stimulation in patients with CSA of various etiologies (Table 1). All patients received implantation of the phrenic nerve stimulation system, with activation of the system after one month in the intervention group (n=73) and activation after six months in the control group (n=78). Activation is delayed one month after implantation to allow for lead healing. The primary efficacy endpoint is percentage of patients

achieving a reduction in Apnea-Hypopnea Index (AHI) of 50%, as interpreted from polysomnography by an assessor blinded to treatment arm. The reduction of 50% was based on assessments showing that a 50% reduction in AHI is associated with reduced mortality risk and is therefore clinically meaningful. Secondary endpoints include mean reductions in CAI, AHI, arousal index, OD14, and Epworth Sleepiness Scale. Quality of life is measured by Patient Global Assessment (PGA), which consists of a 7-point scale (1="markedly improved" to 7="markedly worsened"). Of the 151 patients in the trial, 64% had heart failure, 42% had atrial fibrillation, and a mean left ventricular ejection fraction of 39.6. Six-month per protocol comparative results for the treatment and control groups were published in 2016 by Costanzo .[5] Adverse events were reported in 9% of the intervention group and 8% of the control group (for example, implant site infection, implant site hematoma, and lead dislodgement). Non-serious therapy-related discomfort was reported in 27 (37%) of the intervention group, with all but one case resolved by system reprogramming.

Costanzo (2018) provided 12 months followup results for the intervention arm.[6] At six months followup, 15 of the 73 (21%) in the treatment group were excluded due to no six-month data (n=9: unrelated death, device explant, missed visit, study exit), failed inclusion criteria (n=3), unsuccessful implant (n=2), therapy programmed off (n=1). At 12 months followup, an additional four patients were lost due to unrelated death, device explant, patient refusal, and missed visit. Results from the remaining 54 patients in the intervention group are summarized in Table 3. Subgroup analyses showed consistent improvements in percent experiencing >50% AHI reductions from treatment across all of the following subgroups: age (<65, 65 to <75, and >75), gender, heart failure (yes/no), defibrillator (yes/no), AHI severity (moderate/severe), and atrial fibrillation (yes/no).

Another publication by Costanzo in 2018 provided 12-months follow-up results for the subgroup of patients in the Pivotal Trial who had heart failure.[7] Pooling of results was possible by using 6 and 12 month data from the intervention group and 12 and 18 month data from the control group (the phrenic nerve stimulator was activated in the control group six months after implantation). At baseline, 96 of the patients in the trial had heart failure. By the six-month followup, there had been four deaths, one explant, and five withdrew from the study. By the 12-month followup, there had been an additional five deaths, one implant, and one withdrawal, as well as four missing the final visit. Results at 6 and 12 months followup for the subgroup of patients with heart failure are summarized in Table 2.

Follow-up at 24 months was available for 42 patients in the treatment group, while 22 patients in the treatment group and 28 patients in the control arm had reached 36 month follow-up at the time of study closure.[8] Central apnea events remained low throughout follow-up with a median time to battery depletion of 39.4 months. Median AHI at 24 months and 36 months was 16 and 13, respectively. Serious adverse events related to the implant procedure, device, or delivered therapy occurred in 10% of patients through the 24-month visit. All were reported to be resolved with remedē System revisions or programming.

Five-year outcomes of the Pivotal Trial were published in 2021.[9] Patients in the treatment group and those in the control group, who had therapy activated after the primary endpoint assessment at the six-month visit, were pooled. The 42 patients evaluated for five-year outcomes had a change from baseline of -22 for AHI ($p<0.001$), -23 for CAI ($p<0.001$), 1 for OAI ($p=0.003$), and -5 for ESS ($p=0.008$). Serious adverse events related to the implant procedure, device, or delivered therapy occurred in 15% of patients through the five-year visit, none of which caused long-term harm.

An analysis of the pivotal trial data for safety and efficacy of TPNS in patients with concomitant cardiovascular implantable electronic devices (CIEDs) was reported by Nayak (2020).[10] Of the 151 initially enrolled patients, 64 had a concomitant CIED. There was no difference in safety or efficacy between patients with and without CIEDs.

Table 1. Summary of Key RCT Characteristics

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Intervention	Control
Costanzo (2015)[4]	Germany, Poland, United States	31	2013-2015	Adult patients with moderate to severe CSA of various etiologies confirmed by PSG[a] and medically stable[b]	Implanted phrenic nerve stimulator (remede system) activated at 1 month postprocedure (n=73)	Implanted phrenic nerve stimulator (remede system) activated at 6 months postprocedure (N=78)

[a] AHI>20 events/hr; CAI>50% of all apneas, with>30 central apnea events; OAI<20% of all AHI
[b] For 30 days prior to baseline testing: no hospitalizations for illness, no breathing mask-based therapy, and on stable medications and therapies.
AHI: apnea-hypopnea index; CSA: central sleep apnea; PSG: polysomnography.

Table 2. Summary of Key RCT Results

[a] Data are presented as either % (95% confidence intervals) or mean (standard deviation)
[b] Patients with marked or moderate improvement in 7-point quality of life scale
AHI: Apnea-Hypopnea Index; CAI: central apnea index; CI: confidence interval; ESS: Epworth Sleepiness Scale; HF: heart failure; NA: not applicable; NR: not reported; OAI: obstructive apnea index; PGA: Patient Global Assessment; RCT: randomized controlled trial; SD: standard deviation.

An analysis of the Pivotal Trial data to compare PAP-naïve and prior PAP-treated patients was completed by Schwartz (2021).[11] At baseline, CSA was more severe and symptomatic in the PAP-treated vs. PAP-naïve group (median AHI 52/h vs. 38, central apnea index (CAI) 32/h vs. 18, ESS 13 vs. 10, fatigue severity scale 5.2 vs. 4.5). Active therapy resulted in statistically significant improvements in polysomnographic metrics ($p<0.001$ for AHI, 4% ODI, arousal index, and CAI), with little or no change in the inactive control group. Of PAP-treated and PAP-naïve patients, 98% and 94% indicated they would undergo the implant again.

Baumert (2023) published an analysis of effect of transvenous phrenic nerve stimulation (TPNS) on the composition of the nocturnal hypoxemic burden in patients with CSA using data from the Pivotal Trial.[12] TPNS titrated to reduce respiratory events significantly reduced the ODI in the treatment group more than the control group (-15.85 h-1 ± 1.99, +1.32 h-1 ± 1.85; $p < 0001$) and shortened the relative T90 duration by -3.81 percentage points ± 1.23 vs. 0.49 percentage points ± 1.14 increase ($p = 0.012$). This shortening of T90 was primarily accomplished by reducing the brief cyclic desaturations (T90desaturation: -4.32 percentage points ± 0.98 vs. 0.52 percentage points ± 0.91, $p = 0.0004$) while notable non-specific drifts in SpO2 remained unchanged (T90 non-specific: 0.18 percentage points ± 0.62 vs. -0.13 percentage points ± 0.57; $p = 0.72$). The authors conclude that TPNS reduces the nocturnal hypoxemic burden due to sleep-disordered breathing, and that a considerable nocturnal hypoxemic burden from other sources remains.

Baumert (2023) also published a separate analysis of effect of transvenous phrenic nerve stimulation (TPNS) on nocturnal heart rate perturbations in patients with CSA using data from the Pivotal Trial.[13] TPNS titrated to reduce respiratory events is associated with reduced cyclical heart rate variations in the very low-frequency domain across REM (VLFI: 4.12 ±0.79 % vs. 6.87 ± 0.82 %, $p = 0.02$) and NREM sleep (VLFI: 5.05 ± 0.68 % vs. 6.74 ± 0.70 %, $p = 0.08$) compared to the control group. Low-frequency oscillations were reduced in the treatment arm in REM ($p=0.02$) and NREM sleep ($p=0.03$). The authors concluded that long-term follow-up studies are needed to determine if the reduction in heart rate perturbation by TPNS translates to cardiovascular mortality reduction.

NON-COMPARATIVE STUDIES

Fox (2017) presented data on long term durability of the remedē System, measuring battery lifetime, device exchangeability, lead position stability, and surgical accessibility.[14] Three

consecutive patients, mean age 75.7 years, with CSA and HF with preserved ejection fraction were implanted with the remede phrenic nerve stimulation device due to intolerability of conventional mask therapy. Implantation occurred in 2011 and the patients were followed for four years. Mean battery life duration was 4.2+ 0.2 years. Therapy was well tolerated by the patients, with improvements sustained in AHI, oxygen desaturation index, and quality of life (measured by ESS). Mean device replacement procedure time was 23 minutes, under local anesthesia, with a two-day hospital stay.

Abraham (2015)[15] and Jagielski (2016)[16] presented 6-month and 12-month results from a cohort of 47 patients with CSA of various etiologies who received phrenic nerve stimulation with the remedē system. . Sleep disorder parameters were measured by polysomnography, through 12 months, with an optional sleep testing at 18 months. . Quality of life was measured on a seven-point scale, with patients answering the question, "How do you feel today compared with how you felt before having your device implanted?" CSA etiologies included heart failure (79%), other cardiac (13%), and opiate use (4%). Three deaths occurred during the study period, none attributed to the intervention. Five experienced serious adverse events, three at the beginning of the study (two [hematoma, migraine] due to implantation procedure and one chest pain), and two during 12-month followup (pocket perforation and lead failure). A summary of sleep metric and quality of life results are presented in Table 3.

Table 3. Summary of Non-Comparative Study Results[15, 16]

Outcome	Baseline (n=47) mean± SD	3 months (n=47) mean± SD	6 months (n=41) mean± SD	12 months (n=41) mean± SD	18 months (n=17) mean± SD

SUMMARY OF EVIDENCE

For individuals with central sleep apnea who receive phrenic nerve stimulation, the evidence includes one randomized controlled trial (RCT) and observational studies. Relevant outcomes are change in disease status, functional outcomes, and quality of life. The RCT compared the use of phrenic nerve stimulation to no treatment among patients with central sleep apnea of various etiologies. All patients received implantation of the phrenic nerve stimulation system, with activation of the system after one month in the intervention group and activation after six months in the control group. Activation is delayed one month after implantation to allow for lead healing. At six months follow-up, the patients with the activated device experienced significant improvements in several sleep metrics and quality of life measures. At 12 months

followup, patients in the activated device arm showed sustained significant improvements from baseline in sleep metrics and quality of life. A subgroup analysis of patients with heart failure combined 6 and 12 month data from patients in the intervention group and 12 and 18 month data from the control group. Results from this subgroup analyses showed significant improvements in sleep metrics and quality of life at 12 months compared with baseline. Results from observational studies supported the results of the RCT. No RCTs were identified in which phrenic nerve stimulation was compared with the current standard of care, positive airway pressure or respiratory stimulant medication. An invasive procedure would typically be considered appropriate only if non-surgical treatments had failed, but there is very limited data in which phrenic nerve stimulation was evaluated in patients who had failed the current standard of care, positive airway pressure or respiratory stimulant medication. The evidence is insufficient to determine the effects of the technology on health outcomes.

PRACTICE GUIDELINE SUMMARY

No evidence-based clinical practice guidelines were identified with recommendations regarding the use of phrenic nerve stimulation for central sleep apnea.

SUMMARY

There is not enough research to know if or how well phrenic nerve stimulation works to treat central sleep apnea. This does not mean that it does not work, but more research is needed to know. There are no clinical practice guidelines based on research that recommend phrenic nerve stimulation for this population. Therefore, the use of phrenic nerve stimulation for the treatment of central sleep apnea is considered investigational.

Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy of Intracranial, Skull Base, and Orbital Sites

Effective: January 1, 2024

Next Review: July 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Stereotactic radiosurgery (SRS) and stereotactic body radiotherapy (SBRT) or stereotactic ablative radiotherapy (SABR) are radiotherapy techniques that use highly focused radiation beams to treat both neoplastic and non-neoplastic conditions, in contrast to traditional external radiation beam therapy, which involves the use of relatively broad fields of radiation over a number of sessions that may occur over weeks to months.

MEDICAL POLICY CRITERIA

I. Stereotactic radiosurgery (SRS) and Stereotactic Body Radiation Therapy (SBRT), also known as Stereotactic Ablative Body Radiotherapy (SABR), may be considered **medically necessary** for initial treatment or treatment of recurrence for any of the following indications:

   A. Primary neoplasms of the CNS (See Policy Appendix I at the end of the policy), including but not limited to low grade gliomas and high-grade gliomas

   B. Metastatic lesion(s) to the CNS (solitary or multiple) in patients with a current Karnofsky performance score greater than or equal to 60 or a current ECOG score less than or equal to 2 (See Policy Guidelines)

C. Arteriovenous malformations

D. Chordomas and chondrosarcomas of the skull base

E. Craniopharyngiomas

F. Refractory epilepsy when the following criteria are met:

1. Any seizure activity despite treatment with at least two antiepileptic regimens; and
2. Documentation of clinical agreement of medical appropriateness from a neurosurgeon or multidisciplinary body of physician consultants.

G. Essential tremor or Parkinson's disease when the following criteria are met:

1. Symptoms are ongoing despite treatment with at least two drug regimens; and
2. Documentation of clinical agreement of medical appropriateness from a neurosurgeon or multidisciplinary body of physician consultants.

H. Head and neck cancers within intracranial, skull base, and orbital sites, when there is documented prior radiation treatment to the planned target volume

I. Hemangioblastoma within intracranial, skull base, and orbital sites

J. Hemangiopericytoma within intracranial, skull base, and orbital sites

K. Glomus jugulare and Glomus tympanicum tumors

L. Meningiomas, benign, atypical, or malignant

M. Pituitary adenomas

N. Schwannomas (see Policy Guidelines)

O. Trigeminal neuralgia (tic douloureux) refractory to medical management

P. Uveal melanoma

II. Stereotactic radiosurgery and stereotactic body radiation therapy (also known as Stereotactic ablative body radiotherapy) are considered **investigational** when Criterion I. is not met and for all other intracranial, skull base, and orbital indications including but not limited to cavernous malformations, choroidal neovascularization (CNV), chronic pain, and functional disorders other than trigeminal neuralgia and essential tremor.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

For the purposes of this policy, neoplasm is defined as “an abnormal mass of tissue that results when cells divide more than they should or do not die when they should. Neoplasms may be benign (not cancer), or malignant (cancer).”[1]

SCHWANNOMAS

Schwannomas are tumors that occur along nerves. They are typically benign but may be malignant. These may also be referred to as neuromas, neurinomas "of Verocay" or

neurilemmomas. A common type of schwannoma is a vestibular schwannoma, which is also known as an acoustic neuroma.

PERFORMANCE STATUS MEASUREMENT

Performance status is frequently used in oncology practice as a variable in determining prognosis and management strategies. Either the Karnofsky Performance Status (KPS) or the Eastern Cooperative Oncology Group (ECOG) Performance Status scoring systems may be used.

Karnofsky Performance Status

100	Normal, without symptoms
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or do active work
60	Requires occasional assistance; able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated
20	Very sick; active support treatment is necessary
10	Moribund; fatal processes progressing rapidly

ECOG Performance Status

0	Fully active, able to carry on all pre-disease performance without restriction.
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours.
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours.
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair.

FRACTIONATION

Fractionated stereotactic radiotherapy refers to when SRS or SBRT are performed more than once on a specific site. SRS is commonly delivered in 1 fraction and SBRT or SABR is commonly delivered in 2-5 fractions.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History/Physical and Chart notes, including requirements as outlined by the policy criteria, as applicable to the indication for treatment.
- As applicable, documentation of sites, size and number of lesions
- As applicable, documented ECOG score or Karnofsky performance score

BACKGROUND

Stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) rely on three-dimensional imaging to localize the therapy target. SRS and SRBT have been used for a range of malignant and non-malignant conditions. Because they are more targeted than traditional external radiation therapy, SRS and SRBT are often used for treatment at sites that are difficult to reach via surgery, located close to other vital structures, or subject to movement within the body. The term SBRT will be used to describe treatment also referred to as stereotactic ablative body radiotherapy (SABR).

SRS and SBRT (or SABR) employ similar technological "stereotactic" sophistication with elements of advanced pretreatment imaging for localization of target(s), patient immobilization, control of breathing associated tumor movement, focally targeted treatment planning, and daily image guidance to ensure precise delivery of high daily doses of radiation. As commonly used in the medical literature, SRS refers to intracranial treatments and SBRT refers to extracranial treatments. Alternatively, SRS and SBRT may be defined independent of whether treatment is directed to intra or extra cranial tumors volumes. According to this definition, when such treatment is given as a single fraction, it may be referred to as SRS, and when it is delivered in 2-5 fractions it may be referred to as SBRT or SABR.

The fractionation used for SRS and SBRT is referred to as “hypofractionated” because it is fewer treatments than those used for conventional external beam radiotherapy.” Fractionation of stereotactic radiotherapy aims to optimize the therapeutic ratio; that is the ratio between tumor control and late effects on normal tissues. The main advantage of fractionation is that it allows higher total doses to be delivered to the tumor because of increased tolerance of the surrounding healthy tissues to each individual, fractionated dose. In addition, some lesions

such as large arteriovenous malformations may require more than one procedure to complete the obliteration process.

SRS and SBRT can be administered by several types of devices that are distinguished by their source of radiation, including particle beams (e.g., proton), gamma radiation from cobalt-60 sources, or high-energy photons from linear accelerator (LINAC) systems. The Gamma Knife and linear accelerator systems (including the Cyberknife®) are similar in concept; both use multiple photon radiation beams that intersect at a stereotactically determined target, thus permitting higher doses of radiation delivery with sparing of surrounding normal tissues. The differences between the two relate to how the energy is produced (i.e., through decaying cobalt-60 in the gamma knife devices, or from x-rays in the linear accelerator system) and the number of energy sources used (i.e., multiple energy sources in the gamma knife versus one in the linear accelerator system).

In the United States, certain racial/ethnic groups continue to be at an increased risk of developing or dying from particular cancers. Black men have the highest rate of new cancer diagnoses and Black men and women experience the highest rate of cancer-related death. American Indians and Alaska Natives are disproportionally affected by kidney cancer and also have higher death rates from this cancer when compared to other racial/ethnic groups.

Studies have demonstrated that there are socioeconomic disparities with regard to access to radiation therapy, particularly for patients in ethnic minority groups and those living in rural areas.

IMAGE-GUIDED RADIOSURGERY OR RADIOTHERAPY

Image-guided radiosurgery or radiotherapy is a relatively new development collectively describing units with real-time image guidance systems. Examples include the Cyberknife® device, BrainLAB Novalis®, TomoTherapy®, and LINAC with computerized tomography (CT).

REGULATORY STATUS

Several devices that use cobalt 60 radiation (gamma ray devices) for SRS have been cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process. The most commonly used gamma ray device is the GammaKnife (Elekta; approved May 1999). Gamma ray emitting devices that use cobalt 60 degradation are also regulated through the U.S. Nuclear Regulatory Commission.

A number of LINAC movable platforms that generate high-energy photons have been cleared for marketing by the FDA through the 510(k) premarket notification process including the Novalis Tx®

(Novalis, Westchester, IL); the TrueBeam STx (Varian Medical Systems, Palo Alto, CA, approved December 2012); and the CyberKnife® System (Accuray, Inc.; approved December 1998). LINAC-based devices may be used for intracranial and extracranial lesions.

Note: Particle radiation can also be used without stereotactic guidance. In this setting, the use of particles is referred to as proton, helium, or neutron radiation *therapy*. Proton or helium ion radiation therapies (RT), intraocular RT for age-related macular degeneration, and electromagnetic navigation bronchoscopy for placement of fiducial markers are considered in separate medical policies. See cross-reference section below.

EVIDENCE SUMMARY

The selection of variables used in the delivery of SRS and SBRT is complex and individualized, requiring selection of the device, radiation dose, and the size and shape of treatment margins All of these variables depend on the location, shape, and radiosensitivity of the target tissue and the function and radiosensitivity of the surrounding tissue. Trials that allow direct comparison of all of the possible variables involved in selecting specific SRS and SBRT methods do not broadly exist making it difficult to draw comparative effectiveness conclusions. Further, for many rare conditions, large comparative studies are unlikely. The evidence below will focus on indications with criteria and investigational indications.

Please note that the evidence review below does not compare specific radiation planning and delivery techniques.

TRIGEMINAL NEURALGIA

Tuleasca published a 2018 systematic review of SRS for trigeminal neuralgia to support the development of a guideline endorsed by the International Society of Stereotactic Radiosurgery (ISRS). A total of 65 studies met inclusion criteria, with a total of 6461 patients. One study was prospective and the remainder were retrospective. Crude rates of hypesthesia ranged from 0% to 68.8% (mean 21.7%, median 19%) for gamma knife surgery (GKS), from 11.4% to 49.7% (mean 27.6%, median 28.5%) for LINAC, and from 11.8% to 51.2% (mean 29.1%, median 18.7%) for CyberKnife radiosurgery. Other toxicities reported were dysesthesias, paresthesias, dry eye, deafferentation pain, and keratitis. Actuarial initial freedom from pain without medication was reported to be 28.6% to 100% (mean 53.1%, median 52.1%), 17.3% to 76% (mean 49.3%, median 43.2%), and 40% to 72% (mean 56.3%, median 58%) for GKS, LINAC, and CyberKnife radiosurgery, respectively. Recurrence rates were reported as ranges of 0 to 52.2% (mean 24.6%, median 23%), 19% to 63% (mean 32.2%, median 29%), and 15.8% to 33% (mean 25.8%, median 27.2%) for GKS, LINAC, and CyberKnife radiosurgery, respectively. The authors concluded that although the evidence is limited, radiosurgery is a safe and effective therapy for drug-resistant trigeminal neuralgia.

In 2017, Gubian and Rosahl published a meta-analysis of the safety and efficacy of SRS and microsurgery for trigeminal neuralgia. PRISMA guidelines were followed. A total of 53 studies met inclusion criteria. Success rates initially and at last follow-up (>five years after intervention) were 71.1% and 63.8% for SRS and 86.9% and 84% for microsurgery, respectively. Mean percentage of recurrence at 36-months post-intervention was 25% for SRS and 11% for microsurgery (p=0.0015). The length of recurrence-free intervals was not significantly different between SRS and microsurgery (30.45 and 30.55 months, respectively; p=0.987). The difference in incidence of hearing loss was also not significant (SRS 1.51% vs microsurgery 0.74%), but facial dysesthesia was more frequent in the SRS group (2.3% versus 28.8% for microsurgery; p=0.02).

A 2011 Cochrane systematic review of 11 trials of neurosurgical interventions for trigeminal neuralgia found that there was very low-quality evidence for the efficacy of most neurosurgical procedures for trigeminal neuralgia because of the poor quality of the trials.[2] All procedures produced variable pain relief, but many resulted in sensory side effects. There were no studies of microvascular decompression which observational data suggests gives the longest pain relief. Only one study was identified that used radiosurgery. The trial was intended to determine if increasing the nerve length within the SRS treatment volume would change

outcomes. The study was stopped before accrual was completed and it was noted that pain measurements using validated scales were not made either before or after surgery.

Other nonrandomized studies and case series have reported on the use of SRS for trigeminal neuralgia.[3-8]

Section Summary

Case series identify improvements in pain related to trigeminal neuralgia after treatment with SRS. Comparative studies that evaluate the use of SRS compared with alternative treatments for trigeminal neuralgia are lacking. Only one study specifically addressed the use of radiosurgery and it was stopped before accrual was completed.

REFRACTORY EPILEPSY

Barbaro (2018) published the results of the first randomized controlled trial comparing SRS for the treatment of pharmacoresistant unilateral mesial temporal lobe epilepsy to anterior temporal lobectomy (ATL), the ROSE trial.[9] A total of 37 (64%) patients achieved seizure remission, with 16 (52%) in SRS and 21 (78%) in ATL. Noninferiority of SRS compared to ATL was not demonstrated. SRS did not confer sparing of verbal memory deficits compared to ATL. QOL scores improved significantly in the SRS group at 24 months and remained steady at 36 months, in contrast to the ATL group in whom QOL score improvement was immediately noticeable at 12 months. Adverse events were anticipated cerebral edema and related symptoms for some SRS patients, and cerebritis, subdural hematoma, and others for ATL patients. These all resolved with appropriate protocol specified interventions.

Quigg (2018) published a follow-up report on visual field defects (VFD) observed in patients treated during the ROSE trial.[10] Out of 58 treated patients, 29/31 (93.5%) SRS patients and 25/27 (92.6%) ATL patients completed visual field testing. Ninety-three percent of patients treated with SRS reported VFD compared to 88% of patients treated with ATL (p=0.65). Younger age at diagnosis correlated with worse outcomes; this significance was stronger in the SRS arm compared to the ATL arm (p=0.04 and 0.20), but this difference was not significant upon multivariable regression. Presence or absence of VFD was not correlated with either seizure remission (p=0.22 and p=1.00) or driving status (p=0.53 and p=1.00) for the SRS or ATL treatment arms, respectively.

A 2018 systematic review by Eekers reported on 16 studies including a total of 170 patients.[11] Methodological quality of the included studies was graded using a modified QUADAS checklist. Limitations of the reviewed studies include a lack of control groups and poorly defined exclusion criteria. SRS was reported to have a positive effect on seizure outcome, defined as the total percentage of radiotherapy-adapted Engel class (RAEC) I and II patients, in 12 studies. No favorable effect on seizure outcome was found in two studies, although these contained only two and three patients, respectively. Toxicities reported include radionecrosis, impaired cognitive functioning, and headache, nausea, and vomiting related to increased intracranial pressure and edema. Subsequent resection was reported in nine of the studies. In those studies, 20% of patients underwent subsequent resection. Reasons reported were persisting seizures, cyst formation, edema, intracranial hypertension, and radionecrosis. Authors concluded that there is only level 4 evidence of primary radiotherapy reducing seizure frequency in adult patients and that prospective randomized trials are needed to determine its value.

McGonigal (2017) performed a systematic review of SRS for drug-resistant epilepsy and assessed the level of evidence according to the PRISMA guidelines.[12] A total of 55 articles met inclusion criteria. Level 2 evidence (prospective studies) indicated that SRS may result in superior neuropsychological outcomes and quality of life compared to microsurgery for mesial temporal lobe epilepsy and that SRS has a better risk-benefit ratio for small hypothalamic harmatomas compared to surgical methods. Only Level 4 evidence (case reports, prospective observational studies, and retrospective case series) was available for the other indications and no Level 1 evidence was identified.

In 2016, Feng published a systematic review and meta-analysis of data from 13 studies on the use of SRS to treat mesial temporal lobe epilepsy.[13] They calculated approximately half of the patients were seizure free over a follow-up period that ranged from six months to nine years (pooled estimate, 50.9%; 95% CI, 38.1% to 63.6%), with an average of 14 months to seizure cessation (pooled estimate, 14.08 months; 95% CI, 11.95 to 12.22 months). Nine of 13 included studies reported data for adverse events, which included visual field deficits and headache (the two most common adverse events), verbal memory impairment, psychosis, psychogenic nonepileptic seizures, and dysphasia. Patients in the individual studies experienced adverse events at rates that ranged from 8%, for nonepileptic seizures, to 85%, for headache.

A 1998 TEC Assessment[14] cited two studies of 11 and 9 patients, respectively, in which radiosurgery was used to treat epilepsy. The subsequent literature search revealed three small studies on the use of radiosurgery for medically refractory epilepsy. Regis (2000)[15] selected 25 patients with mesial temporal lobe epilepsy, 16 of whom provided minimum two-year follow-up. Seizure-free status was achieved in 13 patients, two patients were improved, and three patients had radiosurgery-related visual field defects.

A study by Schrottner (1998)[16] included 26 patients with tumor-related epilepsy, associated mainly with low-grade astrocytomas. Mean follow-up among 24 available patients was 2.25 years. Tumor location varied across patients. Seizures were simple partial in six (three with generalization) and complex partial in 18 (five with generalization, one gelastic). Seizures were eliminated or nearly so in 13 patients. Little improvement was observed in four patients and none in seven. Whang and Kwon (1996)[17] performed radiosurgery in 31 patients with epilepsy associated with nonprogressive lesions. A minimum of one-year follow-up was available in 23 patients, 12 of whom were seizure-free (and three of whom had antiseizure medications discontinued), two had seizures reduced in frequency, and nine experienced no change. While the Regis series selected a fairly homogeneous clinical sample, the other two studies were heterogeneous.

Section Summary

For individuals with epilepsy refractory to medical management, the evidence on the use of SRS as a treatment for epilepsy includes case reports in primary epileptic disorders and case reports for tumor-related epilepsy. For mesial temporal lobe epilepsy, there is a pilot prospective non-comparative intervention and a single RCT comparing SRS to anterior temporal lobectomy (ATL).

TREMOR AND PARKINSON DISEASE

SRS has been used for the treatment of tremor via stereotactic radiofrequency thalamotomy.

Martínez-Moreno published a systematic review of stereotactic radiosurgery for tremor in association with International Stereotactic Radiosurgery Society practice guidelines.[18] The systematic review was conducted according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria. A total of 34 studies met inclusion criteria. Of these, 30 were retrospective noncomparative studies and 14 studies had fewer than 10 patients. Three studies were prospective and one was a retrospective comparative study. Rates of tremor reduction were similar across the included studies, with an average of 88%. The one comparative study reported similar tremor control rates between SRS, deep brain stimulation, and radiofrequency thermocoagulation. There were fewer permanent complications and longer latency to clinical response following SRS than the two other modalities. The authors concluded based on level IV evidence that SRS for tremor is well-tolerated and effective.

Dallapiazza (2018) conducted a systematic review comparing the outcomes of various surgical procedures for the treatment of refractory essential tremor, including deep brain stimulation (DBS), thalamotomy with radiofrequency (RF), stereotactic radiosurgery (SRS), and focused ultrasound (FUS).[19] Studies were pooled and graded for their overall level of evidence according to the Oxford Centre for Evidence-based Medicine standards. Measured outcomes included tremor control according to the Fahn-Tolosa-Marin (FTM) rating scale, quality of life (QOL) improvements, and complication rates. Overall, while complication rates were generally lower for SRS compared to other interventions, alternative approaches presented higher control rates and QOL improvements at more robust tiers of evidence.

Raju (2017) assessed outcomes of SRS for medically refractory tremor associated with Parkinson disease (PD) in a retrospective analysis of 33 patients.[20] All patients underwent gamma knife thalamotomy. Median follow-up was 23 months (range, 9 to 144 months). A total of 31 patients (93.9%) experienced improvements in tremor and 23 patients (70.0%) had complete or nearly complete tremor arrest. Improvements in other PD symptoms were also observed, including one patient (3%) with improvements in bradykinesia, three patients (9%) with improvements in rigidity, and three patients (9%) who reduced their dosage of dopa after SRS.

Section Summary

The evidence related to the use of SRS for tremor consists of uncontrolled cohort studies, many of which report outcomes from the treatment of tremor of varying etiologies. Most studies report improvements in standardized tremor scores, although few studies used a blinded evaluation of tremor score, allowing for bias in assessment. No studies that compared SRS with alternative methods of treatment or a control group were identified. Limited long-term follow-up is available, making the long-term risk: benefit ratio of an invasive therapy uncertain.

CHRONIC PAIN

A 2022 systematic review published by Franzini evaluated medial thalamotomy using SRS for the treatment of intractable pain.[21] A total of six studies met inclusion criteria. There was some overlap with the Roberts and Pouratian systematic review below, but three included studied were published after the publication of the previous review. Across the six studies, 125 patients were treated with SRS and 118 were included in the outcome analysis. Meaningful pain reduction was reported in 55% of patients overall (with 38% persisting to last follow-up) and 43.3 to 100% per study. Adverse events were reported in six patients (5%).

Lu (2018) reported a systematic review and meta-analysis of neurosurgical treatments for glossopharyngeal neuralgia.[22] A total of 23 studies were included on nerve section (NS; 6 studies), microvascular decompression (MVD; 11 studies), and SRS (6 studies). The meta-analysis indicated that short-term and long-term pain relief rate was highest after NS (IR, 94%; 95% CI, 88%-98%; IR, 96%; 95% CI, 91%-99%). The short-term and long-term pain relief rate was lowest after SRS (three months postoperatively, IR, 80%; 95% CI, 68%-96%; IR, 82%; 95% CI, 67%-94%). The postoperative complication rate was highest and lowest following MVD (IR, 26%; 95% CI, 16%-38%) and SRS (IR, 0%; 95% CI, 0%-4%), respectively.

In 2017, Roberts and Pouratian performed a systematic review to evaluate the efficacy of SRS for chronic pain.[23] They identified six articles with 113 patients that underwent SRS and had at least a three month follow-up for nonmalignant pain or at least a one month follow-up for malignant pain. At least 35% of patients reported having significant pain relief, but 21% of patients reported adverse events.

Section Summary

The evidence related to the use of SRS for chronic pain is limited and there remains a lack of comparative studies and long-term outcomes. This evidence is not sufficient to understand the safety and effectiveness of SBRT for the treatment of chronic pain or to adequately describe the subpopulation of patients with chronic pain most likely to benefit.

BRAIN METASTASES

Systematic Reviews

Garsa (2021) conducted a systematic review of available evidence comparing WBRT and SRS alone or in combination, as initial or postoperative treatment, with or without systemic therapy for adults with brain metastases due to lung cancer, breast cancer, or melanoma.[24] Despite the identification of 97 studies, statistical analyses were limited due to heterogeneity across the available data. Based on pooled data from 4 RCTs, there was no statistically significant difference in OS when comparing SRS plus WBRT to SRS alone or to WBRT alone (HR, 1.09; 95% CI, 0.69 to 1.73). Based on pooled data from 3 RCTs, OS did not differ when comparing postsurgical WBRT to postsurgical SRS (HR, 1.17; 95% CI, 0.61 to 2.25). Lastly, pooled data from 4 RCTs did not show a significant difference in the risk of serious adverse events with WBRT plus SRS versus WBRT or SRS alone (RR, 1.05; 95% CI, 0.12 to 8.89).

Chen (2021) published a systematic review of the use of SRS for brainstem metastases.[25] A total of 32 studies, all retrospective, including 1,446 patients, met inclusion criteria. Heterogeneity across studies was low to moderate (median I^2=35%; range 30 to 62%). No significant publication bias was identified. According to the meta-analyses, the one-year local control was 86% (95% CI 83 to 88%) based on 31 studies, the objective response rate was 59% (95% CI 47 to 71%) based on 17 studies, and the rate of symptom improvement was 55% (95% CI 47 to 63%) based on 13 studies. Deaths from brainstem metastases progression following SRS occurred in 19 patients across the 19 reporting studies. Grade 3 to 4 toxicities occurred in 2.4% (95% CI 1.5 to 8.7%) of patients.

An Agency for Healthcare Research and Quality Comparative Effectiveness Review of radiation therapy for brain metastases was published in 2020.[26] The review included randomized controlled trials and large observational studies of whole brain radiation (WBRT) and SRS alone or in combination. These were used as initial or postoperative treatment and

with or without systemic therapy. A total of 91 studies met inclusion criteria. These included 60 RCTs that addressed WBRT and 13 RCTs that addressed SRS. For SRS, the authors deemed the evidence insufficient for assessing overall survival, disease-free survival, deaths due to brain metastases, intracranial progression, functional status, and cognitive effects. Differences reported include a statistically significant difference between WBRT using radiosensitizers and WBRT alone, with improved survival associated with the addition of radiosensitizers (hazard ratio [HR] 0.87; 95% CI 0.83 to 0.90; three RCTs; moderate strength of evidence [SoE]). Most outcomes were not different between these groups. These included quality of life, which was not different between patients receiving SRS plus WBRT and patients receiving SRS alone, overall survival, which was not different between surgery plus radiation therapy and surgery alone, and serious adverse events, adverse events, radiation necrosis, fatigue, and seizures, for which there were systemic differences across interventions. The risk of dying from brain metastases was numerically but not statistically different in favor of radiation post-surgery versus surgery alone (relative risk [RR] 0.64; CI 0.22 to 1.84; three RCTs; low SoE).

Liu (2020) conducted a systematic review to compare SRS to surgical resection in the initial treatment of brain metastases.[27] The review included 20 studies (18 retrospective cohorts; 2 RCTs) involving 1,809 patients. Results revealed that SRS and surgical resection were comparable with regard to local control (HR, 1.02; 95% CI 0.64 to 1.64; p=0.92), distant intracranial control (HR, 0.78; 95% CI, 0.38 to 1.60; p=0.49), and OS (HR, 0.91; 95% CI, 0.65 to 1.27; p=0.57) in patients with single or solitary brain metastases. However, the authors noted that a prospective RCT with a larger patient population and a longer follow-up is necessary to confirm their findings.

Loi (2020) published a systematic review of SRS for local failure following SRS of brain metastases.[28] Eleven studies with a total of 335 patients met inclusion criteria. The pooled one-year local failure and median OS were 24% (95% CI 19 to 30%) and 14 months (95% CI 8.8 to 22.0%), respectively. The cumulative crude radionecrosis rate was 13% (95% CI 8 to 19%). According to a subgroup analysis, higher incidence of radionecrosis occurred in studies with median patient age of 59 years and above (13% [95% CI 8 to 19%] vs 7% [95% CI 3 to 12%], p=0.004), while lower radionecrosis incidence occurred following prior While Brain Radiotherapy (WBRT, 19% [95% CI 13 to 25 %] vs 7% [95% CI 30 to 13%], p=0.004). Heterogeneity was reported as acceptable.

Fuentes (2018) published a systematic review of RCTs to compare surgery with SRS for patients with a single brain metastasis.[29] Risk of bias was assessed with the Cochrane tool. Two RCTs met inclusion criteria. These included 85 patients. Both included studies were closed early due to poor participant accrual. Meta-analysis was not possible due to heterogeneity between the studies. Certainty of evidence was rated as low or very low for the various outcomes. Neither RCT reported differences in overall survival between the interventions. There were also no differences in progression-free survival, quality of life, or adverse events.

Khan (2017) published a meta-analysis of comparing WBRT, SRS, and treatment with a combination of the two for brain metastases.[30] Five studies with a total of 763 patients met inclusion criteria and were included in the meta-analysis. Out of those, 26% received WBRT alone, 26% received SRS alone, and 48% received WBRT plus SRS. No significant differences between treatment groups were found for survival benefit or adverse events. However, combination therapy provided significantly better local control than WBRT alone (hazard ratio 2.05; 95% CI 1.36 to 3.09; p=0.0006) or SRS alone (hazard ratio 1.84; 95% CI:

1.26 to 2.70; p=0.002).

In 2017, Ghidini conducted a systematic review on CNS metastases from esophageal and gastric cancer.[31] The authors analyzed data from 37 studies that met the criteria for inclusion. SRS was found to result in better OS, with the caveat that the studies examined included combination therapies that could cause an overestimate of survival.

Randomized Controlled Trials

Since publication of the systematic reviews, no new RCTs that compare SRS to other treatments have been published.

Nonrandomized Comparative Studies

In 2013, Verma retrospectively reviewed patients receiving different radiotherapy modalities for brain metastases with or without tyrosine kinase inhibitor (TKI) therapy.[32] Among 34 patients (89 lesions) those receiving SRS and TKIs had six-month local control rates of 94.7% vs 73.7% in the group who received SRS without TKIs. The difference was not statistically significant (p=0.09).

Tian (2013) reported results from a retrospective, single-institution cohort study comparing neurosurgical resection to SRS for solitary brain metastases from non-small-cell lung cancer (NSCLC). Seventy-six patients were included, 38 of whom underwent neurosurgery.[33] Median survival was 14.2 months for the SRS group and 10.7 months for the neurosurgery group. In multivariable analysis, treatment mode was not significantly associated with differences in OS.

Noncomparative Studies

Noncomparative studies continue to evaluate the use of SRS without WBRT for the management of brain metastases and the role of SRS for the management of larger numbers of brain metastases.[34-40]

Section Summary

For cases of brain metastases, evidence from RCTs, nonrandomized studies, and systematic reviews indicate that the use of SRS improves outcomes in the treatment of brain metastases. SRS appears to be feasible in the treatment of larger numbers (e.g., >10) of brain metastases, and outcomes after SRS treatment do not appear to be worse for patients with larger numbers of metastases, at least for patients with 10 or fewer metastases.

CAVERNOUS MALFORMATIONS

Systematic Reviews

Gao (2021) published a systematic review comparing microsurgery and gamma knife radiosurgery for the treatment of brainstem cavernous malformations.[41] Cohort studies reporting on 20 or more patients of any age with brainstem cavernous malformations with at least 80% completeness of follow-up were included, resulting in an analysis of 43 cohorts with 2,492 patients. Rehemorrhage rates were reduced by both microsurgery (RR=0.04, 95% CI 0.01 to 0.16, p<0.01) and radiosurgery (RR=0.11, 95% CI 0.08 to 0.16, p<0.01). The difference in median number of patients experiencing symptomatic intracranial hemorrhage between groups was statistically significant (microsurgery median 0, range 0 to 33; radiosurgery median 4, range 1 to 14; p<0.05). Persistent focal neurological deficit was also significantly different

between groups (neurosurgery median 5, range 0 to 140; radiosurgery median 1, range 0 to 3; p<0.05)

Poorthuis (2019) performed a systematic review of SRS for cerebral cavernous malformations.[42] A total of 30 studies met inclusion criteria. The median follow-up was 48 months. The annual incidence of death, intracerebral hemorrhage, and nonhemorrhagic persistent focal neurological deficit were 0.18% (95% CI 0.10 to 0.31), 2.40% (95% CI 2.05 to 2.80), and 0.71% (95% CI 0.53 to 0.96), respectively. The composite index including the incidence of all of these outcomes was 3.63% (95% CI 3.17 to 4.16).

Kim (2019) performed a systematic review of outcomes following SRS for brainstem cavernous malformations.[43] A total of 14 studies with 576 patients met inclusion criteria and were included in a meta-analysis. The hemorrhage rate was significantly lower post-SRS versus pre-SRS (pooled incidence rate ratio [IRR] 0.123; p<0.001) and two-years post-SRS versus within two years after SRS (IRR 0.317; p<0.001). At last follow-up, lesion volume was reduced in 47.3% of patients and unchanged in 49.4%. Symptomatic adverse radiation effects were reported in 7.3% of patients, with 2.2% of patients reporting permanent adverse radiation effects.

Wen (2019) performed a systematic review and meta-analysis of gamma knife radiosurgery for cavernous malformations.[44] A total of nine studies met inclusion criteria, representing 747 patients. All studies were retrospective, and one was case-controlled. The authors calculated the overall risk ratio (RR) of hemorrhage rate of pre-GKRS and post-GKRS (6.08 [95% CI 5.04 to 7.35]), the RR comparing hemorrhage rate of pre-GKRS and the first two years post-radiosurgery (3.03 [95% CI 2.65 to 4.11]), and the overall RR (12.13 [95% CI 1.73 to 85.07]) comparing pre-GKRS with two years after GKRS. There was no significant difference of the hemorrhage rate between the first two years following treatment and two years after treatment (RR=2.81; 95% CI 0.20 to 13.42). Adverse events reported in eight of the studies were cyst formation, edema, new lesions, and neurologic deficiency.

Non-randomized studies

Phuong (2017) reported on a case series of 79 patients with symptomatic cerebral cavernomas treated with SRS.[45] Complete response, partial response, and stable disease (best response) were reported in 17%, 82%, and 2%, respectively, of the 60 patients with headache. Complete response, partial response, and stable disease were reported in 31%, 64%, and 5% of the 39 patients with seizures. Complete response, partial response, stable disease, progression, and pseudoprogression were reported in 6%, 75%, 15%, 1%, and 5% of all patients, respectively, with respect to the size of cavernomas at 15 months. Four patients developed recurrent seizures after one year and five patients experienced bleeding within two years after SRS.

A 2014 case series by Lee reported on 31 patients who were treated with SRS for CMs.[46] Treatment followed a single symptomatic bleed in 31 patients (group A) and two or more symptomatic bleeds in 18 patients (group B). The annual hemorrhage rate following SRS within the first two years and after two years (up to a mean follow-up of 64 months) was 7.06% and 2.03% for group A and 9.84% and 1.50% for group B, respectively. Pretreatment hemorrhage rate was 38.36% for group B. Adverse events were reported in four patients, one of which was did not resolve during the trial.

A case series of 30 patients treated with SRS for single or multiple CMs was reported by Huang in 2006.[47] For six patients, radiosurgery was for residual lesions identified following[48] craniotomy. Mean follow-up was 59.9 months. Of the 13 patients presenting with seizures, following SRS eight were seizure-free, three had rare episodes of seizures, and two continued to have seizures. Hemorrhage rate pretreatment for the 22 patients presenting initially as acute hemorrhage was 1.9%. For all 30 patients, posttreatment hemorrhage rate was 1.9%. Posttreatment edema was observed in two patients.

Section Summary

The evidence related to the use of SRS for cavernous malformations consists of case series, which have reported improvements in hemorrhage rates. However, there remains a lack of comparative studies that evaluate long term outcomes.

DURAL ARTERIOVENOUS FISTULAS

Singh (2022) published a systematic review and meta-analysis of 21 studies involving 706 patients with dural arteriovenous fistula (dAVF) treated with SRS.[48] Median clinical follow-up was 2.75 years (range: 3.8 months -15.5 years). Nineteen studies with 688 dAVFs included data on complete obliteration (CO) rates. The pooled CO rate was 68.6% (95% CI 60.7%-76.5%). Thirteen studies with 452 patients included data on symptom improvement. The pooled symptom improvement rate was 97.2% (95% CI 93.2%-100%). Eight studies with 390 patients reported symptom cure rates. The pooled symptom cure rate after SRS was 78.8% (95% CI 69.3%-88.2%). Significant heterogeneity was noted for studies including CO rates, symptom improvement, and symptom cure rate. Twelve studies with 283 patients included data on post-SRS permanent neurological deficit (PND) rates. The pooled PND rate after SRS was 1.3% (95% CI 0.8%-1.8%). There was no significant heterogeneity in the studies reporting PND rates. The authors note that all included studies were retrospective and the analysis has significant risk of bias. Importantly, previous treatment for dAVF, especially embolization, was not controlled for, and the authors were unable to adequately compare SRS alone to multimodality treatment.

OTHER INDICATIONS

SRS has been used for other indications, including rare tumors gamma ventral capsulotomy for obsessive compulsive disorder, and cluster headache. The evidence for these other indications is limited in volume and in quality.[49-51]

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Network (NCCN) provides guidelines for cancer treatment by site that include the use of SRS and SBRT for certain cancers.[52]

Cancer Site	Tumor Type	Recommendation	Version
Bone	Chondrosarcoma Chordoma	Consider SRS to allow high-dose therapy while maximizing normal tissue sparing (category 2A)	1.2024
CNS	Adult intracranial and spinal ependymoma – spine or brain reoccurrence	• Resection with radiotherapy if no prior radiotherapy; consider use of SRS if geometrically favorable (category 2A) • If unresectable, radiotherapy if no prior radiotherapy; consider use of SRS if geometrically favorable (category 2A)	1.2023

Cancer Site	Tumor Type	Recommendation	Version
CNS	Glioma: Reirradiation	Highly focal techniques like intensity-modulated RT (IMRT), proton therapy, or SRS may be required in reirradiation settings in order to improve dose distribution to critical structures, and reduce overlap with prior radiation fields. Treatment may be performed with highly focused modern SRS techniques for lower volume disease10; fractionated IMRT, including doses of 35 Gy in 10 fractions for recurrent glioblastoma11, and proton therapy to help spare previously irradiated normal brain.	1.2023
CNS	Meningiomas	Observe (preferred for small asymptomatic tumors) or if accessible, surgery with or without RT (external beam or SRS; Recommendations based on WHO grade: Grade 3 – RT; Grade 2 with incomplete resection: RT; Grade 2 with complete resection – consider RT; Grade 1: observation or consider RT for symptomatic patients) or RT (external beam or SRS)	2.2023
CNS	Limited Brain Metastases, primary treatment	For newly diagnosed or stable systemic disease or reasonable systemic treatment options exist, SRS (preferred) or WBRT. SRS is preferred when safe, especially for low tumor volume, to both the resection cavity and any other non-resected brain metastases. WBRT is generally not recommended but may be appropriate in some rare clinical circumstances. For disseminated systemic disease with poor systemic treatment options, SRS in select patients.	1.2023
CNS	Limited Brain Metastases, recurrence	• If local recurrence and previous surgery only, options include surgery followed by SRS or RT to the surgical bed and single dose or fractionated stereotactic RT (category 2A) • If local recurrence and previous WBRT or SRS, options include surgery followed by SRS or RT to the surgical bed or single dose (category 2B) or fractionated SRS (category 2A) • If distant brain recurrence and limited brain metastases, options include surgery followed by SRS or RT to the surgical bed and single dose or fractionated stereotactic RT (category 2A)	1.2023
CNS	Extensive Brain Metastases, primary treatment	WBRT or SRS (category 2A). SRS can be considered for patients with good performance status and low overall tumor volume and/or radioresistant tumors such as melanoma.	1.2023
CNS	Leptomeningeal Metastases	SRS or RT (involved-field and/or whole brain) to bulky disease and neurologically symptomatic (such as cranial neuropathies) or painful sites. Consider craniospinal irradiation (CSI) in select patients	1/2023
Uveal Melanoma	Primary treatment	SRS is an option for tumors with: • Largest diameter >19mm (any thickness) OR • Thickness >10mm (any diameter) OR • Thickness >8mm with optic nerve involvement (any diameter). SRS is the least often used form of definitive radiotherapy for the treatment of primary or recurrent intraocular tumors.	1.2023

NCCN Categories

- **Category 1:** Based upon high-level evidence, there is uniform NCCN consensus that the intervention is appropriate.
- **Category 2A:** Based upon lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate.
- **Category 2B:** Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate.

- **Category 3:** Based upon any level of evidence, there is major NCCN disagreement that the intervention is appropriate.

*All recommendations are category 2A unless otherwise noted.

AMERICAN SOCIETY FOR RADIATION ONCOLOGY (ASTRO)

Central Nervous System

- ASTRO, the American Society of Clinical Oncology (ASCO), and the Society for Neuro-Oncology (SNO) published 2022 guidelines on the treatment of brain metastases that include the following recommendations:[53]
    - Radiation therapy should not be offered to patients with asymptomatic brain metastases who have:
        - Performance status Karnofsky Performance Status (KPS) ≤ 50 or less, or
        - Performance status KPS < 70 and no systemic therapy options (Type: evidence-based; Evidence quality: low; Strength of recommendation: moderate).
    - SRS alone (as opposed to WBRT or combination of WBRT and SRS) should be offered to patients with one to four unresected brain metastases, excluding small-cell carcinoma. (Type: evidence-based; Evidence quality: intermediate; Strength of recommendation: moderate).
    - SRS alone should be offered to patients with one to two resected brain metastases if the surgical cavity can be safely treated and considering the extent of remaining intracranial disease. (Type: evidence-based; Evidence quality: intermediate; Strength of recommendation: moderate)
    - SRS, WBRT, and the combination of SRS plus WBRT are all reasonable options for patients with more than four unresected or more than two resected brain metastases and better performance status (eg, KPS ≥ 70). SRS may be preferred for patients with better prognosis or where systemic therapy that is known to be active in the CNS is available (Type: informal consensus; Evidence quality: low; Strength of recommendation: weak).

Glioblastoma

- “SRS and hypofractionated stereotactic RT appear to provide promising outcomes compared with chemotherapy, with median survival from reirradiation typically 8 to 12 months”.[54]

AMERICAN HEART ASSOCIATION SCIENTIFIC STATEMENT

In 2017, the American Heart Association and American Stroke Association published a scientific statement on the management of brain arteriovenous malformations (AVMs).[55] The statement concludes that the available literature supports the use of SRS for small- to moderate volume brain AVMs that are generally 12 cm^3 of less in volume or located in deep or eloquent regions of the brain.

AMERICAN ACADEMY OF NEUROLOGY

The American Academy of Neurology published evidence-based recommendations in the Treatment of Essential Tremor Practice Parameter in 2005 (updated in 2011 and reaffirmed in

2022).[56, 57] It states “There is insufficient evidence regarding the surgical treatment of head and voice tremor and the use of gamma knife thalamotomy (Level U).”

CONGRESS OF NEUROLOGICAL SURGEONS

The Congress of Neurological Surgeons published 2019 evidence-based guidelines on “Use of Stereotactic Radiosurgery in the Treatment of Adults with Metastatic Brain Tumors.” These guidelines make the following level 3 recommendations regarding SRS:

- SRS is recommended as an alternative to surgical resection in solitary metastases when surgical resection is likely to induce new neurological deficits, and tumor volume and location are not likely to be associated with radiation-induced injury to surrounding structures.
- SRS should be considered as a valid adjunctive therapy to supportive palliative care for some patients with brain metastases when it might be reasonably expected to relieve focal symptoms and improve functional quality of life in the short term if this is consistent with the overall goals of the patient.
- After open surgical resection of a solitary brain metastasis, SRS should be used to decrease local recurrence rates.
- For patients with solitary brain metastasis, SRS should be given to decrease the risk of local progression.
- For patients with 2 to 4 brain metastases, SRS is recommended for local tumor control, instead of whole brain radiotherapy, when their cumulative volume is < 7 mL.
- The use of stereotactic radiosurgery alone is recommended to improve median overall survival for patients with more than 4 metastases having a cumulative volume < 7 mL.

In 2021, the Congress of Neurological Surgeons published updated guidelines on the treatment of recurrent glioblastoma in adults with radiotherapy.[58] These guidelines provide the following Level III recommendation: “When the target tumor is amenable for additional radiation, re-irradiation is recommended as it provides improved local tumor control, as measured by best imaging response. Such re-irradiation can take the form of conventional fractionation radiotherapy, fractionated radiosurgery, or single fraction radiosurgery.”

INTERNATIONAL STEREOTACTIC RADIOSURGERY SOCIETY

The International Stereotactic Radiosurgery Society (ISRS) has published a variety of relevant clinical practice guidelines and practice opinions related to SRS. For select guidelines, recommendations are based on a ranking of evidence quality with a corresponding strength of recommendation rating scheme:

Strength of Evidence

- Class I:
    - High quality randomized trial with statistically significant difference or no statistically significant difference but narrow confidence intervals
    - Systematic review of Class I RCTs (and study results were homogenous)
- Class II:
    - Lesser quality (eg, <80% follow-up, no blinding, or improper randomization
    - Prospective comparative study
    - Systematic review of Class II studies or Class I studies with inconsistent results
    - Case control study

    - Retrospective comparative study
- Class III:
    - Case series
    - Expert Opinion

Strength of Recommendation

- Level I: High degree of clinical certainty (Class I evidence or overwhelming Class II evidence)
- Level II: Clinical certainty (Class II evidence or a strong consensus of Class III evidence)
- Level III: Clinical uncertainty (Inconclusive or conflicting evidence or opinion)

Recommendations and conclusions from various ISRS guidelines and practice opinions include:

Intracranial noncavernous sinus benign meningioma: Current literature supporting SRS for this condition "lacks level I and II evidence. However, when summarizing the large number of level III studies, it is clear that SRS can be recommended as an effective evidence-based treatment option (recommendation level II) for grade 1 meningioma.[59]

Non-functioning pituitary adenomas: SRS is an effective and safe treatment for patients with non-functioning pituitary adenomas via consensus opinion.[60] The position paper states that "encouraging short-term data support hypofractionated stereotactic radiotherapy for select patients, and mature outcomes are needed before definitive recommendations can be made."

Benign (World Health Organization Grade I) cavernous sinus meningiomas: Current literature is "limited to level III evidence with respect to outcomes of SRS in patients with cavernous sinus meningiomas. Based on the observed results, SRS offers a favorable benefit to risk profile for patients with cavernous sinus meningioma."[61]

Arteriovenous malformations: Current literature cautiously suggests that "SRS appears to be a safe, effective treatment for grade I-II arteriovenous malformation and may be considered a front-line treatment, particularly for lesions in deep or eloquent locations." However, the literature is "low quality, limiting interpretation."[62]

Epilepsy: Current literature states that "radiosurgery is an efficacious treatment to control seizures in mesial temporal lobe epilepsy, possibly resulting in superior neuropsychological outcomes and quality of life metrics in selected subjects compared to microsurgery."[12]

Tremor: For medically refractory tremor, "SRS to the unilateral thalamic ventral intermediate nucleus, with a dose of 130 to 150 Gy, is a well-tolerated and effective treatment....and one that i recommended by the International Stereotactic Radiosurgery Society."[18]

Trigeminal neuralgia: Current literature is "limited in its level of evidence, with only 1 comparative randomized trial reported to date. At present, one can conclude that stereotactic radiosurgery is a safe and effective therapy for drug-resistant trigeminal neuralgia."[63]

Dural arteriovenous fistulas: SRS is recommended for patients with "complex dural arteriovenous fistula who are planned for embolization and are at high risk for not achieving complete obliteration with embolization alone; dural arteriovenous fistula who have received previous embolization without complete obliteration and have refractory symptoms; high-risk

noncavernous sinus dural arteriovenous fistula or symptomatic cavernous sinus dural arteriovenous fistula who are not candidates for or have refused both embolization or microsurgery."[48]

SUMMARY

There is enough research to show that use of stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) of intracranial, skull base, and orbital sites for initial treatment or treatment of recurrence improves health outcomes for the following conditions: primary neoplasms of the central nervous system; metastasis to CNS with adequate performance score; arteriovenous malformations; chordomas and chondrosarcomas of the skull base; craniopharyngiomas; drug-resistant epilepsy when criteria are met; head and neck cancers when reirradiation is delivered; hemangioblastoma; hemangiopericytoma; glomus jugulare and glomus tympanicum tumors; meningiomas; pituitary adenomas; schwannomas; trigeminal neuralgia that is refractory to medical management; and uveal melanoma. In addition, clinical practice guidelines recommend the use of SRS or SBRT for many of these indications. Therefore, the use of SRS and SBRT may be considered medically necessary when policy criteria are met for these indications.

For all other tumors or indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) of intracranial, skull base, and orbital sites leads to improved health outcomes. Therefore, SRS and SBRT of intracranial, skull base, and orbital sites is considered investigational when policy criteria are not met.

CODES

NOTE: Coding for stereotactic radiosurgery typically consists of a series of CPT codes describing the individual steps required; medical radiation physics, clinical treatment planning, attachment of stereotactic head frame, treatment delivery and clinical treatment management.

The correct code to use for image fusion performed to provide enhanced delineation of target and normal critical structures is CPT code 77399 (Unlisted procedure, medical radiation physics, dosimetry and treatment devices, and special services); however, it is considered part of the treatment planning.

Treatment Planning Services:

Treatment delivered with LINAC based MLC may involve planning with the following codes.

Codes	Number	Description
	77338	Multi-leaf collimator (MLC) device(s) for intensity modulated radiation therapy (IMRT), design and construction per IMRT plan

NOTE: Treatment delivery:

The codes used for treatment delivery will depend on the energy source used, typically either photons or protons.

Codes	Number	Description
CPT	32701	Thoracic target(s) delineation for stereotactic body radiation therapy (SRS/SBRT), (photon or particle beam), entire course of treatment
	77371	Radiation therapy delivery, stereotactic radiosurgery (SRS), complete course of treatment of cranial lesion(s) consisting of 1 session; multi-source Cobalt 60 based
	77372	Radiation therapy delivery, stereotactic radiosurgery (SRS), complete course of treatment of cranial lesion(s) consisting of 1 session; linear accelerator based
	77373	Stereotactic body radiation therapy, treatment delivery, per fraction to 1 or more lesions, including image guidance, entire course not to exceed 5 fraction
	77435	Stereotactic body radiation therapy, treatment management, per treatment course, to 1 or more lesions, including image guidance, entire course not to exceed 5 fractions

NOTE: Codes for treatment delivery primarily reflects the cost related to the energy source used, and not physician work.

Clinical treatment management:

Codes	Number	Description
CPT	77432	Stereotactic radiation treatment management of cerebral lesion(s) (complete course of treatment consisting of one session.)
	61796	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 simple cranial lesion
	61797	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional cranial lesion, simple (List separately in addition to code for primary procedure)
	61798	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 complex cranial lesion
	61799	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional cranial lesion, complex (List separately in addition to code for primary procedure)
	61800	Application of stereotactic headframe for stereotactic radiosurgery (List separately in addition to code for primary procedure)
	63620	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 spinal lesion
	63621	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional spinal lesion (List separately in addition to code for primary procedure)
HCPCS	C9795	Stereotactic body radiation therapy, treatment delivery, per fraction to 1 or more lesions, including image guidance and real-time positron emissions-based delivery adjustments to 1 or more lesions, entire course not to exceed 5 fractions

Codes	Number	Description
	G0339	Image guided robotic linear accelerator-based stereotactic radiosurgery, complete course of therapy in one session, or first session of fractionated treatment.
	G0340	Image guided robotic linear accelerator-based stereotactic radiosurgery, delivery including collimator changes and custom plugging, fractionated treatment, all lesions, per session, second through fifth sessions, maximum five sessions per course of treatment

APPENDIX I: WHO Classification of Tumors of the Central Nervous System	
Gliomas, glioneuronal tumors, and neuronal tumors	**Cranial and paraspinal nerve tumors**
Adult-type diffuse gliomas	Schwannoma
Astrocytoma, IDH-mutant	Neurofibroma
Oligodendroglioma, IDH-mutant, and 1p/19q-codeleted	Perineurioma
Glioblastoma, IDH-wildtype	Hybrid nerve sheath tumor
Pediatric-type diffuse low-grade gliomas	Malignant melanotic nerve sheath tumor
Diffuse astrocytoma, *MYB*- or *MYBL1*-altered	Malignant peripheral nerve sheath tumor
Angiocentric glioma	Paraganglioma
Polymorphous low-grade neuroepithelial tumor of the young	**Meningioma**
Diffuse low-grade glioma, MAPK pathway-altered	**Mesenchymal, non-meningothelial tumors**
Pediatric-type diffuse high-grade gliomas	Soft tissue tumors
Diffuse midline glioma, H3 K27-altered	Fibroblastic and myofibroblastic tumors
Diffuse hemispheric glioma, H3 G34-mutant	Solitary fibrous tumor
Diffuse pediatric-type high-grade glioma, H3-wildtype and IDH-wildtype	Vascular tumors
Infant-type hemispheric glioma	Hemangiomas and vascular malformations
Circumscribed astrocytic gliomas	Hemangioblastoma
Pilocytic astrocytoma	Skeletal muscle tumors
High-grade astrocytoma with piloid features	Rhabdomyosarcoma
Pleomorphic xanthoastrocytoma	Uncertain differentiation
Subependymal giant cell astrocytoma	*Intracranial mesenchymal tumor, FET-CREB fusion-positive*
Chordoid glioma	*CIC*-rearranged sarcoma
Astroblastoma, *MN1*-altered	Primary intracranial sarcoma, *DICER1*-mutant
Glioneuronal and neuronal tumors	Ewing sarcoma
Ganglioglioma	Chondro-osseous tumors
Desmoplastic infantile ganglioglioma / desmoplastic infantile astrocytoma	Chondrogenic tumors
Dysembryoplastic neuroepithelial tumor	Mesenchymal chondrosarcoma
Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters	Chondrosarcoma
Papillary glioneuronal tumor	Notochordal tumors
Rosette-forming glioneuronal tumor	Chordoma (including poorly differentiated chordoma)
Myxoid glioneuronal tumor	**Melanocytic tumors**
Diffuse leptomeningeal glioneuronal tumor	Diffuse meningeal melanocytic neoplasms
Gangliocytoma	Meningeal melanocytosis and meningeal melanomatosis

APPENDIX I: WHO Classification of Tumors of the Central Nervous System	
Multinodular and vacuolating neuronal tumor	Circumscribed meningeal melanocytic neoplasms
Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)	Meningeal melanocytoma and meningeal melanoma
Central neurocytoma	**Hematolymphoid tumors**
Extraventricular neurocytoma	Lymphomas
Cerebellar liponeurocytoma	CNS lymphomas
Ependymal tumors	Primary diffuse large B-cell lymphoma of the CNS
Supratentorial ependymoma	Immunodeficiency-associated CNS lymphoma
Supratentorial ependymoma, *ZFTA* fusion-positive	Lymphomatoid granulomatosis
Supratentorial ependymoma, *YAP1* fusion-positive	Intravascular large B-cell lymphoma
Posterior fossa ependymoma (multiple subtypes)	Miscellaneous rare lymphomas in the CNS
Spinal ependymoma (multiple subtypes)	MALT lymphoma of the dura
Myxopapillary ependymoma	Other low-grade B-cell lymphomas of the CNS
Subependymoma	Anaplastic large cell lymphoma (*ALK*+/*ALK*−)
Choroid plexus tumors	T-cell and NK/T-cell lymphomas
Choroid plexus papilloma	Histiocytic tumors
Atypical choroid plexus papilloma	Erdheim-Chester disease
Choroid plexus carcinoma	Rosai-Dorfman disease
Embryonal tumors	Juvenile xanthogranuloma
Medulloblastoma	Langerhans cell histiocytosis
Medulloblastomas, molecularly defined (multiple types)	Histiocytic sarcoma
Medulloblastomas, histologically defined	**Germ cell tumors**
Other CNS embryonal tumors	Teratoma (multiple types)
Atypical teratoid/rhabdoid tumor	Germinoma
Cribriform neuroepithelial tumor	Embryonal carcinoma
Embryonal tumor with multilayered rosettes	Yolk sac tumor
CNS neuroblastoma, *FOXR2*-activated	Choriocarcinoma
CNS tumor with *BCOR* internal tandem duplication	Mixed germ cell tumor
CNS embryonal tumor	**Tumors of the sellar region**
Pineal tumors	Adamantinomatous craniopharyngioma
Pineocytoma	Papillary craniopharyngioma
Pineal parenchymal tumor of intermediate differentiation	Pituicytoma, granular cell tumor of the sellar region, and spindle cell oncocytoma
Pineoblastoma	Pituitary adenoma/PitNET

APPENDIX I: WHO Classification of Tumors of the Central Nervous System	
Papillary tumor of the pineal region	Pituitary blastoma
Desmoplastic myxoid tumor of the pineal region, *SMARCB1*-mutant	**Metastases to the CNS**
	Metastases to the brain and spinal cord parenchyma
	Metastases to the meninges

Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy for Tumors Outside of Intracranial, Skull Base, or Orbital Sites

Effective: January 1, 2024

Next Review: July 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Stereotactic radiosurgery (SRS) and stereotactic body radiotherapy (SBRT) or stereotactic ablative radiotherapy (SABR) are radiotherapy techniques that use highly focused radiation beams to treat both neoplastic and non-neoplastic conditions, in contrast to traditional external radiation beam therapy, which involves the use of relatively broad fields of radiation over a number of sessions that may occur over weeks to months.

MEDICAL POLICY CRITERIA

I. Stereotactic radiosurgery (SRS) and Stereotactic Body Radiation Therapy (SBRT), also known as Stereotactic Ablative Body Radiotherapy (SABR), may be considered **medically necessary** for initial treatment or treatment of recurrence for any of the following indications:

   A. Head and neck cancers outside of intracranial, skull base, and orbital sites, when there is documented prior radiation treatment to the planned target volume

   B. Hemangiopericytoma outside of intracranial, skull base, or orbital sites

C. Hepatobiliary tumor, including biliary tract cancer, intrahepatic cholangiocarcinoma and extrahepatic cholangiocarcinoma; excluding hepatocellular carcinoma (see Criterion D) and metastatic hepatic tumors from different primary cancers (see Criterion F).

D. Hepatocellular carcinoma (hepatoma) when all of the following criteria are met:

1. Five or fewer hepatic lesions; and
2. Size of largest lesion is 6 cm diameter or less; and
3. Karnofsky performance score greater than or equal to 60 or an ECOG score less than or equal to 2 (See Policy Guidelines).

E. Primary lung cancer: Non-small cell lung cancer (NSCLC) and Small-cell lung cancer (SCLC); tumor stage T1 or T2 and node negative.

F. Oligometastases when the following criteria are met:

1. Five or fewer synchronous metastatic lesions in any one metastatic site; and
2. Primary is controlled, stable, or expectation of the same; and
3. Metastases are limited to one to three organs; and
4. Karnofsky performance score greater than or equal to 60 or an ECOG score less than or equal to 2 (See Policy Guidelines).

G. Pancreatic adenocarcinoma, locally advanced, borderline resectable, inoperable (See Policy Guidelines) or local recurrence after resection

H. Paraganglioma

I. Prostate cancer; very low, low, and intermediate-risk (See Policy Guidelines)

J. Renal cell cancer, inoperable primary, when a urological surgeon has documented inoperability

K. Schwannomas (see Policy Guidelines)

L. Spinal or paraspinal tumors (primary or metastatic) including but not limited to hemangioblastoma

II. Stereotactic radiosurgery and stereotactic body radiation therapy (also known as Stereotactic ablative body radiotherapy) are considered **investigational** when Criterion I. is not met and for all other indications outside of intracranial, skull base, or orbital sites, including but not limited to: Primary tumors of the following sites: cervix, endometrium, esophagus, hemangiomas, large bowel, ovaries, rectum, and small bowel.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

For the purposes of this policy, neoplasm is defined as “an abnormal mass of tissue that results when cells divide more than they should or do not die when they should. Neoplasms may be benign (not cancer), or malignant (cancer).”[1]

SCHWANNOMAS

Schwannomas are tumors that occur along nerves. They are typically benign but may be malignant. These may also be referred to as neuromas, neurinomas "of Verocay" or neurilemmomas. A common type of schwannoma is a vestibular schwannoma, which is also known as an acoustic neuroma.

PERFORMANCE STATUS MEASUREMENT

Performance status is frequently used in oncology practice as a variable in determining prognosis and management strategies. Either the Karnofsky Performance Status (KPS) or the Eastern Cooperative Oncology Group (ECOG) Performance Status scoring systems may be used.

Karnofsky Performance Status

100	Normal, without symptoms
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or do active work
60	Requires occasional assistance; able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated
20	Very sick; active support treatment is necessary
10	Moribund; fatal processes progressing rapidly

ECOG Performance Status

0	Fully active, able to carry on all pre-disease performance without restriction.
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours.
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours.
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair.

Pancreatic Adenocarcinoma Resectability

See National Comprehensive Cancer Network criteria defining resectability at diagnosis of pancreatic adenocarcinoma.[2]

Prostate Cancer Risk Groups

The National Comprehensive Network (NCCN) Clinical Practice Guideline for Prostate Cancer defines very low risk prostate cancer as clinical T1c stage, Gleason score less than or equal to 6 /Grade Group 1, and PSA <10ng/ml and low risk prostate cancer as cT1-T2a, Gleason score less than or equal to six/Grade Group 1, and PSA less than 10ng/mL. Intermediate risk is defined as cT2b-cT2c or Gleason score of seven/Grade Group 2 or 3, or PSA 10-20ng/ml.[3]

FRACTIONATION

Fractionated stereotactic radiotherapy refers to when SRS or SBRT are performed more than once on a specific site. SRS is commonly delivered in 1 fractions and SBRT or SABR is commonly delivered in 2-5 fractions.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History/Physical and Chart notes, including requirements as outlined by the policy criteria, as applicable to the indication for treatment.
- As applicable, documentation of sites, size and count of lesions
- As applicable, documented ECOG score or Karnofsky performance score
- As applicable, absent or minimal extra hepatic disease for extracranial site treatment
- For prostate cancer, PSA and Gleason score.

BACKGROUND

Stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) rely on three-dimensional imaging to localize the therapy target. SRS and SRBT have been used for a range of malignant and non-malignant conditions. Because they are more targeted than traditional external radiation therapy, SRS and SRBT are often used for treatment at sites that are difficult to reach via surgery, located close to other vital structures, or subject to movement within the body. The term SBRT will be used to describe treatment also referred to as stereotactic ablative body radiotherapy (SABR).

SRS and SBRT (or SABR) employ similar technological "stereotactic" sophistication with elements of advanced pretreatment imaging for localization of target(s), patient immobilization, control of breathing associated tumor movement, focally targeted treatment planning, and daily image guidance to ensure precise delivery of high daily doses of radiation. As commonly used in the medical literature, SRS refers to intracranial treatments and SBRT refers to extracranial treatments. Alternatively, SRS and SBRT may be defined independent of whether treatment is directed to intra or extra cranial tumors volumes. According to this definition, when such treatment is given as a single fraction, it may be referred to as SRS, and when it is delivered in 2-5 fractions it may be referred to as SBRT or SABR.

The fractionation used for SRS and SBRT is referred to as “hypofractionated” because it is fewer treatments than those used for conventional external beam radiotherapy.” Fractionation of stereotactic radiotherapy aims to optimize the therapeutic ratio; that is the ratio between tumor control and late effects on normal tissues. The main advantage of fractionation is that it allows higher total doses to be delivered to the tumor because of increased tolerance of the surrounding healthy tissues to each individual, fractionated dose. In addition, some lesions such as large arteriovenous malformations may require more than one procedure to complete the obliteration process.

SRS and SBRT can be administered by several types of devices that are distinguished by their source of radiation, including particle beams (e.g., proton), gamma radiation from cobalt-60 sources, or high-energy photons from linear accelerator (LINAC) systems. The Gamma Knife and linear accelerator systems (including the Cyberknife®) are similar in concept; both use multiple photon radiation beams that intersect at a stereotactically determined target, thus permitting higher doses of radiation delivery with sparing of surrounding normal tissues. The differences between the two relate to how the energy is produced (i.e., through decaying cobalt-60 in the gamma knife devices, or from x-rays in the linear accelerator system) and the number of energy sources used (i.e., multiple energy sources in the gamma knife versus one in the linear accelerator system).

IMAGE-GUIDED RADIOSURGERY OR RADIOTHERAPY

Image-guided radiosurgery or radiotherapy is a relatively new development collectively describing units with real-time image guidance systems. Examples include the Cyberknife® device, BrainLAB Novalis®, TomoTherapy®, and LINAC with computerized tomography (CT).

REGULATORY STATUS

Several devices that use cobalt 60 radiation (gamma ray devices) for SRS have been cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process. The most commonly used gamma ray device is the GammaKnife (Elekta; approved May 1999). Gamma ray emitting devices that use cobalt 60 degradation are also regulated through the U.S. Nuclear Regulatory Commission.

A number of LINAC movable platforms that generate high-energy photons have been cleared for marketing by the FDA through the 510(k) premarket notification process including the Novalis Tx®

(Novalis, Westchester, IL); the TrueBeam STx (Varian Medical Systems, Palo Alto, CA, approved December 2012); and the CyberKnife® System (Accuray, Inc.; approved December 1998). LINAC-based devices may be used for intracranial and extracranial lesions.

Note: Particle radiation can also be used without stereotactic guidance. In this setting, the use of particles is referred to as proton, helium, or neutron radiation *therapy*. Proton or helium ion radiation therapies (RT), intraocular RT for age-related macular degeneration, and electromagnetic navigation bronchoscopy for placement of fiducial markers are considered in separate medical policies. See cross-reference section below.

EVIDENCE SUMMARY

The selection of variables used in the delivery of SRS and SBRT is complex and individualized, requiring selection of the device, radiation dose, and the size and shape of treatment margins. All of these variables depend on the location, shape, and radiosensitivity of the target tissue and the function and radiosensitivity of the surrounding tissue. Trials that allow direct comparison of all of the possible variables involved in selecting specific SRS and SBRT methods do not broadly exist making it difficult to draw comparative effectiveness conclusions. Further, for many rare conditions, large comparative studies are unlikely. The evidence below will focus on indications with criteria and investigational indications.

Please note that the evidence review below does not compare specific radiation planning and delivery techniques.

Lung Cancer

Systematic Reviews

Viani (2022) published a meta-analysis evaluating the efficacy of SBRT versus surgery for early-stage NSCLC.[4] Thirty studies met inclusion criteria, with 29,511 patients (17,146 patients in the surgery group and 12,365 patients in the SBRT group). Of these, 26 were retrospective studies with propensity score matching, one was a randomized clinical trial, one was a retrospective study with adjustment for prognostic covariates, and two were retrospective studies without adjustment for covariates. Statistically significant publication bias for OS was identified at three years in favor of surgery (p=0.027). A statistically significant difference between groups in favor of surgery was identified in three-year OS (HR=1.35; 95% CI 1.22 to 1.44; I^2=66%) and three-year cancer-specific survival (HR=1.23; 95% CI 1.09 to 1.37; I^2=17%). Three-year LC was not significantly different between groups (HR = 0.97; 95% CI 0.93 to 1.08; I^2=19%). Subgroup analyses identified no significant differences between groups in OS in the T1N0M0 subgroup or cancer-specific survival between the sublobar resection subgroup and the SBRT group.

Zhang (2022) published a systematic review of 87 studies involving SBRT (n=12,811) and 18 studies involving RFA (n=1,535) for patients with inoperable stage I NSCLC.[5] The local control rates with SBRT were 98%, 95%, 92%, and 92%, respectively, at one, two, three, and five years; the local control rates for RFA were significantly lower (75%, 31%, 67%, and 41%, respectively, at one, two, three, and five years; p<0.01 for all comparisons). The OS rates were similar between SBRT and RFA at one year (87% vs 89%, respectively; p=0.07) and two years (71% vs 69%, respectively; p=0.42), whereas the OS was significantly improved with SBRT over RFA at three years (58% vs 48%; p<0.01) and five years (39% vs 21%; p<0.01). The most common complication of SBRT was radiation pneumonitis (9.1%), whereas pneumothorax was the most common complication of RFA (27.2%).

A systematic review by Alcibar (2021) evaluated the use of SBRT for treating inoperable stage III non-small cell lung cancer.[6] A total of six studies with 134 patients met inclusion criteria.

Half of the studies were prospective and the half were retrospective. Overall median follow-up was 18.75 months. Median local control was 76% and grade 3 or higher toxicity occurred in 12% of patients.

Ijsseldijk (2020) conducted a systematic review and meta-analysis comparing oncologic outcomes of surgery versus SBRT for patients with stage I NSCLC.[7] The analysis included a total of 100 studies. Results revealed that long-term OS and disease-free survival after lobar resection was better than SBRT in all comparisons, and for the majority of comparisons, sublobar resection was better than SBRT. Included studies were heterogeneous and of low quality; however, results remained essentially unchanged after many stratifications and sensitivity analyses.

In 2019 Li published a systematic review comparing SBRT to surgery for early-stage NSCLC. A total of 14 cohort studies (n=1,438 participants) met inclusion criteria.[8] Matching was performed for the main bias sources between the groups, including age, gender, tumor diameter, forced expiratory volume in one second, and Charlson comorbidity index. There was a statistically significant benefit for surgery over SBRT for early-stage NSCLC, with pooled OR for one-, three-, and five-year OS of 1.56 (95% CI 1.12 to 2.15), 1.86 (95% CI 1.50 to 2.31), and 2.43 (95% CI 1.8 to 3.28), respectively. The five-year distant control was 2.74 (95% CI 1.12 to 6.67). No significant differences were identified between groups for one-year or three-year disease-free survival, locoregional control, or distant control or five-year locoregional control.

In 2014, Zheng reported results from a systematic review and meta-analysis comparing survival after SBRT with survival after surgical resection for the treatment of stage I NSCLC.[9] The authors included 40 studies reporting outcomes from SBRT, including 4850 patients, and 23 studies reporting outcomes after surgery published in the same time period, including 7071 patients. For patients treated with SBRT, the mean unadjusted OS rates at one, three, and five years were 83.4%, 56.6%, and 41.2%, respectively. The mean unadjusted OS rates at one, three, and five years were 92.5%, 77.9%, and 66.1%, respectively, with lobectomy, and 93.2%, 80.7%, and 71.7% with limited lung resections. After adjustment for surgical eligibility (for the 27 SBRT studies that reported surgical eligibility) and age, in a multivariable regression model, the treatment modality (SBRT vs surgical therapy) was not significantly associated with OS (p=0.36).

A review by Nguyen (2008)[10] cites a number of studies of SBRT for early-stage lung cancer receiving a biologic equivalent dose of 100 Gy or more. Three of the studies cited reported 5-year survival that ranged from 30% to 83%; in the largest series of 257 patients, the five-year survival was 42%. Koto reported on a phase two study of 31 patients with stage one NSCLC.[11] Patients received 45 Gy in 3 fractions, but those with tumors close to an organ at risk received 60 Gy in 8 fractions. With a median follow-up of 32 months, the three-year OS was 72%, while disease-free survival was 84%. Five patients developed grade two or greater pulmonary toxicity. While comparative studies were not identified, older studies have reported three-year disease-specific survival rates of 49% for those with stage one disease.[12]

Randomized Controlled Trials

Peng (2023) performed an RCT to assess the efficacy and safety of SBRT plus targeted therapy with epidermal growth factor tyrosine kinase inhibitors (EGFR-TKIs) in patients with Stage IV NSCLC who had EGFR sensitive mutations and fewer than five metastatic lesions.[13] After three months of first line treatment with demonstrated response, 62 patients were

randomized to either receive SBRT with continued EGFR-TKI therapy (31 patients) or continued EGFR-TKI therapy alone (31 patients). After a median follow-up of 29.4 months eight (26.67%) patients in the SBRT group were living, compared to five (16.3%) in the EGFR-TKI group. Median PFS was 17.3 months in the SBRT group and 9.0 months in the control group (HR=0.52, 95% CI 0.31 to 0.89, p=0.016). Overall survival was also statistically significant (p=0.033) with median survival of 35.2 months in the SBRT+EGFR-TKI group and 23.2 months in the EGFR-TKI group. The study suggests that adding SBRT to EGFR targeted therapy prolongs survival by delaying acquired resistance to therapy, but larger randomized trials are needed.

Altorki (2021) published an RCT assessing neoadjuvant durvalumab with compared to without SBRT.[14] A total of 60 patients with potentially resectable early-stage NSCLC were randomized to receive durvalumab monotherapy (n=30) or the durvalumab plus radiotherapy (n=30). There was a statistically significant difference in major pathological response rate between the monotherapy and SBRT-treated groups (6.7% [95% CI 0.8 to 22.1] vs. 53.3% [34.3 to 71.7%]; p<0.0001). Grade 3 to 4 adverse events were reported in 17% of monotherapy- and 20% of SBRT-treated patients. The second cycle of durvalumab was withheld in three (10%) of 30 patients in the SBRT-treated group due to immune-related adverse events (grade 3 hepatitis, grade 2 pancreatitis, and grade 3 fatigue and thrombocytopenia). Two patients in each group experienced serious adverse events. There were no treatment-related deaths or any deaths within 30 days of surgery.

Nonrandomized Comparative Studies

Numerous nonrandomized, comparative studies have compared SBRT with surgery for NSCLC. A few of them used matching and are therefore the strongest methodologically of this group. Chi (2019) reported results of a cohort study comparing surgery and SBRT for the treatment of early-stage NSCLC using data from the National Cancer Database.[15] Survival comparisons used the multivariable Cox proportional hazards model and propensity score matching incorporating preoperative risk factors significantly associated with OS. A total of 104,709 patients were included in the analysis. Of these, 91,330 were in the surgery group and 13,379 were in the SBRT group. For the propensity score–matched cohorts, 12,632 patients undergoing sublobar resection were compared with 12,632 patients undergoing SBRT and 12,632 patients undergoing lobar resection were compared with 12,632 patients undergoing SBRT. Resection, both sublobar (HR, 0.56; 95% CI 0.54 to 0.58, p<0.001) and lobar (HR, 0.47; 95% CI 0.45 to 0.49, p<0.001) were associated with reduced mortality risk compared with SBRT. Survival comparisons calculated using a stratified multivariable Cox model to adjust for confounding variables also showed an association between surgery and a reduction in mortality risk. This association was not found for less extensive surgery when 0 nodes were examined in patients aged 80 years or older with stage T2 to T3 tumors (HR for lobectomy, 0.90; 95% CI 0.65 to 1.25; p=0.53) and in selected operable patients older than 75 years with stage T1 tumors (HR for lobectomy, 1.07; 95% CI 0.57 to 2.00; p=0.84). Wu (2020) performed a similar analysis comparing sublobar resection versus SBRT or ablation for stage I NSCLC using data from the National Cancer Database. This analysis also identified shorter OS for SBRT and ablation versus sublobar resection.[16]

Lam (2018) performed a matched analysis of cases in the National Cancer Database of stage 1a and 1b NSCLC treated with primary RF ablation or SBRT.[17] A total of 4,454 SBRT- and 335 RF-treated patients were included. There were significantly more comorbidities (p<0.001) and unplanned readmission within 30 days (p<0.001) in the RF ablation group. A multivariate

Cox regression analysis of OS for the unmatched groups showed no significant difference (p=0.285). In the matched groups, no difference was found with one-, three- and five-year OS of 85.5%, 54.3%, and 31.9% in the SBRT group vs 89.3%, 52.7%, and 27.1% in the RF ablation group (p=0.835).

von Reibnitz (2018) analyzed 497 patients with early-stage NSCLC (T1-T2N0M0) treated with conventional radiation (n=127) or SBRT (n=398).[18] Median follow-up was 24.4 months. The Kaplan-Meier method was used to estimate OS and the Cox regression model was used to compare between groups. Propensity score matched analysis was performed using seven patient and clinical variables: age, gender, Karnofsky performance status (KPS), histology, T stage, biologically equivalent dose (BED), and history of smoking. Three-year local failure and OS rates were 38.9% for conventional radiation and 13.6% for SBRT (p<0.001) and 38.9% for conventional radiation and 53.1% for SBRT, respectively. Propensity score matching indicated a statistically significant improvement of OS for SBRT (p=0.0497).

Two matched analyses used the SEER (Surveillance, Epidemiology, and End Results) database to identify patients. Yu (2015) identified elderly patients with stage I NSCLC who received either SBRT or surgery from 2007 to 2009.[19] Propensity matching was used to select two surgery patients for each SRS patient. A total of 367 SBRT patients were matched with 711 surgery patients. Early mortality at three months was significantly better for the SBRT group compared to the surgery group (2.2% vs 6.1%, p=0.005). However, late mortality at 24 months was significantly worse for the SBRT group (40.1%) compared with the surgery group (22.3%; p<0.001). Across the 24-month follow-up, patients in the SBRT group had fewer complications (incidence rate ratio, 0.74; 95% CI, 0.64 to 0.87). A similar study was performed by Ezer (2015),[20] and the two studies likely had overlapping populations. A total of 362 patients with stage I or II NSCLC and negative lymph nodes were matched with patients who received limited resection. There was no difference in OS for the SBRT patients compared with the surgery patients (HR=1.19; 95% CI, 0.97 to 1.47). Complications were less common in patients undergoing SBRT (14% of total) compared with patients undergoing resection (28%; p<0.001).

Tubin (2019) compared the novel SBRT-based PArtial Tumor irradiation of HYpoxic clonogenic cells (SBRT-PATHY) to standard of care in unresectable stage IIB/IV bulky NSCLC.[21] A total of 60 patients who were considered inoperable or unsuitable for radical radio-chemotherapy were treated using SBRT-PATHY (group I, n = 20 patients), recommended standard of care chemotherapy (group II, n = 20 patients), and institutional conventional palliative radiotherapy (group III, n = 20 patients). The median follow-up was 13 months. No statistically significant differences between groups were identified for one-year overall survival (75, 60, and 20% in groups 1, 2 and 3, respectively; p = 0.099) or one-year cancer specific survival (90, 60, and 20% in groups 1, 2, and 3, respectively (p = 0.049). However, multi-variate analysis for cancer specific survival was significant for treatment effect with SBRT-PATHY (p<0.001) independent of age, sex, performance status, histology, stage, treated bulky site and tumor diameter. Bulky tumor control rate was 95, 20, and 20% in groups 1, 2, and 3, respectively. Compared to chemotherapy and conventional palliative radiotherapy, toxicity was lower and symptom control was improved in the SBRT-PATHY group.

Jeppeson (2013) compared SBRT with conventional radiotherapy for patients with medically inoperable NSCLC (T1-2N0M0).[22] The study included 100 subjects treated with SBRT and 32 treated with conventional radiotherapy. At baseline, the SBRT-treated patients had smaller tumor volume, lower FEV_1, and a greater proportion of T1 stage disease. Median OS was 36.1

months versus 24.4 months for SBRT and conventional radiotherapy, respectively (p=0.015). Local failure-free survival rates at one year were 93% in the SBRT group versus 89% in the conventional radiotherapy group and at five years 69% versus 66%, SBRT and conventional radiotherapy, respectively (p=0.99).

Noncomparative Studies

Raman (2018) reported an institutional prospective database review of 180 central and 26 ultracentral lung tumors.[23] Most patients received 60 Gy in eight fractions or 48 Gy in four fractions. Rates of toxicity were 8.4% for grade 2 or higher in the central group an d7.9 in the ultracentral group. No grade 4 or 5 toxicities were reported. The two-year cumulative rates of local, regional, and distant failure were 3.3% vs 0 (p=0.36), 9.1% vs 5.0% (P = .5), and 17.7% vs 18.7% (P = .63) in the central and ultracentral groups, respectively.

A report of a seven-year follow-up of 65 patients treated with SBRT for medically inoperable, clinical stage I NSCLC was published in 2017 by Sun.[24] A dose of 50 Gy was delivered in four fractions. Recurrence occurred in 27.7% of patients at a median of 14.5 months following SBRT. Five- and seven-year estimated local, regional, and distant recurrence were 8.1, 10.9, and 11.0%, and 8.1, 13.6, and 13.8%, respectively. Five- and seven-year estimated OS were 55.7 and 47.5% and PFS were 49.5 and 38.2%, respectively. Three patients experienced grade 3 treatment-related adverse events, but there were no reported grade 4 or 5 adverse events.

In a 2017 study of 71 patients undergoing SBRT for stage I NSCLC by Miyakawa, dose escalation was used with the goal of attaining improved local control of large tumors.[25] Doses used were 48, 50, and 52 Gy for tumors with a longest diameter of < 1.5 cm, 1.5-3 cm, and > 3 cm, respectively. OS and PFS at the median follow-up of 61 months for living patients (44 months for all patients) were 65% and 55%, respectively. The cumulative incidence of local recurrence was 15% at five years.

A retrospective database study (n=3,147) by Nanda (2015) evaluated patients aged 70 years or older with early stage (T1-T3N0M0) NSCLC for three years.[26] Overall survival was compared between stereotactic body radiotherapy alone and no treatment. SBRT was associated with improved survival in elderly patients who have concurrent comorbid conditions compared with no treatment.

Timmerman (2007) evaluated the toxicity and efficacy of SBRT in a high-risk population of patients with early stage but medically inoperable lung cancer.[27] in a phase two North American multicenter study of patients aged 18 years or older with biopsy-proven peripheral T1-T2N0M0 non-small-cell tumors (<5 cm in diameter) and medical conditions precluding surgical treatment. The prescription dose was 18 Gy per fraction × 3 fractions (54 Gy total), with the entire treatment lasting between 1.5 to two weeks. The primary end point was two-year actuarial primary tumor control; secondary end points were DFS (ie, primary tumor, involved lobe, regional, and disseminated recurrence), treatment-related toxicity, and OS. A total of 59 patients accrued, 55 of whom were evaluable (44 patients with T1 tumors, 11 patients with T2 tumors) with a median follow-up of 34.4 months (range, 4.8-49.9 months). Only one patient had primary tumor failure; the estimated three-year primary tumor control rate was 97.6% (95% CI, 84.3% to 99.7%). Three patients had recurrence within the involved lobe; the three-year primary tumor and involved lobe (local) control rate was 90.6% (95% CI, 76.0% to 96.5%). Two patients experienced regional failure; the local-regional control rate was 87.2% (95% CI, 71.0% to 94.7%). Eleven patients experienced disseminated recurrence; the three-

year rate of disseminated failure was 22.1% (95% CI, 12.3% to 37.8%). The rates for DFS and OS at three years were 48.3% (95% CI, 34.4% to 60.8%) and 55.8% (95% CI, 41.6% to 67.9%), respectively. The median OS was 48.1 months (95% CI, 29.6 months to not reached). Protocol-specified treatment-related grade three adverse events were reported in seven patients (12.7%; 95% CI, 9.6% to 15.8%); grade four adverse events were reported in two patients (3.6%; 95% CI, 2.7% to 4.5%). No grade five adverse events were reported. The authors concluded that patients with inoperable NSCLC who received SBRT had a survival rate of 55.8% at three years, high rates of local tumor control, and moderate treatment-related morbidity.

In 2014, Stanic reported additional analysis of pulmonary toxicity in participants from the Timmerman study.[28] During two-year follow-up pulmonary function test results were collected. Mean percentage of predicted FEV1 and DLCO declines were 5.8% and 6.3%, respectively. There was no significant decline of oxygen saturation. Baseline pulmonary function testing was not predictive of any pulmonary toxicity following SBRT. Whole lung V5, V10, V20 and mean dose to the whole lung were almost identical between patients who developed pneumonitis and patients who were pneumonitis-free. Poor baseline pulmonary function testing did not predict decreased overall survival. Patients with poor baseline pulmonary function testing as a reason for medical inoperability had higher median and overall survivals than patients with normal baseline pulmonary function testing but with cardiac morbidity.

Hof (2007) reported on outcomes (median follow-up, 15 months) for 42 patients with stages I and II lung cancer who were not suitable for surgery and who were treated with stereotactic radiotherapy.[29] In this series, at 12 months, OS was 75% and DFS was 70%. Better local control was noted with higher doses of radiation.

In a prospective evaluation of 185 medically inoperable patients with early (T1-T2N0M0) NSCLC treated with SBRT, Allibhai (2014) evaluated the influence of tumor size on outcomes.[30] Over a median follow-up of 15.2 months, tumor size (maximum gross tumor diameter) was not associated with local failure but was associated with regional failure (p=0.011) and distant failure (p=0.021). Poorer OS (p=0.001), DFS (p=9.001), and cause-specific survival (p=0.005) were also significantly associated with tumor volume more significant than diameter.

Harkenrider (2014) reported outcomes after SBRT for 34 patients with unbiopsied lung cancer, with estimated rates of two-year regional control, distant control, and OS of 80%, 85%, and 85%, respectively.[31]

Section Summary

Although limited randomized data are available, studies have shown that SBRT for patients with stage one NSCLC who are not candidates for surgical resection because of comorbid conditions or for those with early stage disease who refuse surgery, survival rates may be comparable with surgical resection.

Hepatic and Hepatobiliary Tumors

In order to understand the impact of SBRT in the management of hepatocellular carcinoma and other hepatic malignancies, well-designed randomized controlled trials (RCTs) are preferred. However, these are often difficult to perform given the populations involved.

Therefore, this evidence section includes meta-analyses of nonrandomized studies and larger nonrandomized studies in addition to RCTs.

Systematic Reviews

Yang (2023) performed a systematic review and meta-analysis to compare the efficacy and safety of radiofrequency ablation (RFA) to SBRT in patients with inoperable HCC.[32] Seventeen studies involving 22,180 patients were included. One and two-year OS rates were better in the RFA group (OR 0.69, 95% CI 0.50-0.96, p=0.141; OR 0.69, 95% CI 0.53-0.89, p=0.082); however, 3-5 year OS rates were similar in both groups (OR 0.94, 95% CI 0.65-1.38, p=0.001; OR 0.98, 95% CI 0.68-1.34, p=0.016) moderate to high (I2=29.6-69.7%) heterogeneity. SBRT groups had higher rates of local control (freedom from local progression; FFLP) compared to RFA at one, two, and three years (OR 2.19, 95% CI 1.44-3.34, P=0.303; OR 1.57, 95% CI 1.12-2.19, P=0.268; OR 2.22, 95% CI 1.7-2.9, p=0.474). Heterogeneity was low to moderate (I2=0-20.4%). No significant differences were found in the reported treatment-related complications, but the SBRT group had worse outcomes related to liver function and failure (p<0.01). The authors state baseline characteristics (e.g., liver function) likely contributed to the differences in the groups and future studies need to take into account baseline differences such as tumor size and location, prior treatment, and liver function.

Wu (2022) reported a systematic review compare external beam radiation therapy modalities for HCC with macrovascular invasion (MVI).[33] A total of 44 studies including 3,730 patients were included. Particle therapy had a pooled one-year OS (60.9%) that was significantly greater than conventional radiotherapy (45.3%; p=0.005) and SBRT (44.9%; p=0.002). Particle therapy and SBRT had significantly objective response rate compared to conventional radiotherapy, whereas only particle therapy was significantly greater than conventional radiotherapy with respect to local control rate. The most frequent types of grade ≥ 3 complications were hematological toxicity, hepatotoxicity, dermatological toxicity.

Bisello (2021) performed a systematic review of SBRT for the treatment of intrahepatic cholangiocarcinoma.[34] Six publications with a total of 145 patients met inclusion criteria. SBRT followed previous systemic or local treatments for 28.6 to 66.7% of patients. No meta-analysis was conducted. Median follow-up was reported in five studies and was 16 months (range 8.8 to 18.0). Median OS was reported in all studies and was 14 months (range 10 to 48 months). Reports of tumor response, local control, and toxicities were not consistently.

Shanker (2021) published a systematic review analyzing local control, survival and toxicity outcomes following SABR for HCC.[35] A total of 49 cohorts including 2,846 patients met inclusion criteria. Pooled LC rates were 91.1% (95% CI 88.3 to 93.2) at one year, 86.7% (95% CI 82.7 to 89.8) and two years, and 84.2% (95% CI 77.9 to 88.9) at three years. Pooled OS rates were 78.4% (95% CI 73.4 to 82.6) at one year, 61.3% (95% CI 55.2 to 66.9) at two years, and 48.3% (95% CI 39.0 to 57) at three years. Grade 3 and grade 4/5 toxicity rates, calculated as population-weighted medians, were 6.5% (IQR 3.2 to 16) and 1.4% (IQR 0 to 2.1), respectively.

Long (2021) reported a systematic review of therapeutic outcome of SBRT for small liver-confined HCC (≤ 3 lesions with longest diameter ≤ 6 cm).[36] A total of 14 observational studies including 1,238 patients met inclusion criteria. Pooled one-year OS and LC rates were 93.0% (95% CI 88.0 to 96.0%) and 96.0% (95% CI 91.0 to 98.0%), respectively. Pooled three-year OS and LC rates were 72.0% (95% CI 62.0 to 79.0%) and 91.0% (95% CI 85.0 to 95.0%), respectively. Subgroup differences were identified for Child-Pugh class one- and three-year

OS rate, but not for number of lesions, pretreatment situation, age (median/mean age of 65), macrovascular invasion, tumor size, or radiation dose (median BED10 of 100 Gy). Pooled rates of grade 3 or greater hepatic complications and radiation-induced liver disease were 4.0% (95% CI 2.0 to 8.0%) and 14.7% (95% CI 7.4 to 24.7%), respectively.

Lee (2020) evaluated the efficacy of SBRT versus RFA for the treatment of liver malignancies via a meta-analysis of 11 studies involving 2,238 patients.[37] Of the 11 studies, eight involved treating patients for early HCC and three for liver metastases. Results revealed that the pooled two-year local control rate was significantly improved in the SBRT versus RFA arm (83.8% versus 71.8%; p=0.024). The pooled two-year control rate was also significantly higher in the SBRT versus RFA arm among patients in the liver metastases studies only (83.6% versus 60%; p<0.001) while no such significant difference was seen in HCC studies (84.5% versus 79.5%; p=0.431). Pooled analysis of OS in HCC studies showed an odds ratio of 1.43 (95% CI 1.05 to 1.95; p=0.023), favoring RFA. Only two liver metastases studies had comparative survival data; no significant difference was seen.

Dobrzycka (2019) published a systematic review on outcomes following SBRT for early-stage hepatocellular carcinoma.[38] A total of 16 studies met inclusion criteria, 14 of which were retrospective. The average diameter of the treated tumor was 23 mm. Weighted one-year local control was 94.1% based on 11 studies. Seven and four studies reported two- and three-year local control, respectively, and the weighted means from those studies were 92.2% and 93.7%. Weighted one-year mean OS was 90.9% based on 14 studies. Nine and four studies reported two- and three-year OS, respectively, and the weighted means from those studies were 67.4% and 73.3%. Based on all 16 included studies, 171 grade 1 to 2 toxicities (17.5%) and 53 ≥ grade 3 toxicities (5.3%) were reported.

Frakulli (2019) performed a systematic review SBRT for the treatment of advanced cholangiocarcinoma.[39] Studies were included if they analyzed at least 10 patients with advanced cholangiocarcinoma. A total of 10 studies with 231 patients met inclusion criteria. Nine of the 10 showed moderate to serious risk of bias, as calculated by the ROBINS-I risk of bias tool. Median follow up was 15 months (range: 7.8-64.0 months). Pooled one- and two-year OS was 58.3% (95% CI: 50.2-66.1%) and 35.5% (95% CI: 22.1-50.1%), respectively. Pooled local control at one-year was 83.4%, (95% CI: 76.5-89.4%). There was one treatment-related death.

A 2012 systematic review conducted by Tao and Yang, assessed the efficacy and safety of SBRT for treating primary and secondary hepatic neoplasms.[40] The review included prospective clinical trials published in English. Fifteen studies involving 158 patients with primary tumors and 341 patients with metastases to the liver were included. Treatment was performed in 1 to 10 fractions to total doses of 18 to 60 Gy. Most studies that were included reported outcomes for patients with both primary and metastatic disease, without separating out outcome data for primary tumors only. In addition, some studies reported on outcomes for primary liver tumors including cholangiocarciomas. At Indiana University, in a phase I study, Cardenes (2010) treated 17 HCC patients with Child-Turcotte-Pugh (CTP) CTP-A or CTP-B, one to three lesions and cumulative tumor diameter of 6 cm or less.[41] Patients with CTP-A were treated in three fractions with the dose escalated from 12 to 16 Gy. For patients with CTP-B, the dose was modified to 5 fractions starting at 8 Gy per fraction and was not escalated because two patients treated at 3 × 14 Gy developed grade three hepatic toxicity. The one-year OS was 75%, and there were no local failures during the median 24 months of follow-up.

Meng (2009) conducted a systematic review and meta-analysis of transcatheter arterial chemoembolization (TACE) in combination with radiotherapy compared with TACE alone for unresectable hepatocellular carcinoma (HCC) using meta-analysis of data from the literature involving available trials.[42] Seventeen trials involving 1476 patients were identified. Five were RCTs, and 12 were non-RCTs. In terms of quality, five RCTs were graded B, and the 12 nonrandomized studies were graded C. Results showed that TACE plus radiotherapy significantly improved survival and tumor response over TACE alone. The authors concluded that considering the strength of the evidence, additional RCTs are needed before combination TACE and radiotherapy can be routinely recommended.

Randomized Controlled Trials

Shi (2022) compared SBRT after surgical resection with hepatectomy to hepatectomy alone in 76 patients with microvascular invasion (MVI)-positive early stage HCC.[43] Seventy-six patients were randomized to either surgery or surgery with adjuvant SBRT at the surgical margin, and there were 38 subjects in each arm. In the SBRT group DFS was 92.1% in one year, 65.8% in two years, and 56.1% at three years, and DFS in the surgery control group was 76.3%, 36.8%, and 26.3% (p=0.005). OS at one, three, and 5 years was 100%, 89.5%, and 75.0% in the SBRT group and 100%, 68.4%, and 53.7% in the surgery control group (p=0.053). Nearly one third of the people in the SBRT group (12/38) experienced radiotherapy-related adverse events but none were grade 3 or higher.

Nonrandomized Comparative Studies

Larger studies and those addressing the policy criteria (e.g. number of lesions) are addressed below.

Yang (2019) compared the outcomes of SBRT and conventionally fractionated radiotherapy in HCC patients with portal vein invasion.[44] A total of 104 patients were evaluated, 45 in the SBRT group and 59 in the conventionally fractionated radiotherapy group. The differences in rates of overall response (62.2% vs. 33.8%; p=0.003), one-year OS (34.9% vs. 15.3%; p=0.012), and in-field progression-free survival (69.6% vs. 32.2%; p=0.007) were statistically significant, with higher values in the SBRT group for all measures. After propensity score matching, the rates all remained higher in the SBRT group. No significant differences were identified in incidence of radiation-induced liver disease or increase of Child-Pugh score greater than or equal to 2 within three months of radiotherapy.

Bettinger (2019) reported on a multi-center retrospective comparative study of SBRT (n=122) or sorafenib (n=901), a tyrosine kinase inhibitor, for the treatment of advanced HCC.[45] Unadjusted median OS was 18.1 months (95% CI, 10.3 to 25.9) for SBRT and 8.8 (95% CI, 8.2 to 9.5) for sorafenib. Adjusted median OS was 17.0 months (95% CI, 10.8 to 23.2) and 9.6 (95% CI, 8.6 to 10.7), respectively. No survival benefit was observed for patients with SBRT in patients with portal vein thrombosis. Over 80% of patients were male in each study arm. Patients in the sorafenib group had significantly worse ECOG PS scores (p<0.001), were more frequently pre-treated with radiofrequency ablation (RFA) (p<0.001) or transarterial chemoembolization (TACE) (p=0.016), had a higher incidence of multifocal disease and extrahepatic metastases (p<0.001), and had more advanced illness on the basis of the Barcelona Clinic Liver Cancer (BCLC) staging system (Grade B, intermediate and Grade C, advanced; p<0.001). Although propensity score matching was utilized to adjust for differences in baseline characteristics, the data are limited by extensive heterogeneity in the respective treatment populations. Presently, the FDA indication for the use of sorafenib is for patients with

unresectable HCC. Due to the inclusion of patients who had previously been treated by surgery and with early or intermediate stage disease on the basis of BCLC criteria, it is unclear whether some patients were candidates for re-resection, potentially limiting the relevance of this study.

Roman (2019) performed a retrospective analysis of short- and long-term outcomes of SBRT (n=118) and surgical treatment (n=142) for patients with liver malignancies.[46] Median OS was 27.63 months for all patients, 22.93 months in the SBRT group, and 30.65 months in the surgical group. According to a Kaplan-Meier analysis, there was no statistically significant difference in disease specific survival between groups (p=0.082).

Nakano (2018) reported results of a retrospective analysis of 281 patients with one to three small (≤3 cm in diameter) hepatocellular carcinoma tumors who were treated with curative intent via surgical resection or SBRT.[47] The surgical resection group on average was younger, had more tumors, and had better hepatic function than those in the stereotactic body radiotherapy group (p<0.05). The five-year OS rate was 75.2% vs 47.8% (p=0.0149) in the surgical resection and SBRT groups, respectively. The five-year disease-free survival rate was 33.8% vs 16.4% (p=0.0512) in the surgical resection and SBRT groups, respectively. According to the multivariate analysis, surgical resection was a significant favorable factor for OS and disease-free survival.

Parikh (2018) secondary analysis of the Surveillance, Epidemiology, and End Results (SEER)-Medicare linked database to compare SBRT with RFA as primary treatment for early-stage HCC.[48] A total of 408 patients treated with RFA and 32 with SBRT were included. Ninety-day hospitalization and one-year mortality were not significantly different between groups. Overall survival was significantly better in the RFA group (p<0.001). In a multivariate analysis, advanced age, higher stage, decompensated cirrhosis, and treatment with SBRT (HR 1.80; 95%CI: 1.15-2.82) were associated with worse survival, but in the propensity score adjusted analysis, survival and costs were similar between the two groups.

Su (2017) retrospectively compared the efficacy of SBRT and liver resection for small HCC (less than or equal to 5 cm).[49] A total of 117 patients with small HCCs with one or two nodules were included, with 82 receiving SBRT and 35 undergoing liver resection. No significant differences between groups were found in OS or PFS. Prior to propensity score matching, the one-, three-, and five-year OS was 96.3%, 81.8%, and 70.0% in the SBRT treated patients and 93.9%, 83.1%, and 64.4% in the resection patients, respectively (p=0.558). One-, three-, and five-year PFS in the SBRT and resection groups were 100%, 91.8%, and 74.3% and 96.7%, 89.3%, and 69.2%, respectively. Hepatotoxicity was also similar between groups.

In 2016, Wahl reported on single U.S. site experience with 224 patients with nonmetastatic HCC accumulated between 2004 and 2012.[50] Radiofrequency ablation (RFA) was used to treat 161 patients and 249 lesions with a freedom from local progression (FFLP) rate at one year of 83.6% and two years of 80.2%. SBRT was used to treat 63 patients with 83 lesions with a FFLP rate of 97.4% at one year and 83.8% at two years.

In an attempt to extend the use of SBRT to larger lesions, Shin (2010) treated six patients with large tumors (median tumor volume, 1288 mL; range, 1008-1815 mL) with no worse than CTP-A liver disease and without extrahepatic metastases.[51] The 4 × 8–10 Gy regimen was relatively safe with only one case of grade three changes in transaminases. However, one-year OS was only 33%, in part due to advanced disease. One-year LC and OS rates were

50% to 100% and 33% to 100%, respectively. There were 13 cases of radiation-induced liver disease and four, grade five; six, grade four; and 69, grade three adverse events reported.

Comparison with TACE

Comito (2022) performed a single center RCT parallel-group superiority trial comparing SBRT to a second course of TACE for the curative treatment of unresectable early or intermediate stage HCC in patients with residual disease after initial TACE treatment.[52] Forty patients were randomized to SBRT (n=21) or continued TACE (n=19). There were no significant differences in baseline patient and treatment characteristics between the study groups. Local control was better with SBRT with 84% of SBRT cases having local control at one year, vs. 23% of TACE cases. PFS was also superior with SBRT. PFS with SBRT was 37% at one year and 21% at two years, compared to PFS with TACE of 13% at one year and 6% at two years. Distant recurrence-free survival (DRFS) was longer in the TACE arm but the difference was not statistically significant (p=0.494). Median OS in both study arms was 30 months and OS was not significantly different between the two treatment groups (p=0.472).

In 2019, Shen reported results of a comparison between SBRT and TACE.[53] A total of 188 patients with medium-sized HCC (3 to 8 cm) were treated with TACE (n=142) or SBRT (n=46). For surviving patients, the median follow-up was 26.6 months and for all patients it was 17.1 months. The three-year infield control was 63.0% and 73.3% for TACE- and SBRT-treated patients, respectively. The three-year OS was 22.9% and 47.7% for the TACE- and SBRT-treated patients, respectively. Treatment modality, sex, and recurrence status were independent predictors of infield control, which number of tumors, treatment modality, albumin-bilirubin grade, tumor volume, Eastern Cooperative Oncology Group status, and recurrence status were independent predictors of OS. According to the propensity score matching analysis, the SBRT group had superior three-year infield control (p=0.007) and three-year OS (p<0.001) compared with the TACE group.

Sapir (2018) assessed 209 patients that underwent TACE (n=84) or SBRT (n=125) for HCC at a single institution.[54] Baseline differences between the groups included age (SBRT 65 versus TACE 61; p=0.01), tumor size (SBRT 2.3 cm versus TACE 2.9 cm; p<0.01), and frequency of liver transplantation (SBRT 8% versus TACE 18%; p=0.01). However, there were no significant differences in number of tumors treated per patient, underlying liver disease, or baseline liver function. One- and two-year local control were significantly different between treatment groups (SBRT 97 and 91% versus TACE 47 and 23%, respectively). Toxicities grades 3 and higher were reported in 8% of the SBRT group and 13% of the TACE group.

Cai (2018) included 121 patients with primary hepatocellular carcinoma in a retrospective comparison of transarterial chemoembolization (TACE), gamma knife, and a combination of the two.[55] The TACE alone group included 46 patients, the gamma knife alone group 36 patients, and the combination group 39 patients. Statistically significant differences were reported for overall survival rates between the three groups at 6, 12, and 18 months (TACE alone 50%, 34.8%, and 28.3%; gamma-knife alone 36.1%, 30.6%, and 16.7%; TACE and gamma-knife combined 84.6%, 71.8%, 61.5%). However, there was no significant difference between groups in overall survival at 24 months. (p=0.117). Median survival time for the TACE, gamma knife, and combination groups was seven months, three months, and 20 months, respectively, with the differences reported as significant. There were also statistically significant differences reported in leukopenia, but not in thrombocytopenia, anemia, nausea, vomiting, or liver function lesions.

In 2015, Jacob evaluated HCC lesions 3 cm or more and compared TACE alone (n=124) with TACE plus SBRT (n=37) from 2008 to 2013.[56] Sorafenib, the tyrosine kinase inhibitor (TKI), was used by 36.1% of the TACE alone group and 41.9% in the combination therapy group. Both groups had received pre- and posttreatment chemotherapy. Local recurrence was significantly decreased in the TACE plus SBRT group (10.8%) in comparison with the TACE-only group (25.8%) (CI, not reported, p=0.04). After censoring for liver transplantation, OS was found to be significantly increased in the TACE plus SBRT group (33 months) compared with the TACE-only group (20 months) (CI, not reported, p=0.02). Chronic HCV infection was the cause of HCC in most patients in both groups.

In 2016, Su, reported on a single-site experience with 77 HCC lesions greater than 5 cm treated with SBRT followed by TACE and 50 patients who had SBRT alone.[57] The patients who had SBRT alone either refused TACE or had hepatic arteriovenous fistulas precluding TACE. The median follow-up was 20.5 months and median tumor size was 8.5 cm (range, 5.1-21.0 cm). The PFS and local relapse-free survival did not differ significantly between groups.

In 2014, Zhong reported on a single-site experience with 72 of 1086 HCC patients consecutively treated with SBRT between 2006 and 2012.[58] These patients had lesions 10 cm or larger and incomplete ablation with prior TACE. The median total dose of 35.6 Gy was delivered over 12 to 14 days with a fractional dose of 2.6 to 3.0 Gy at 6 fractions per week. A complete response (CR) achieved in 6 (8.3%), partial response (PR) in 51 (70.8%), stable disease (SD) in 9 (12.5%) and progressive disease (PD) in 6 patients (8.3%) within a median follow-up of 18 months.

Bridge to Transplantation

The increasing prevalence of chronic liver conditions progressing to HCC such as HCV infection and alcoholic cirrhosis has led to interest in the use of SBRT and other liver-directed therapies as bridge therapy to transplantation for persons who are on organ waitlists.

Wong (2021) reported outcomes in patients bridged to liver transplantation for HCC. A prospective cohort of SBRT-treated patients was compared with a retrospective cohort of TACE- or HIFU-treated patients.[33] A total of 40 SBRT patients, 59 TACE patients, and 51 HIFU patients were evaluated. The primary endpoint of tumor control rate at one year post-bridging therapy was 92.3%, 43.5%, and 33.3% after SBRT, TACE, and HIFU, respectively (p=0.02). Time-to-progression at one and three years was significantly different between groups (10.8%, 18.5% in SBRT, 45%, 54.9% in TACE, and 47.6%, 62.8% in HIFU; p<0.001). There were no statistically significant differences between groups in perioperative complications and patient and recurrence-free survival rates after transplant.

Sapisochin (2017) performed an intention-to-treat analysis to examine the safety and efficacy of SBRT as a bridge to liver transplantation for HCC.[59] A total of 379 patients were treated with SBRT (n=36), TACE (n=99), or RFA (n=244). The dropout rate was not significantly different between groups (p=0.7). The numbers of patients transplanted per group were 30, 79, and 203 in the SBRT, TACE, and RFA groups, respectively. The one-, three-, and five-year actuarial survival from time of listing was not significantly different between groups and the values reported ranged from 83-86%, 72-75%, and 56-61%, respectively. The one-, three-, and five-year survival from the time of transplant was also not significantly different between groups (83%, 75% and 75% in the SBRT group, 96%, 75% and 69% in the TACE group, and 95%, 81% and 73% in the RFA group, p=0.7).

Section Summary

The current evidence base is largely heterogenous and includes mostly prospective cohort studies that report outcomes for patients with HCC. Many of the studies were conducted on patients eligible for transplant or who were not eligible for other treatment modalities. Local control and overall survival among the study participants were generally over 70% at one-three-years follow-up. Studies reported a reduction in these outcomes after two-three years follow-up. Multiple studies reported better outcomes when tumors were 6 cm or less. It is important to note that multiple studies reported severe adverse events (≥ grade three) after SBRT for a small number of study participants. The use of SBRT, either alone or in conjunction with other liver-directed therapies, is emerging as a bridge to transplant.

Prostate Cancer

Systematic Reviews

Foerster (2021) published a systematic review of SBRT for high-risk prostate cancer. A total of 21 studies met inclusion criteria.[60] The majority evaluated SBRT of the prostate alone, while three reported on prostate and pelvic node SBRT. Acute and chronic GU toxicity grade ≥2 was 12 to 46.7% and 7 to 60%, respectively, in studies that included pelvic nodal irradiation and 0 to 89% and 2 to 56.7%, respectively in the prostate-only studies. Acute and chronic grade ≥2 GI toxicity was 0% to 4% and 4 to 50.1%, respectively, in studies that included pelvic nodal irradiation, and 0 to 18% and 0 to 40%, respectively, for studies without pelvic nodes irradiation. The range of biochemical control rates was 82 to 100% after two years and 56 to 100% after three years.

A systematic review and meta-analysis by Valle (2021) evaluated local salvage therapies after radiotherapy for prostate cancer.[61] A total of 150 studies met inclusion criteria. The within modality between study heterogeneity was significant and therefore adjustment was required. Adjusted five-year recurrence-free survival was not significantly different between any modality and radical prostatectomy, but severe GU toxicity was significantly higher with radical prostatectomy than with any form of radiotherapeutic salvage. Severe GI toxicity was significantly lower in patients with high-dose-rate brachytherapy salvage than with radical prostatectomy (adjusted rates 1.8 vs. 0.0%, $p<0.01$). No other significant differences were identified between groups for severe GI toxicity.

Achard (2020) performed a systematic review of SBRT vs. elective nodal radiotherapy for nodal oligorecurrent prostate cancer.[62] A total of 22 articles were included, four of which were prospective phase II trials. PFS rates were better in the elective nodal radiotherapy-treated patients (52 to 80%) than in those treated with SBRT (16 to 58%). The toxicity rate was slightly lower in the SBRT group.

Jackson (2019) performed a systematic review and meta-analysis on SBRT for localized prostate cancer. [63] Thirty-eight prospective studies between 1990 and 2018 were retrieved featuring low- (45%), intermediate- (47%), and high-risk (8%) patients (n=6116). Most common dose received was 7.25 Gy/fraction (range 5 to 10) in a median of 5 fractions (range 4 to 9). Five-and seven-year biochemical relapse-free survival (bRFS) rates were 95.3% (95% CI 91.3 to 97.5; I^2 87.96; Q value 74.9, $p<0.001$)) and 93.7% (95% CI 91.4 to 95.5), respectively. Late grade 3 or higher genitourinary (GU) or gastrointestinal (GI) toxicity rates were 2.0% (95% CI, 1.4 to 2.8) and 1.1 (95% CI, 0.6 to 2.0), respectively. In 33 studies that reported on the use of androgen-deprivation therapy (ADT), 15% of patients received ADT alongside SBRT. The

impact of ADT on pooled outcomes is unknown. Furthermore, studies did not stratify bRFS rates by patient risk level, contributing to high heterogeneity in the results.

Kishan (2019) pooled long-term outcomes from 10 single-center and two multi-center prospective trials evaluating SBRT for the treatment of low-to-intermediate risk prostate cancer (n=2142).[64] Doses of SBRT ranged from 33.5 to 40.0 Gy in 4 to 5 fractions. Overall, 115 patients (5.4%) received concurrent ADT. Mean overall follow-up duration was 6.9 years (interquartile range [IQR], 4.9 to 8.1). For patients with low, intermediate-favorable, and intermediate-unfavorable, and any intermediate risk level, biochemical recurrence rates were 4.5% (95% CI 3.2 to 5.8), 8.6% (95% CI 6.2 to 11.0), 14.9% (95% CI 9.5 to 20.2), and 10.2% (95% CI 8.0 to 12.5), respectively. Corresponding overall survival rates were 91.4% (95% CI, 89.4 to 93.0), 93.7% (95% CI, 91.0 to 95.6), 86.5% (95% CI, 80.6 to 90.7), and 91.7% (95% CI, 89.2 to 93.6), respectively. There were 13 (0.6%) and 2 (0.09%) reported cases of acute grade 3 or higher genitourinary (GU) or gastrointestinal (GI) toxicities. The incidence of late grade 3 or higher GU and GI toxicities was 2.4% (95% CI, 1.8 to 3.2) and 0.4% (95% CI, 0.2 to 0.8), respectively. The analysis was limited by heterogeneity in toxicity reporting and scoring criteria and lack of comparative studies.

Loi (2019) published a systematic review assessing sexual function in prostate cancer patients who had been treated with SBRT.[65] A total of 12 studies representing 1221 patients who had not received androgen-deprivation therapy (ADT) and were available at final follow-up were analyzed. Studies used varying definitions for erectile dysfunction (ED); some were based on the Sexual Health Inventory for Men (SHIM) scale whereas others were based on the Expanded Prostate Cancer Index Composite (EPIC)-26. At 60 months, ED was reported by 26 to 55% of previously sexually functioning patients in 5 of 12 studies.

Linney and Barrett (2018) performed a systematic review of the literature on the use of SBRT for early-stage prostate cancer. Sixteen articles met inclusion criteria. The range of reported biochemical progression-free survival rates was 77.1 to 100% for SBRT and 55 to 98% for conventionally fractionated EBRT. Rates of grades 1, 2, and 3 acute genitourinary toxicity were reported as 13.3 to 71%, 12 to 25% and 0 to 3% for SBRT and 28.7 to 51.9%, 15.6 to 41.4%. and 1.1 to 8.1% for EBRT, respectively. Authors noted a lack of randomized trials and long-term follow-up.

Randomized Controlled Trials

Poon (2021) reported results of a randomized trial comparing SBRT (36.25 Gy delivered in five fractions over two weeks) and conventionally fractionated radiotherapy (76 Gy delivered in 38 fractions over 7.5 weeks) for the treatment of low- and intermediate-risk localized prostate cancer.[66] A total of 64 men were randomized to receive SBRT (n=31) or conventional fractionation (n=33). Median follow-up was 2.3 years. There were no significant differences between groups in the primary endpoint, variation in patient-reported quality of life (PRQOL) at one year assessed by changes in the Expanded Prostate Cancer Index Composite (EPIC) questionnaire scores, at 3, 6, 9 and 12 months. There were statistically significant differences between groups in grade ≥ 1 acute and one-year late gastrointestinal toxicities, with 35% vs. 87% acute toxicities for conventional fractionation versus SBRT, respectively ($p<0.0001$), and 64% vs. 84% toxicities at one year for conventional fractionation versus SBRT, respectively ($p=0.03$).

Brand (2019) reported acute toxicity findings from a randomized trial comparing SBRT with conventionally fractionated and moderately hypofractionated radiotherapy (PACE-B study).[67]

A total of 874 men with WHO performance status 0-2, low-risk or intermediate-risk prostate adenocarcinoma (Gleason 4 + 3 excluded) were enrolled in this international, phase 3, open-label, randomized, non-inferiority trial. Patients were randomly assigned to receive conventionally fractionated or moderately hypofractionated radiotherapy (n=4,41; 78 Gy in 39 fractions over seven to eight weeks or 62 Gy in 20 fractions over four weeks, respectively), or stereotactic body radiotherapy (n-433; 36.25 Gy in five fractions over one to two weeks). The primary endpoint of the trial was freedom from biochemical or clinical failure, and the coprimary outcomes for this acute toxicity substudy were worst grade 2 or more severe Radiation Therapy Oncology Group (RTOG) gastrointestinal or genitourinary toxic effects score up to 12 weeks after radiotherapy. No statistically significant differences in toxicity were reported. Grade 2 or more severe toxic gastrointestinal events were reported in 12 and 10% of patients in the conventionally fractionated or moderately hypofractionated group and stereotactic body radiotherapy groups, respectively (p=0.38). Grade 2 or worse genitourinary toxicity were reported in 27 and 23% of the conventionally fractionated or moderately hypofractionated group and stereotactic body radiotherapy groups, respectively (p=0.16).

Tree (2022) published a follow-up toxicity analysis of the PACE-B study after two years.[68] Outcomes of interest were the cumulative incidence of grade 2 or worse genitourinary or gastrointestinal toxicity, grade 2 or worse erectile dysfunction, and other symptoms, including hot flashes, other pain, fatigue, anorexia, weight loss, and radiation dermatitis. Data was available for 796 of 844 patients (91%) at 24 months. Nine patients died between radiotherapy treatment and the 24-month follow-up; and no deaths were treatment-related. Cumulative grade 2 or worse genitourinary (GU) toxicity rates were higher in the SBRT group, using both radiation therapy oncology group (RTOG) grades (p=0.0015) and Common Terminology Criteria for Adverse Events (CTCAE) grades (p=0.0001). The most frequent GU toxicity was urinary frequency, but grade 3 urinary frequency was rare; less than 1% in both groups. Cumulative gastrointestinal toxicity at grade 2 or worse nearly the same in both treatment groups using both RTOG and CTCAE measures (p=0.92; p=0.91), and incidence of gastrointestinal toxicity was low overall. Erectile dysfunction and other symptoms were not significantly different.

Nonrandomized Comparative Studies

Gogineni (2021) compared low-dose-rate (LDR) brachytherapy and SBRT for the treatment of low- and intermediate-risk prostate cancer.[69] Sequential low- and intermediate-risk prostate cancer patients treated definitively with SBRT (n=118) and low-dose-rate brachytherapy (n=219). Five-year biochemical control was 91.6% and 97.6% for low-dose-brachytherapy and SBRT, respectively (p=0.108). The difference between groups in pre- to post-treatment increase in American Urologic Association (AUA) scores was statistically significant, with the LDR and SBRT groups reporting 17.2 and 10.3, respectively at one month (p<0.001) and 14.0 and 9.7, respectively, at three months (p<0.001). The LDR and SBRT groups reported 0.8% and 2.5% late grade 3 GU toxicity (p=0.238) and 0.0% and 2.5% late grade 3 GI toxicity (p=0.018).

Patel (2020) reported a comparison of SBRT and EBRT using data from the National Cancer database on men > 40 years old with localized prostate cancer treated with radiation therapy and concomitant ADT with curative intent.[70] Median follow-up was 74 months. Regardless of risk group, there was no difference in estimated six-year OS between radiation therapy modality. The multivariate analysis did not identify any difference in risk of death following

SBRT versus EBRT (unfavorable intermediate: adjusted HR 1.09, 95% CI 0.68 to 1.74, p=0.72; high risk: adjusted HR 0.93, 95% CI 0.76 to 1.14, p=0.51).

In 2014, Yu compared toxicities after treatment with either SBRT (n=1335) or IMRT (n=2670) as primary treatment for prostate cancer, using claims data for Medicare beneficiaries.[71] The authors identified early stage prostate cancer patients aged 66 to 94 years treated from January 2008 to June 2011 who received either IMRT (n=53,841) or SBRT (n=1335) as primary treatment. SBRT patients were matched in a 2:1 manner based on potential confounders. SBRT was associated with higher rates of genitourinary (GU) toxicity. By six months after treatment initiation, 15.6% of SBRT patients had a claim indicative of treatment-related GU toxicity versus 12.6% of IMRT patients (odd ratio [OR]=1.29; 95% CI 1.05 to 1.53; p=0.009). By 12 months posttreatment, 27.1% of SBRT versus 23.2% of IMRT patients had a claim indicative of GU toxicity (OR=1.23; 95% CI 1.03 to 1.43; p=0.01), and by 24 months after treatment initiation, 43.9% of SBRT versus 36.3% of IMRT patients had a claim indicative of GU toxicity (OR=1.38;95% CI 1.12 to 1.63; p=0.001). At six months posttreatment, there was increased gastrointestinal (GI) toxicity for patients treated with SBRT, with 5.8% of SBRT patients having had a claim indicative of GI toxicity versus 4.1% of IMRT patients (OR=1.42; 95% CI, 1.00 to 1.85; p=0.02), but at 12 and 24 months posttreatment, there were no significant differences in GI toxicity between groups.

Katz (2012) compared quality of life (QOL) after either radical prostatectomy (n=123) or SBRT (n=216) in patients with early-stage prostate cancer.[72] QOL was assessed using the Expanded Prostate Cancer Index Composite (EPIC), addressing urinary, sexual and bowel function. The EPIC data from the SBRT group was compared with the surgery group at baseline, three weeks, 5, 11, 24 and 36 months (SBRT group) and baseline, 1, 6, 12, 24, and 36 months (surgery group). The largest differences in QOL occurred one to six months after treatment, with larger declines in urinary and sexual QOL occurring in the surgery group, but a larger decline in bowel QOL after SBRT. The long-term urinary and sexual QOL declines remained clinically significantly lower for the patients who underwent prostatectomy but not for the SBRT patients.

Noncomparative Studies

Multiple cohort studies have report outcomes for patients treated with a standard dose of SRS or SBRT, or for groups of patients treated with SRS or SBRT at escalating doses. [73-96] Other noncomparative studies have reported on reirradiation using SBRT for recurrence[97] and on specific outcomes after SBRT for prostate cancer, including rates of patient-reported urinary incontinence,[98] rectal tolerance,[99] and health-related QOL outcomes.[100]

Section Summary

Data on the use of SBRT in prostate cancer consists primarily of single-arm assessments of acute and late toxicity and early PSA outcome data retrospectively compared with historical controls and a few looking at recurrence-free survival with a follow-up of three years or longer. Studies have shown promising initial results on the use of SBRT in prostate cancer with seemingly low toxicity rates and relatively high rates of biochemical recurrence-free survival.

Pancreatic Cancer

This section will focus on systematic reviews, comparative studies and larger case series.

Systematic Reviews

Liu (2021) reported a meta-analysis of survival outcomes following SBRT for locally advanced and borderline resectable pancreatic cancer.[101] A total of 19 studies met inclusion criteria. Overall study quality was rated as good using the Newcastle-Ottawa scale. For patients with locally advanced pancreatic cancer, the pooled median OS rates were 57% at one year, 19% at two years, and 10% at three years. The median PFS was 10 months. Pooled PFS rates at one, two, and three years were 36%, 12%, and 4%, respectively. Pooled incidence rates of acute gastrointestinal (GI), acute hematologic and late GI toxicity (grade≥3) were 2%, 4% and 8%, respectively. For patients with borderline resectable pancreatic cancer, pooled one- and two-year OS rates were 75% and 29%, respectively, while pooled one- and two-year PFS rates were 48% and 18%, respectively. The median PFS was 12.2 months and incidence rates of toxicity (grade ≥ 3) were 0%.

Zaorsky (2019) reported a systematic review of SBRT with varying doses for nonmetastatic pancreatic cancer.[102] A total of 15 studies met inclusion criteria and included 508 patients. Median follow-up was nine months. Local control rates were 60% to 83%. Acute and late grade 3+ toxicity were 3.5% and 5%, respectively. There were no significant differences in local control at one year or acute toxicity between biologically equivalent doses (calculated with an α/β of 10) <70 Gy versus ≥70 Gy.

Buwenge (2018) published a systematic review that evaluated the impact of SBRT on pain reduction.[103] Fourteen studies were identified, seven prospective and seven retrospective. Of these, 12 reported the percentage of pain relief in 190 patients. In these studies, global overall response rate to pain in patients with pain at presentation (complete and partial) was 84.9%, and heterogeneity was high. Acute and late toxicity (grade ≥3) rates were 3.3% to 18.0% and 6.0% to 8.2%, respectively. A 2022 update included 19 studies and continued to report high heterogeneity.[104] The pooled rate of complete response, reported in three studies, was 51.9% (95% CI 39.3 to 64.3%), and the rate of partial plus complete pain response, reported in nine studies, ranged between 44.4 and 100% (median: 78.6%).

A 2017 systematic review from Petrelli evaluated the safety and efficacy of SBRT for the treatment of pancreatic cancer. Nineteen studies, with a total of 1009 patients, including nonrandomized and single-center series with mixed populations, were analyzed.[105] No publication bias was identified, but the heterogeneity among studies was substantial. A meta-analysis calculated the OS rate at one year and the median OS to be 51.6% and 17 months, respectively. The rate of acute severe toxicity ranged from 0% to 36%. The authors concluded that no evidence supports the claim that SBRT results in better outcomes than conventional RT, but there are benefits of SBRT, including shorter treatment time.

Groot (2016) published a systematic review comparing outcomes from re-resection, chemoradiotherapy, and SBRT in patients with isolated local recurrence (ILR) after initial curative-intent resection of primary pancreatic cancer.[106] A total of 18 studies reporting on 313 patients was included for analysis, which included four retrospective case series (n=60) on SBRT. Morbidity and mortality were reported for re-resection (29% and 1%), chemoradiotherapy (54% and 0%), and SBRT (3% and 1%). Morbidity for re-resection was defined as the sum of surgical complications and non-surgical 30-daycomplications. For chemoradiotherapy and SBRT, it was defined as toxicities of grade 3 or higher as defined by the Common Terminology Criteria for Adverse Events v4.0 guidelines. Mortality was defined as death within 30 days post-intervention. Median survival post-treatment was 32 months (range, 16 to 32), 19 months (range, 16 to 19), and 16 months (range, 9 to 16) for re-resection, chemoradiotherapy, and SBRT, respectively. The disease-free interval for the re-resection

group tended to be longer than for chemoradiotherapy or SBRT, a finding that is known to correlate with improved outcomes for patients with ILR. Acute and late toxicity rates were reported for chemoradiotherapy (52% and 2%) and SBRT (3% and 2%), respectively. The analysis was limited by heterogeneity in treatments, including inconsistent use of combination systemic therapies.

Comparative Studies

Ma (2022) conducted a RCT focused on adjuvant therapy for stage II pancreatic adenocarcinoma.[107] After surgical resection 38 patients were randomized to receive SBRT followed by gemcitabine chemotherapy, or gemcitabine therapy alone. Most patients in both groups (34/38) experienced tumor recurrence prior to the last follow-up. Median OS was 28 months in the gemcitabine-only arm and 15 months in the SBRT arm. The HR for death was 0.56 (95% CI 0.23-1.36, p=0.20). There were no significant differences in adverse events between the two groups.

Arcelli (2020) reported a multicenter case-control study comparing SBRT plus chemotherapy and conventionally fractionated chemoradiation for locally advanced pancreatic cancer.[108] A total of 80 patients were matched according to age (over versus equal to or younger than 65 years), tumor diameter (two cut-offs: </≥3.0 and </≥3.9 cm), clinical tumor stage and clinical nodal stage, neoadjuvant CHT, and adjuvant CHT. There were no statistically significant differences in acute or late toxicity, DMFS, PFS, or OS between the two cohorts. Median one-year and two-year LC was 53.1% and 40.5% in the chemoradiation cohort and 80.4% and 49.8% in the SBRT cohort, respectively. There was no significant difference in OS between groups (p=0.031).

Wu (2019) reported the effects of SBRT and conventionally fractionated radiation therapy, both with concurrent chemotherapy, on total lymphocyte counts in patients with pancreatic adenocarcinoma.[109] Included patients were treated with conventionally fractionated radiation therapy with concurrent Nelfinavir (n=28), SBRT with concurrent Nelfinavir (n=27), or SBRT with concurrent chemotherapy (n=45). The conventionally fractionated group had significantly lower median lowest total lymphocyte counts (p<0.0001) and median total lymphocyte count over time (p<0.0001). There was no significant difference in median OS between SBRT and conventional fractionation.

Park (2017) published a retrospective review of patients treated with SBRT (n=44) or IMRT (n-226) for unresectable stage I-III pancreatic adenocarcinoma.[110] Baseline characteristics were analyzed and only age was found to be significantly different between groups. There were no significant differences in OS, local or distant failure, or subsequent resection. Acute grade 2+ gastrointestinal toxicity, grade 2+ fatigue, and grade 3+ hematologic toxicity were significantly different between groups, with IMRT associated with higher levels (p=0.008, p<0.0001, p=0.001, respectively).

In 2017, Zhong published a retrospective database analysis comparing conventional fractionated radiotherapy (CFRT) with SBRT for locally advanced primary pancreatic carcinoma.[111] Using a large hospital-based registry, the National Cancer Data Base (NCDB), clinical outcomes were described in 10,534 cases (CFRT in 7819, SBRT in 631) diagnosed and treated between 2004 and 2012. To minimize the treatment selection bias, a propensity score matching method was used. A logistic regression model predicting CFRT treatment vs SBRT treatment was used to calculate propensity scores for covariates of interest. The covariates chosen were ones found to be significant in the multivariate analysis or ones

thought to be clinically significant and included the following: patient age, AJCC clinical T and N staging, chemotherapy use, Charlson-Deyo comorbidity score, year of diagnosis, and receipt of definitive surgery. In the multivariate analysis, treatment with SBRT was associated with significantly improved OS with a hazard ratio of 0.84 (95% CI, 0.75 to 0.93; p<.001). With matched propensity score analysis, a total of 988 patients were analyzed, with 494 patients in each cohort. The median follow-up time was 26 months. After propensity matching as described above, SBRT usage continued to be associated with significantly improved OS with a median survival of 13.9 months vs 11.6 months (p<0.001). Kaplan-Meier curves for the propensity-matched groups demonstrate a significantly better OS curve for the SBRT cohort (p=0.001) with two-year OS rates of 21.7% and 16.5% for the SBRT and CFRT groups, respectively (p=0.001).

Section Summary

Combined chemoradiotherapy plays a significant role in the treatment of locally advanced pancreatic cancer. The role of SBRT as a radiation technique for pancreatic tumors has not been established, and it is not clear which patients would most likely benefit. However, studies have shown promising LC rates, and outcomes are comparable to other forms of EBRT but with shorter treatment time.

Renal Cell Carcinoma

Stereotactic radiotherapy (SRT) is being considered in the setting of oligoprogression to delay the need to change systemic therapy. Cheung (2021) conducted a prospective multicenter study to evaluate the use of SRT in oligoprogressive mRCC patients to determine the local control (LC), progression-free survival (PFS), cumulative incidence of changing systemic therapy, and overall survival (OS) after SRT to oligoprogressive metastatic renal cell carcinoma (mRCC) lesions in patients who are on tyrosine kinase inhibitor (TKI) therapy.[112] Patients with mRCC who had previous stability or response after ≥3 months of TKI therapy were eligible if they developed progression of five of fewer metastases. Thirty-seven patients with 57 oligoprogressive tumors were enrolled. Oligoprogressive tumors were treated with SRT, and the same TKI therapy was continued afterward. Competing risk analyses and the Kaplan-Meir methodology were used to report the outcomes of interest. The median duration of TKI therapy prior to study entry was 18.6 months; one year of LC of the irradiated tumors was 93% (95% confidence interval [CI] 71-98%). The median PFS after SRT was 9.3 mo (95% CI 7.5-15.7 months). The cumulative incidence of changing systemic therapy was 47% (95% CI 32-68%) at 1 yr, with a median time to change in systemic therapy of 12.6 months (95% CI 9.6-17.4 months). One-year OS was 92% (95% CI 82-100%). There were no grade 3-5 SRT-related toxicities. LC of irradiated oligoprogressive mRCC tumors was high, and the need to change systemic therapy was delayed for a median of >1 year. The use of stereotactic radiotherapy in metastatic kidney cancer patients, who develop growth of a few tumors while on oral targeted therapy, can significantly delay the need to change to the next line of drug therapy.

Correa (2019) published a PRISMA-based systematic review and meta-analysis of SBRT for primary RCC.[113] The primary outcome was LC (defined as tumor-size reduction and/or absence of local progression). The secondary outcomes were toxicity and renal function. A total of 26 studies met inclusion criteria. Of the 372 patients included, 78.5% had confirmed RCC histology upon pre-treatment biopsy and 80% had localized disease (stage I-II) while 20% had stage III to IV disease. The random-effect estimate of local control, based on 25

studies, was 97.2% (95% CI 93.9 to 99.5%). For toxicity (grade 3 to 4) and renal function (post-SBRT change in estimated glomerular filtration rate), random effect estimates, based on 23 and 8 studies, respectively, were, 1.5% (95% CI 0.0 to 4.3%), and -7.7 ml/min (95% CI -12.5 to -2.8). Heterogeneity was minimal (I^2 0 to 20%).

Siva (2018) retrospectively evaluated 223 patients who received single- or multi-fraction SBRT for primary RCC.[114] Average maximum tumor dimension was 43.6 mm (SD 27.7 mm) Grade 1 and 2 toxicity were reported in 35.6% of patients and grade 3 and 4 toxicities were reported in 1.3%. The rates of LC at two and four years were 97.8% and 97.8%, respectively. Cancer-specific survival, and progression-free survival were 95.7%, and 77.4%, respectively, at two years and 91.9%, and 65.4%, respectively, at four years.

A 2017 systematic review by Prins assessed options for the treatment of T1 renal cell carcinoma (RCC) for patients where surgery is not the treatment of choice.[115] Treatment options assessed included active surveillance, radiofrequency ablation, cryoablation, microwave ablation, and SBRT. PRISMA criteria were used to assess the literature and a total of 73 articles with methodological quality between 2b and 4 met inclusion criteria. No RCTs were identified. The authors concluded that all of the assessed treatment modalities were options for patients unfit to undergo invasive treatment, but that due to the quality of available studies was low.

In 2016, Yamamoto reported on 14 patients (11 males, 3 females) who received SBRT for RCC at a single site between April 2010 and February 2014.[116] The dose constraints for planning organ at risk volume of 10-fraction SBRT were 30 Gy for patients who retained both kidneys and 26 Gy in patients with single kidneys. Significant renal atrophic change was observed at a median observation interval of 16.9 months (range, 12.0 to 21.8 months). No patient experienced worsening of hypertension or required hemodialysis.

Ranck (2013) reported outcomes for 18 patients with RCC with limited metastases who were treated with SBRT.[117] For patients with five or fewer metastatic lesions, all lesions were treated; in patients with greater than five lesions, rapidly-growing lesions or those close to vital organs were treated. In all, 39 metastatic lesions were treated, with a median of two lesions per patient. The two-year lesion-control rate was reported as 91.4% in the 12 patients who underwent treatment for all metastases, over a median follow-up of 21.3 months. However, in these patients, two-year freedom from new metastases was 35.7%. OS was 85% at two years. No patients who underwent treatment at all lesion sites died.

Section Summary

The literature on the use of SBRT for RCC consists of very small case series, which generally report high rates of LC. However, little evidence about the impact on patient outcomes can be derived from these data, nor any comparison made between this treatment modality and more established treatment modalities for RCC.

Paraganglioma

Glomus jugulare tumors (GJTs) are benign paragangliomas of the jugular foramen. Traditional management of these tumors involves surgical resection; however, considering the proximity of these tumors to important neurovasculature, stereotactic radiosurgery (SRS) may be an appropriate noninvasive treatment to consider. Campbell (2023) published a systematic review and meta-analysis focused on tumor control and treatment complications from surgery vs.

stereotactic radiosurgery (SRS) for jugular paraganglioma.[118] Data from 107 studies involving 3498 patients (2215 surgical patients and 1283 patients who were treated with SBRT). All studies were retrospective. The quality of the evidence was deemed “good” for 85 studies using the Newcastle-Ottawa Scale. The SRS group was older than the surgery group. The SRS group had larger tumor volume and were more likely to have had prior surgery. The SRS group was also more likely to present with dysphagia, tongue weakness, and headache, while the surgery group was more likely to have tinnitus and deafness. Recurrence rates were low for both groups but were lower for SRS (7% long-term recurrence vs. 15% with surgery). Surgery was associated with more complications, specifically cranial nerve (CN) VII, IX, X, XI, and XII palsies, cerebral spinal fluid leaks and postoperative dysphagia. A major limitation of the study was the authors were unable to analyze the available data for statistical significance. However, the study shows that both treatments are effective in the treatment of jugular paraganglioma.

Ong (2022) published a systematic review and meta-analysis to evaluate SRS as a treatment option for GJTs.[119] An online search using PubMed, Web of Science, Scopus, and Cochrane databases was performed in March 2019 for articles on radiosurgery treatment of GJTs. The screening process followed Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. The final analysis comprised 23 studies including 460 patients. Average rates of tinnitus, hearing loss, and lower cranial nerve deficit as presenting symptoms were 56% (95% confidence interval [CI], 46%-66%), 56% (95% CI, 44%-68%), and 42% (95% CI, 31%-54%), respectively. Overall clinical status improvement rate after treatment was 47% (95% CI, 37%-57%). Rates of tinnitus, hearing loss, and lower cranial nerve improvement after treatment were 54% (95% CI, 44%-63%), 28% (95% CI, 19%-40%), and 22% (95% CI, 11%-39%), respectively. The mean follow-up time across studies was 47 months (range, 4-268 months). The aggregate tumor control rate at the time of follow-up was 95% (95% CI, 93%-97%). The tumor control rate of 95% and 47% symptomatic improvement suggest that SRS may be a suitable treatment modality for these hypervascular skull base tumors.

Primary Spinal Tumors

Conti (2022) published a systematic review and meta-analysis of radiosurgery for benign spinal hemangiomas.[120] Three series of cases involving 24 patients were assessed. The review found that the complete response rate from radiosurgery was 45.7% and the overall response rate was 94.1%. The review found that radiosurgery was effective for spinal hemangioma but did not include studies that compare radiosurgery to other treatments for spinal hemangioma.

Oligometastases

In order to understand the impact of SBRT on metastatic cancer outcomes well-designed randomized controlled trials (RCTs) are preferred. However, these are often difficult to perform given the populations involved. Therefore, this evidence section includes meta-analyses of nonrandomized studies and larger nonrandomized studies in addition to RCTs.

Systematic Reviews

Bone metastasis is a frequent cause of cancer-related pain and external beam radiation therapy can be an effective palliative treatment. The role of SBRT is being investigated as a way to improve pain and local control for people with metastasis to the bones. Ito (2022) published a systematic review and meta-analysis of RCTs comparing SBRT to conventional

radiotherapy (cEBRT) for painful bone metastases.[121] Seven studies involving 964 patents were assessed. Two studies were phase III and five were phase II trials. Four studies were of spinal metastasis, one was of bone metastases, and three studies involved both spine and bone metastases. In the studies 522 patients were treated with SBRT and 442 were treated with conventional radiotherapy. Overall pain response rates at three months were 45% in the SBRT arm and 36% in the cEBRT group, which was not significant (RR=1.19; 95% CI 0.93-1.53; p=0.14). A focused analysis of studies involving spine metastases also was not statistically significant with response rates of 40% in the SBRT arm and 35% in the cEBRT arm (RR=0.14; 95% CI 0.71-1.84; p=0.44). No significant differences were seen in adverse events, quality of life, or survival. The authors state that the results of the meta-analysis may be inconsistent with retrospective research in particular that favors SBRT because SBRT tends to be offered to patients in better condition than those who are treated with cEBRT.

Viani (2021) reported a systematic review evaluating the efficacy of SBRT for the treatment of breast cancer metastases.[122] The ten studies that met inclusion criteria included 467 patients. Local control rates were 97% (95% CI 95 to 99%) and 90% (95% CI 84 to 94%) and OS was 93% (95% CI 89 to 96%) and 81% (95% CI 72 to 88%) at one and two years, respectively. The rate of any grade 2 was 4.1 % (95% CI 0.1 to 5%) and any grade 3 toxicity was 0.7% (0 to 1%), respectively.

Deodato (2021) reported a systematic review of outcomes following SBRT for nodal metastases.[123] A total of 29 studies including 969 patients met inclusion criteria. There was statistically significant heterogeneity in patient and treatment characteristics. Pooled two-year LC was 79.3% (95% CI 72.8% to 85.7%) based on 11 reporting studies and pooled two-year PFS was 35.9% (95% CI 22.1% to 49.7%) based on eight reporting studies. Grade ≥ 3 and grade 5 toxicity rates were 2.0% and 0.2%, respectively.

Yan (2020) performed a systematic review of SBRT for oligometastatic prostate cancer involving 10 studies (six observational cohorts; one phase I single arm prospective trial; one phase II single arm prospective trial; two phase II RCTs) with 653 patients and 1,111 lesions.[124] Results revealed an overall local control rate of 97% (95% CI 94 to 100), median ADT-free survival of 24.7 months (95% CI 20.1 to 29.2 months), two-year biochemical free survival of 33% (95% CI 11 to 55), two-year PFS of 39% (95% CI 24 to 54), and two-year ADT-free survival of 52% (95% CI 41 to 62). Patients treated with SBRT were half as likely to experience PSA progression than those on observation when evaluating RCT data alone.

Yegya-Raman (2020) assessed the efficacy and safety of SBRT for oligometastatic gynecologic malignancies. A total of 16 unique studies with 667 patients met inclusion criteria.[125] Metastases were located in the abdomen (44.2%), pelvis (18.8%), thorax (15.5%), neck (4.6%), central nervous system (4.3%), bone (1.6%), and other/unspecified (11%). Response rate ranged from 49 to 97%, with seven of the eight studies reporting over 75% response rate. Local control ranged from 71% to 100% and median PFS ranged from 3.3 to 21.7 months. No grade ≥ 3 toxicities were observed in 9/16 (56%) studies.

Tsao (2019) completed a systematic review of SBRT for extracranial oligometastatic NSCLC involving four prospective phase II randomized trials (n=188), four prospective nonrandomized studies (n=140), and 11 retrospective studies (n=1,288). Results revealed a median OS ranging from 13.5 to 55 months and a PFS ranging from 4.4 to 14.7 months.[126] The authors noted that results from mature phase III RCTs are needed to fully determine the benefits and risks of SBRT for oligometastatic NSCLC.

In 2019, the Canadian Agency for Drugs and Technology in Health (CADTH) published a rapid response report addressing the clinical effectiveness and cost-effectiveness of SBRT for oligometastatic cancer.[127] Four publications met inclusion criteria, including three retrospective cohort studies and one economic evaluation. None of the included studies of clinical effectiveness found a significant difference in overall survival or progression-free survival following SBRT compared with other treatments. One study reported that local control of adrenal metastases was superior following real-time tumor-tracking radiotherapy compared to SBRT. The report concluded that the evidence was of limited quality and may not improve overall survival rates compared to other cancer treatments.

Zaorsky (2019) conducted a systematic review and meta-analysis of SBRT for oligometastatic renal cell carcinoma.[128] A total of 28 studies with 1602 unique patients were included. For extracranial disease, the summary effect size for one-year local control and the one-year survival rates were 89.1% (95% CI 83.6 to 93.7%, I^2=71%) and 86.8% (95% CI 62 to 99.8%, I^2=95%), respectively, and for intracranial disease were 90.1% (95% CI 83.5 to 95.3%, I^2=74%) and 49.7% (95% CI 41.1 to 58.3%, I^2=74%), respectively. For extracranial and intracranial disease, incidence of grade 3 to 4 toxicity was 0.7% (95% CI 0 to 2.1%, I^2=0%) and 1.1% (95% CI 0 to 7.4%, I^2=53%), respectively.

Spencer (2019) reported a systematic review of outcomes following SBRT for bone metastases.[129] A total of 57 studies met inclusion criteria. No meta-analysis was conducted due to clinical and methodological diversity and risk of bias present in the included studies. The majority of studies addressed spinal metastases, while eight included other sites of disease. A wide range of median OS was reported in the included studies, from 8 to 34 months. The authors concluded that this suggested a high risk of selection bias in the included observational studies. The measurement and definitions of pain response varied across studies, and only 10.5% of studies used the international consensus endpoint definitions of pain response. For the studies that addressed tumors in a location other than the spine, the total treated population pain response rates were 60 to 88% and local control rates were 70 to 96%.

Vilela (2018) performed a systematic review of the safely and effectiveness of SBRT for oligometastatic recurrent prostate cancer.[130] Fourteen studies met inclusion criteria and included 661 patients. A total of 899 lesions were treated, 561 nodal, 336 bone, 2 liver. Androgen deprivation therapy-free survival and median progression free survival were between one and three years. Using the GRADE system, the quality of evidence was assessed as low. Among the studies with a low risk of bias, local control varied between 82 to 100%. Acute and late grade 2 toxicity were reported in 2.4% and 1.1% of patients, respectively. One case of acute and two cases of late grade 3 toxicity were reported.

In 2020, Viani published a systematic review on the same topic as the above Vilela systematic review, SBRT for oligometastatic recurrent prostate cancer.[131] The 2020 systematic review included six studies not included in the Vilela publication. Two were identified during the Vilela search and excluded and five were published after the Vilela search dates. Overall, Viani identified 23 observational studies that met the inclusion criteria. According to the meta-analysis, the proportional rates of local control and progression-free survival were 0.976 (95% CI 0.96 to 0.98) and 0.413 (95% CI 0.378 to 0.477), respectively. The androgen deprivation-free survival was 20.1 months. There was a linear relationship between biologically effective dose and local control (p=0.017). Acute and late grade 2 or higher toxicity were reported in 1.3 and 1.2%, respectively.

In a 2018 systematic review, Petrelli analyzed the efficacy of SBRT to treat colorectal cancer liver oligometastases.[132] Eighteen studies met inclusion criteria. A total of 656 patients were included in the random-effect model pooled-analysis. Pooled one- and two-year survival were 67.18% (95% CI 42.1 to 92.2) and 56.5% (95% CI 36.7 to 76.2), respectively. Median PFS was 11.5 months and median OS was 31.5 months. The pooled one-year and two-year LC were 67% (95% CI 43.8 to 90.2) and 59.3% (95% CI 37.2 to 81.5), respectively. Reported mild to moderate and severe liver toxicity were 30.7% and 8.7%.

Kobiela (2018) published a systematic review of local control in colorectal cancer liver and lung oligometastases following treatment with SBRT.[133] A total of 15 studies met inclusion criteria. One-year LC ranged from 50% to 100% for liver metastases and 62% to 92% for lung metastases. Two-year LC ranged from 32% to 91% for liver metastases and 53% to 92% for lung metastases.

Comparative Studies

Ryu (2023) performed an RCT comparing SRS to cEBRT for localized vertebral metastases of the spine.[134] The study involved 339 adult patients with treatment naïve vertebral metastases and a baseline pain score of at least 5/10. The primary end point was pain response at three months. Patients were randomized to receive SRS or cEBRT. Complete response was defined as pain score of 0, no increase in narcotic pain medication, and no progressive pain at the other treated spine. Partial response was an improvement of at least three points from baseline pain score and no increase in narcotic medication. There was not a significant difference in pain response at three months (p=0.99). At 12 months, 46.6% of the patients were alive and pain response differences were still not significant (p=0.49). There were no significant differences in adverse events at three months (p=0.99) or at one year (p=0.38).

Ito (2022) published a single-center, single-arm, phase 2 study aimed to prospectively evaluate the outcomes of separation surgery and SBRT for metastatic epidural spinal cord compression (MESCC).[135] Patients with symptomatic MESCC due to a solid carcinoma were enrolled. The protocol for treatments comprised preoperative embolization, separation surgery, and spine SBRT. Surgical procedures were performed via the posterior approach, with decompression and a fixation procedure. The prescribed dose for spine SBRT was 24 Gy in 2 fractions. The primary endpoint was the 12-month local failure rate. The secondary endpoints were ambulatory functions and adverse effects. A total of 33 patients were registered between November 2017 and October 2019. All patients met the inclusion criteria, and all but one completed the protocol treatment. Of the included patients, 23 (70%) had radioresistant lesions. The Bilsky grade at registration was 1c in 3 patients, 2 in 8 patients, and 3 in 21 patients. The median follow-up duration after registration was 15 months (range, 3-35 months). Three months after the administration of treatments according to the protocol, 90% of patients (26 of 29) had disease of Bilsky grade $\leq$1. The 12-month local failure rate was 13%. Twenty patients could walk normally or with a cane 12 months after registration. Radiation-induced myelopathy, radiculopathy, and vertebral compression fracture were observed in 0, 1, and 6 patients, respectively. Separation surgery with SBRT for MESCC was effective in decompression and long-term local control.

McBride reported a randomized, phase II trial assessing nivolumab with vs. without SBRT.[136] A total of 62 patients with metastatic or recurrent head and neck squamous cell carcinoma were randomly assigned to receive nivolumab (n=30) or nivolumab plus SBRT (n=32). No statistically significant differences between groups were identified for ORR (34.5% [95% CI,

19.9% to 52.7%] v 29.0% [95% CI, 16.1% to 46.6%]; p=0.86), overall survival (p=0.75), progression-free survival (p=0.79), response duration (p= .26), or grade 3 to 5 toxicities (13.3% v 9.7%; p=0.70).

Phillips (2020) conducted the phase 2, randomized Observation vs Stereotactic Ablative Radiation for Oligometastatic Prostate Cancer (ORIOLE) study, which enrolled 54 men with recurrent hormone-sensitive prostate cancer and one to three metastases detectable by conventional imaging who had not received ADT within six months of enrollment or three or more years total.[137] These men were randomly assigned to stereotactic ablative radiotherapy or observation in a 2:1 ratio; 36 to treatment and 18 to observation. Results revealed that progression at six months was observed significantly more frequently in patients in the observation group versus active treatment (61% versus 19%; p=0.005). Stereotactic ablative radiotherapy was also associated with significant improvement in median PFS (not reached versus 5.8 months; HR, 0.30; 95% CI 0.11 to 0.81; p=0.002). No adverse effects of grade 3 or greater were reported.

Palma (2019) compared SBRT versus standard of care palliative treatment in patients with oligometastatic cancers in the randomized, phase 2, open-label Stereotactic Ablative Radiotherapy for the Comprehensive Treatment of Oligometastases (SABR-COMET) trial.[138] This multicenter study enrolled 99 adults with a controlled primary tumor and one to five metastatic lesions. After stratification by the number of metastases, patients were randomly assigned in a 1:2 ratio to either palliative standard of care or standard of care plus SBRT to all metastatic lesions. Results revealed a median OS of 28 months (95% CI, 19 to 33) in the control group versus 41 months (95% CI, 26 to not reached) in the SBRT group (HR, 0.57; 95% CI 0.30 to 1.10; p=0.09). Grade 2 or worse adverse events occurred more frequently in the SBRT group (29% versus 9%; p=0.026) and treatment-related deaths were reported in 3 patients in the SBRT group versus 0 in the control group. In a subsequent publication of long-term results of the SABR-COMET trial, the five-year OS rate was 17.7% in the standard of care arm versus 42.3% in the SBRT arm (p=0.006).[139] The five-year PFS was not reached in the standard of care group but was 17.3% in the SBRT group (p=0.001). No new grade 2 to 5 adverse events were reported and there were no differences in QOL between the groups.

Harrow (2022) published a follow-up study of outcomes beyond five years from the SABR-COMET trial.[140] OS after eight years was 27.2% in the SABR arm and 13.6% in the control arm (p=0.008). Patients in the SABR arm experienced more grade $\geq$2 toxic effects (30.3% vs. 9.1%; (p=0.019; however there were no new grade 3 to 5 toxic effects. Differences in quality of life and overall use of systemic therapy were not significant, but people in the SABR arm were less likely to be treated with chemotherapy (33.3% vs. 54.6%, p=0.043).

A number of studies were published in 2018 that evaluated the safety and efficacy of SBRT of oligometastases. Most addressed lung[141-145] or liver[146-148] metastases, although some addressed both[149] and others addressed adrenal[150, 151], bone[152-154], and other sites[155, 156]. The largest and those that are prospective or comparative are discussed below.

A 2018 retrospective study published by Franzese compared SBRT with microwave ablation.[157] Data from 135 patients with liver metastases were extracted and analyzed. Median follow-up time was 24.5 months (2.4 to 95.8). The one-year freedom from local progression was significantly longer in the SBRT group than the microwave ablation group (SBRT group 91%; 95% CI 81 to 95; versus the microwave ablation group 84%; 95% CI 0.72

to 0.91). The likelihood of local relapse was lower in the SBRT-treated group (adjusted hazard ratio 0.31; 95% CI 0.13 to 0.70, p=0.005).

Lung Oligometastases

Virbel (2021) performed a systematic review of the evidence regarding the use of SBRT for the treatment of oligometastatic lung disease.[158] The search dates were limited to January 1, 2015 to December 31, 2020. A total of 18 studies met inclusion criteria. No meta-analysis was completed. Oligometastatic disease was defined differently between articles, with eight studies defining it as one to five, one article as one to four, three articles as one to three, and six articles with no definition. The median number of treated metastases was between one and two in the included studies. Of the four included studies that evaluated the relationship between tumor size and LC, three reported that size impacted LC, with larger size associated with worse outcomes, and one reported no relationship. Overall, the authors concluded that SBRT is safe and effective in patients with oligometastases limited to one to three organs.

Choi (2020) published a systematic review and meta-analysis of tumor control and OS following SBRT for pulmonary oligometastases from colorectal cancer.[159] Fourteen studies including a total of 495 colorectal cancer patients with pulmonary oligometastases met inclusion criteria. The pooled estimate LC rate at one, two, three, four, and five years after SBRT was 81.0%, 71.5%, 56.0%, and 61.8%. The OS rate was 86.9%, 70.1%, 57.9%, and 43.0%, respectively, at the same time points. Two studies reported rates of grade 3 or higher pulmonary toxicity, and those rates were 2.2% and 10.8%.

Londero (2020) compared surgery versus SBRT for the treatment of pulmonary metastases in a systematic review of 79 studies (61 on surgical treatment and 18 on SBRT).[160] Results revealed no difference in short-term survival when comparing pulmonary metastasectomy and SBRT; however, survival rates were improved in the long-term among patients who underwent surgery. Mortality and morbidity after treatment were 0 to 4.7% and 0 to 23% for surgery and 0 to 2% and 4% to 31% for SBRT. The authors concluded that surgical metastasectomy remains the treatment of choice for pulmonary oligometastases.

A systematic review by Siva (2010) on the use of SBRT for pulmonary oligometastases estimated from the largest studies included in the review a two-year weighted OS rate of 54.5%,[161] ranging from higher rates in a study by Norisha (2008) of 84%[162] to lower rates, such as 39%, reported from a multi-institutional trial.[163]

Liver Oligometastases

The liver is the most common site of metastatic spread of colorectal cancer (CRC). Data show that surgical resection of limited liver metastases can result in long-term survival in select patients. However, only 10% to 20% of patients with metastatic CRC to the liver are surgical candidates. In patients who are not considered to be candidates for surgery, a variety of locally ablative techniques have been developed, the most common of which are RFA and transarterial chemoembolization. Retrospective analyses of RFA for liver metastases from CRC have shown wide variability in five-year OS rates, ranging from 14% to 55%.[164]

Retrospective series on the use of SBRT have reported LC rates ranging from 57% to 100% (median follow-up ranged 10 months – 4.3 years), as reported in a review by Alongi.[164] Prospective studies have reported one-year OS rates ranging from 61% to 85% and two-year OS rates ranging from 30% to 62%.[164] Another systematic review by Tree concluded similar

findings evaluating similar studies.[165] In addition, the review concluded that the rate of adverse events was low with less than 5% of patients experiencing severe toxicity (grade three or more).

In one of the larger series, Méndez Romero (2021) reported outcomes of 515 patients based on a web-based registry.[166] A total of 668 liver metastases were registered, with 80.3% coming from colorectal cancer, 8.9% from lung cancer, and 4% from breast cancer. Actuarial one-year local control and OS were 87% and 84%, respectively. The rate of grade 3 or higher toxicity was 3.9%.

McPartlin (2017) assessed 60 patients, of whom 82% received previous chemotherapy, 23% previously underwent focal liver treatment, and 38% had extrahepatic disease at the time of SBRT.[167] Only one acute toxicity greater than grade 2 was reported. Median overall survival was 16.0 months and local control rate per lesion at one and four years was 49.8% and 26.2%, respectively.

Chang (2011) studied outcomes of SBRT for colorectal liver metastases in a pooled patient cohort from three institutions with colorectal liver metastases.[168] Patients were included if they had one to four lesions, received one to six fractions of SBRT, and had radiologic imaging three months or more posttreatment. Sixty-five patients with 102 lesions treated from 2003 to 2009 were retrospectively analyzed. Forty-seven (72%) patients had one or more chemotherapy regimens before stereotactic body radiotherapy, and 27 (42%) patients had two or more regimens. The median follow-up was 1.2 years (range, 0.3-5.2 years). The median dose was 42 Gy (range, 22-60 Gy). One- and two-year LC rates were 67% and 55%, respectively. One- and two-year OS rates were 72% and 38%, respectively.

In 2012, Lanciano reported on the single-center experience with SBRT to treat patients with metastases from multiple primary sites.[169] The patients were heavily pretreated with 87% having had prior systemic chemotherapy for treatment of liver metastases or liver tumor and 37% having had prior liver-directed therapy. These therapies included surgical resection, chemoembolization, RFA, photodynamic therapy, or previous external-beam radiation. There were four patients who had more than one prior liver-directed treatment. In 2014, Yuan reported on the single-site experience of a cohort of patients with liver metastases from multiple primary sites; 56% of whom had received prior systemic therapy.[32] Patients were considered to have a favorable prognosis with primary tumors originating from the colon, breast, or stomach, as well as sarcomas. In this group, the median overall survival was not reached and the one-year and two-year overall survival rates were 89.6% and 72.2%, respectively.

These studies have had relatively short follow-up times, typically less than two years. They are also limited by relatively small numbers of patients in the studies and differences in the systemic therapies administered, which may affect treatment outcomes.

Adrenal Gland Oligometastases

The most frequent primary tumor that metastasizes to the adrenal glands is NSCLC. Longer OS times have been reported with resection of clinically isolated adrenal metastases when compared with nonsurgical therapy, which has included locally ablative techniques, embolization and EBRT. A recent multicenter analysis reported one- and two-year OS of 72.3% and 53.5% one- and two-year LC of 85.4% and 79.2% following treatment of adrenal metastases of lung primary tumor with SBRT.[170]

Bone Oligometastases

Pielkenrood (2022) reported results of a randomized controlled trial comparing conventional radiotherapy versus SBRT (the VERTICAL trial).[171] A total of 110 patients with painful bone metastases were randomized 1:1 to receive conventional radiotherapy or SBRT. Intention-to-treat (ITT) and per-protocol (PP) linear mixed model analysis adjusting for baseline scores were used to assess changes in quality of life (QoL) over time. According to both analyses, QL scores improved over time comparably between groups with the exception of functional interference and psychological aspects in the ITT. At 12 weeks, the improvement in functional interference was significantly greater in the conventional radiotherapy group than that in the SBRT group (25.5 vs 14.1 points, respectively; p=0.04). At eight weeks, the improvement in psychosocial aspects scores was significantly greater in the conventional radiotherapy group than that in the SBRT group (12.2 vs 7.3; p=0.04).

Mazzola (2022) reported outcomes of a multiinstitutional study of SBRT for the treatment of bone oligometastatic prostate cancer.[172] Patients undergoing androgen deprivation therapy were excluded. A total of 40 patients were included, of whom 70% had a single oligometastatic lesion, 22.5% had two lesions, 5% had three lesions, and 2.5% had four lesions. SBRT was delivered in three to five fractions for a total of 24 to 40 Gy (median 30 Gy). The median follow-up was 22 months. One- and two-year rates of local control (LC) rates were 96.3% and 93.9%, and distant progression-free survival (DPFS) rates were 45.3% and 27%. A second SBRT course was proposed with concurrent ADT in seven patients and ADT alone was delivered in 11 patients due to polymetastatic spread. One- and two-year ADT-free survival rates were 67.5% and 61.8%.

Ito (2021) published a multicenter prospective noncomparative study on palliative SBRT for painful non-spine bone metastases.[173] A total of 38 patients with 41 osseous lesions from primarily lung (22%), prostate (15%), uterine (15%), and renal (12%) cancers. Median follow-up after registration was eight months. The three- and six-month pain responses for evaluable lesions was 78% and 75%, respectively. The six-month LC was 92%. Post-radiation bone fracture occurred in 17% of patients and grade 2 limb edema in 7%.

Sahgal (2021) published an RCT of SBRT versus conventional EBRT for painful spinal metastases.[174] Eligibility criteria were age 18 years and older, painful (defined as ≥2 points with the Brief Pain Inventory) MRI-confirmed spinal metastasis, no more than three consecutive vertebral segments to be included in the treatment volume, Eastern Cooperative Oncology Group performance status of 0 to 2, a Spinal Instability Neoplasia Score of less than 12, and no neurologically symptomatic spinal cord or cauda equina compression. A total of 229 patients were randomized to receive conventional EBRT (n=115) or SBRT (n=114). An intention-to-treat analysis was performed including all patients. Median follow-up was 6.7 months. Complete response for pain was achieved at three months in 35% of the SBRT group and 14% of the EBRT group (p=0.0002; multivariable adjusted analysis: OR=3.47, 95% CI 1.77 to 6.80, p=0.0003). Grade 3 pain occurred in five [4%] of 115 patients in the conventional EBRT group and five (5%) of 110 patients in the SBRT group. No treatment-related deaths were reported.

Napieralska (2014) reported a series 48 cases of prostate cancer bone metastases (in 32 patients) treated with SBRT primarily for pain control.[175] The size of the treated lesions ranged from 0.7 to 5.5 cm (mean, three dimension), and 31 (65%) of the treated metastases were located in the spine. At three-month follow-up, 17 patients had complete pain relief, two had

partial pain relief, and two had no pain reduction. At the end of the follow-up period, complete pain relief was observed in 28 patients and partial pain relief in 16 patients.

Section Summary

The evidence for the use of SBRT to treat oligometastases primarily consists of relatively small, noncomparative studies that confirm clinically important rates of local control. However, the evidence consistently reports a high rate of tumor control for isolated or few metastases (≤ 3 or ≤ 5). The local tumor control is good and reported at one-year to be in the range of 70% to 100%. The overall survival varied widely after two-years (21% to 84%) among the studies. Although some adverse events were reported, the overall rates for adverse events were low.

Other Indications

SBRT has been investigated for the treatment of additional conditions, including cardiac arrhythmias[176] and ventricular tachycardia[177]. The evidence for these other indications is limited in volume and in quality.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Network (NCCN) provides guidelines for cancer treatment by site that include the use of SRS and SBRT for certain cancers.[178]

Cancer Site	Tumor Type	Recommendation	Version
Bone	Osteosarcoma	For primary treatment of resectable pulmonary, visceral, or skeletal metastases. In general, SRS/SBRT should be considered as clinically indicated to deliver high radiation dose and maximize normal tissue sparing.	**3.2023**
Bone	Ewing sarcoma	Consider use of SRS/SBRT, especially for oligometastases.	**3.2023**
Bone	Chondroma/ chondrosarcoma	Consider specialized techniques, which include SRS for resectable and unresectable chondromas and chondrosarcomas.	**3.2023**
CNS	Recurrent spinal ependymoma	Consider stereotactic radiosurgery (SRS) if geometrically favorable.	**1.2023**
CNS	Primary spinal cord tumors	In some instances focal SRS/SBRT to spinal tumors like hemangioblastoma may be appropriate, with care to respect normal tissue constraints of spinal cord and surrounding structures Meningioma: Stereotactic or image-guided therapy is recommended when using tight margins or when close to critical structures.	**1.2023**
CNS	Metastatic spine tumors	Stereotactic radiation approaches (SRS/stereotactic body radiotherapy [SBRT]) for spinal cases may be preferred for patients with life expectancy ≥3 months where tumor ablation is a goal of treatment, in tumors considered radioresistant (eg, renal cell, melanoma, sarcoma, hepatocellular, some colorectal and NSCLC cases), and in select patients for optimal pain relief. Stereotactic radiation approaches may also be preferred in the setting of tumor recurrence after	**1.2023**

		prior radiation as a strategy to limit radiation dose to the spinal cord or other critical structures.	
CNS	Leptomeningeal metastases	SRS or RT to bulky disease and neurologically symptomatic or painful sites.	**1.2023**
Colorectal	Metastatic to liver or lung	Colon and Rectal: In patients with a limited number of liver or lung metastases, radiotherapy to the metastatic sites can be considered in highly selected cases or in the setting of a clinical trial. Radiotherapy should not be used in the place of surgical resection. Radiotherapy should be delivered in a highly conformal manner. The techniques can include 3-D conformal radiation therapy, IMRT, or SBRT.	**2.2023** **3.3023**
Head and Neck	Palliative radiation for advanced cancer, or reirradiation	**Palliative radiation** using CD-CRT, IMRT, and SBRT should be considered in the advanced cancer setting when curative intent is not appropriate. **Reirradiation** with 3D-CRT, SBRT, PBT, or IMRT If the area in consideration overlaps with the previously radiated volume, the prior radiotherapy should have been more than 6 months from the appearance of new disease. In certain rare circumstances, reirradiation with intraoperative RT (IORT) or brachytherapy may be considered in high-volume centers with expertise in these techniques. Before reirradiation, the patient should have a reasonable ECOG performance status of 0–1. Patients who are more than 2 years from prior radiation, who have surgery to remove gross disease prior to reirradiation, and who are free of organ dysfunction (eg, laryngectomy, feeding tube) have better outcomes. The incidence of myelopathy is thought to increase after a cumulative biologically effective dose (BED) of 120 Gy, 53 but this risk is increased if large fraction sizes (≥2.5 Gy/fraction) are used. Radiation volumes should include known disease only to minimize the volume of tissue receiving very high doses in regions of overlap. Prophylactic treatment of subclinical disease (eg, elective nodal irradiation) is therefore not routinely indicated. When using SBRT techniques for reirradiation, careful selection of patients is advised. The best outcomes are seen in patients with smaller tumors and no skin involvement. Caution should be exercised in cases of circumferential carotid artery involvement.	**2.2023**
Hepatobiliary Cancer	Hepatocellular carcinoma	• All unresectable tumors irrespective of the location may be amenable to RT (3D conformal RT, intensity-modulated RT [IMRT], or stereotactic body RT [SBRT]). Image-guided RT is strongly recommended when using RT, IMRT, and SBRT to improve treatment accuracy and reduce treatment related toxicity. • There is growing evidence for the usefulness of SBRT in the management of HCC.SBRT can be considered as an alternative to ablation/	**1.2023**

		embolization techniques or when these therapies have failed or are contraindicated. • SBRT (typically 3–5 fractions) is often used for patients with 1 to 3 tumors.	
Hepatobiliary Cancer	Biliary Tract Cancers	Image-guided RT (IGRT) is strongly recommended when using RT, intensity-modulated RT (IMRT), and stereotactic body RT (SBRT) to improve treatment accuracy and reduce treatment-related toxicity. All unresectable tumors irrespective of the location may be amenable to RT (3D-CRT, IMRT, or SBRT).	**2.2023**
Kidney	Non-clear cell and clear cell renal cell carcinoma	• Metastasectomy or SBRT or ablative techniques for oligometastatic disease (category 2A). • SBRT may be considered for medically inoperable patients with Stage I (category 2B) or Stage II/III kidney cancer (category 3)	**1.2024**
Lung	Non-small-cell lung cancer; Initial treatment	Medically inoperable Stage I -Stage IIB: Definitive radiation therapy, preferably SABR	**3.2023**
Lung	Non-small-cell lung cancer – Stage IV; Treatment of thoracic disease T1-3, N0	Surgical resection or SABR	**3.2023**
Lung	NSCLC: Resectable recurrence	Reresection (preferred) and/or external-beam RT or SABR.	**3.2023**
Lung	Small cell lung cancer (SCLC)	SABR/SBRT is effective for patients with clinical limited stage I to IIA (T1-2, N0) SCLC, especially if medically inoperable or patient refuses surgery. Principles of SABR for SCLC are similar to those for NSCLC.	**3.2023**
Lung	Progression on biomarker directed therapy	Asymptomatic or symptomatic with limited progression (3-5 sites, excluding brain): Consider definitive local therapy (e.g., SABR or surgery) for limited lesions.	**3.2023**
Pancreas	Pancreatic adenocarcinoma – Locally advanced	• If good or intermediate performance status, in selected patients, locally advanced without systemic metastases, induction chemotherapy followed by chemoradiation or SBRT; or chemoradiation or SBRT in patients who are not candidates for induction chemotherapy. . As second-line therapy following disease progression, SBRT is an option if not previously given and if primary site is the sole site of progression.	**2.2023**
Pancreas	Pancreatic adenocarcinoma - Local recurrence after resection in Pancreatic operative bed	• Clinical trial (preferred) or Systemic therapy +/- chemoradiation or SBRT (if not previously done) or SBRT or Palliative and best supportive care (category 2A)	**2.2023**
Prostate	Prostate cancer	• SBRT has acceptable efficacy and toxicity in the following risk groups: very low and low, favorable intermediate, unfavorable intermediate, and high and very high. • SBRT is acceptable in practices with appropriate technology, physics, and clinical expertise • SBRT for patients with unfavorable intermediate risk or high risk, prophylactic nodal radiation can	**2.2023**

		be considered. Brachytherapy combined with ADT (without EBRT), or SBRT combined with ADT can be considered when delivering longer courses of EBRT would present a medical or social hardship. • SBRT for metastases can be considered for patients with limited metastatic disease to the vertebra or paravertebral region when ablation is the goal, in patients with oligometastatic progression where progression-free survival is the goal, and in symptomatic patients where the lesion occurs in or immediately adjacent to a previously irradiated field	
Skin	Melanoma – metastatic	Ablative treatment for intact extracranial metastases – higher doses utilizing conformal techniques such as stereotactic body radiation therapy (SBRT) may offer more durable local control. SBRT may be considered for selected patients with oligometastasis. (category 2A)	**2.2023**
Soft tissue sarcoma – extremity, superficial trunk, head/neck	Sarcoma – synchronous or recurrent stage IV disease	• If single organ and limited tumor bulk amenable to local therapy, consider SBRT (category 2A) • If disseminated metastases, SBRT is a palliative option (category 2A)	**2.2023**
Thyroid	Papillary, follicular, or Hurthle cell carcinoma – structurally persistent/recurrent locoregional or distant metastatic disease not amenable to radioactive iodine	• Non-radioiodine-avid unresectable locoregional recurrent/persistent disease or non-radioiodine-avid soft tissue metastases (eg lung, liver, muscle) excluding CNS metastases: consider EBRT (SBRT/IMRT) • Soft tissue metastases, excluding CNS: Consider resection of distant metastases and/or EBRT (SBRT/IMRT)/ other local therapies when available to metastatic lesions if progressive and/or symptomatic • Bone metastases: For asymptomatic weight-bearing sites or if symptomatic, consider SBRT • CNS metastases: for solitary lesions, either neurosurgical resection or SRS is preferred (category 2A)	**2.2023**

NCCN Categories

- **Category 1:** Based upon high-level evidence, there is uniform NCCN consensus that the intervention is appropriate.
- **Category 2A:** Based upon lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate.
- **Category 2B:** Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate.
- **Category 3:** Based upon any level of evidence, there is major NCCN disagreement that the intervention is appropriate.

*All recommendations are category 2A unless otherwise noted.

AMERICAN COLLEGE OF CHEST PHYSICIANS

Non-Small-Cell Lung Cancer

- In patients with stage I or II NSCLC with no medical contraindications to operative intervention, surgical resection is recommended (grade 1B-strong recommendation based on moderate evidence)[179]

- In patients with stage I NSCLC who cannot tolerate lobectomy or segmentectomy:[179]
  - SBRT and wedge resection are recommended over no treatment (Grade 2C).
  - SBRT is favored over wedge resection in these cases unless surgical resection may provide the benefit of definitive histologic analysis and nodal information that will result in a change in the patient's management.
  - SBRT is also favored in these patients if adequate surgical margin is unlikely with wedge resection.

- For high-risk stage I NSCLC tumors <5 cm, SBRT is preferred over conventional fractionated RT for definitive treatment when normal dose constraints can be respected.[180]
- For tumors within 2 cm of the proximal bronchial tree, a modified SBRT treatment schedule is suggested to decrease treatment-related toxicity.[180]
- For second primary lung cancer, SRS is an emerging technology, particularly when there is limited pulmonary reserve.[179]

Lung Cancer

- In lung cancer patients with 1-3 brain metastases, stereotactic radiosurgery (SRS) alone is the recommended initial therapy (Grade 1A).[181]

AMERICAN SOCIETY FOR RADIATION ONCOLOGY (ASTRO)

Non-Small-Cell Lung Cancer

For patients with T1-2, N0 non-small cell lung cancer who are medically operable, ASTRO makes the following recommendations related to the use of SBRT:[182]

- "For patients with "standard operative risk" (i.e., with anticipated operative mortality of <1.5%) and stage I NSCLC, SBRT is not recommended as an alternative to surgery outside of a clinical trial."
- "For patients with "high operative risk" (i.e., those who cannot tolerate lobectomy, but are candidates for sublobar resection) stage I NSCLC, discussions about SBRT as a a potential alternative to surgery are encouraged. Patients should be informed that while SBRG may have decreased risks from treatment in the short term, the longer-term outcomes >3 years are not well-established."

Small Cell Lung Cancer

For patients with stage I or II node negative limited stage small cell lung cancer (SCLC) who are medically inoperable, ASTRO recommends either SBRT or conventional fractionation (Strength of recommendation: Strong; Quality of evidence: Moderate).[183]

Pancreatic Cancer

For patients with pancreatic cancer, ASTRO makes the following recommendations related to the use of SBRT:[184]

- Following surgical resection of pancreatic cancer, adjuvant SBRT is only recommended on a clinical trial or multi-institutional registry. (Strength of recommendation: Strong; Quality of evidence: Very Low)
- For patients with borderline resectable pancreatic cancer and select locally advanced pancreatic cancer appropriate for downstaging prior to surgery, a neoadjuvant therapy

regimen of systemic chemotherapy followed by multifraction SBRT is conditionally recommended. (Strength of recommendation: Conditional; Quality of evidence: Low)
- For patients with locally advanced pancreatic cancer not appropriate for downstaging to eventual surgery, a definitive therapy regimen of systemic chemotherapy followed by either (1) conventionally fractionated RT with chemotherapy, (2) dose-escalated chemoradiation, or (3) multifraction SBRT without chemotherapy is conditionally recommended. (Strength of recommendation: Conditional; Quality of evidence: Low)

AMERICAN SOCIETY OF CLINICAL ONCOLOGY

Human Epidermal Growth Factor Receptor 2 (HER2)-Positive Advanced Breast Cancer Brain Metastases

The American Society of Clinical Oncology (ASCO) makes the following recommendations for patients with brain metastases from HER2-positive advanced breast cancer:[185]

- For patients with a favorable prognosis for survival and a single brain metastasis, treatment options include surgery with postoperative radiation, stereotactic radiosurgery (SRS), whole-brain radiotherapy (WBRT; SRS), fractionated stereotactic radiotherapy (FSRT), and SRS (WBRT), depending on metastasis size, resectability, and symptoms. After treatment, serial imaging every 2 to 4 months may be used to monitor for local and distant brain failure.
- For patients with a favorable prognosis for survival and limited (two to four) metastases, treatment options include resection for large symptomatic lesion(s) plus postoperative radiotherapy, SRS for additional smaller lesions, WBRT (SRS), SRS (WBRT), and FSRT for metastases 3 to 4 cm.
- For metastases 3 to 4 cm, treatment options include resection with postoperative adiotherapy. In both cases, available options depend on resectability and symptoms.
- For patients with progressive intracranial metastases despite initial radiation therapy, options include SRS, surgery, WBRT, a trial of systemic therapy, or enrollment onto a clinical trial, depending on initial treatment. For patients in this group who also have diffuse recurrence, best supportive care is an additional option.

Locally Advanced, Unresectable Pancreatic Cancer

ASCO makes the following recommendations for patients with locally advanced, unresectable pancreatic cancer:[186]

- “Initial systemic therapy with combination regimens is recommended for most patients who meet the following criteria: Eastern Cooperative Oncology Group (ECOG) PS 0 or 1, a favorable comorbidity profile, and patient preference and a support system for aggressive medical therapy. There is no clear evidence to support one regimen over another, and physicians may offer therapy on the basis of extrapolation from data derived from studies in the metastatic setting. For some patients, conformal radiation therapy (CRT) or stereotactic body radiotherapy (SBRT) may be offered up front on the basis of patient and physician preference.” (evidence quality intermediate)
- “A short course of palliative radiotherapy (conventional RT or SBRT) may be offered to patients with LAPC who meet the following criteria: prominent local symptoms, such as abdominal pain and/or worsening jaundice and/or gastrointestinal (GI) bleeding; local infiltration into the GI tract causing impending gastric outlet or duodenal obstruction; and patient preference.” (evidence quality intermediate)

Localized Prostate Cancer

In 2018, ASCO produced a guideline in collaboration with ASTRO and the American Urological Association addressing the use of hypofractionated radiation therapy for localized prostate cancer.[187] The guideline defines hypofractionation as EBRT delivered with a fraction size greater than or equal to 500 cGy. The guideline makes the following evidence-based recommendations:

- "In men with low-risk prostate cancer who decline active surveillance and choose active treatment with EBRT, ultrahypofractionation may be offered as an alternative to conventional fractionation." (Conditional recommendation, moderate quality of evidence)
- "In men with intermediate-risk prostate cancer receiving EBRT, ultrahypofractionation may be offered as an alternative to conventional fractionation. The task force strongly encourages that these patients be treated as part of a clinical trial or multi-institutional registry." (Conditional recommendation, low quality of evidence)
- "In men with high-risk prostate cancer receiving EBRT, the task force does not suggest offering ultrahypofractionation outside of a clinical trial or multi-institutional registry due to insufficient comparative evidence." (Conditional recommendation, low quality of evidence)

Salivary Gland Malignancy

In 2021, ASCO published a guideline on the management of salivary gland malignancy. The only reference to SRS or SBRT is a recommendation stating that surgery (metastatectomy) or SBRT may be offered for adenoid cystic carcinoma and/or low-grade tumors with indolent biology with limited metastases (i.e., ≤ 5 metastases).

SUMMARY

Hepatic Tumors

There is enough evidence to show that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) improve health outcomes for patients with hepatic tumors including biliary tract cancer and cholangiocarcinoma. Therefore, the use of SRS and SBRT for the treatment of hepatic tumors (primary or metastatic) may be considered medically necessary when policy criteria are met.

For all other tumors or indications when policy criteria is not met, there is not enough research to show improved health outcomes with stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT). Therefore, all other indications for the use of SRS or SBRT for hepatic tumors are considered investigational.

Hepatocellular and Hepatobiliary Carcinoma

There is enough research to show that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) for hepatocellular carcinoma (HCC) and hepatobiliary cancer improve health outcomes in patients with less than five tumors and less than 6 centimeters in diameter. Therefore, SRS and SBRT for the treatment of HCC may be considered medically necessary when policy criteria are met.

There is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for hepatocellular carcinoma (HCC) or hepatobiliary cancer when the criteria are not met. Therefore, the use of SRS and SBRT for all other indications for HCC is considered investigational.

Lung Metastases

There is enough research to show that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) improve health outcomes for people with lung metastases (e.g., local control and acceptable treatment-related toxicity) in a select group of patients with a limited number of metastases. Therefore, the use of SRS or SBRT for lung metastases may be considered medically necessary when policy criteria are met.

Outside this subgroup, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with lung metastases. Therefore SRS and SBRT of lung metastases are considered investigational when policy criteria are not met.

Oligometastases

There is enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiotherapy (SBRT) may improve health outcomes for patients with oligometastases with a limited number of metastases. Current clinical practice guidelines recommend SRS or SBRT as a treatment option for oligometastatic disease in certain scenarios. Therefore, SRS and SBRT for the treatment of oligometastatic disease may be considered medically necessary when policy criteria are met.

Outside this subgroup when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with oligometastases. Therefore, the use of SRS and SBRT for oligometastases when policy criteria are not met are considered investigational.

Osteosarcoma

There is enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiotherapy (SBRT) may improve health outcomes for patients with osteosarcoma. Current clinical practice guidelines recommend SRS or SBRT as a treatment option for osteosarcoma metastatic disease. Therefore, SRS and SBRT for the treatment of osteosarcoma metastatic disease may be considered medically necessary when policy criteria are met.

For all other indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with osteosarcoma. Therefore, the use of SRS and SBRT for osteosarcoma when policy criteria are not met are considered investigational.

Pancreatic Adenocarcinoma

There is enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiotherapy (SBRT) may improve health outcomes for patients with pancreatic adenocarcinoma that is locally advanced, borderline resectable, inoperable, or locally recurrent after resection. Current clinical practice guidelines recommend SRS or SBRT as a

treatment option for pancreatic adenocarcinoma in these scenarios. Therefore, SRS and SBRT for the treatment of pancreatic adenocarcinoma may be considered medically necessary when policy criteria are met.

For all other indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with pancreatic adenocarcinoma. Therefore, the use of SRS and SBRT for pancreatic adenocarcinoma when policy criteria are not met are considered investigational.

Primary Lung Cancer

Non-comparative studies have consistently shown that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) for patients with lung cancer, node negative, tumor stage T1a, T1b, T2a, or T2b, have survival rates comparable to patients who have undergone surgical resection. In addition, clinical practice guidelines recommend the use of SRS or SBRT for primary lung cancer. Therefore, SRS and SBRT may be considered medically necessary for patients with primary lung cancer, when policy criteria are met.

When policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with primary lung cancer. Therefore, SRS and SBRT for primary lung cancer are considered investigational when policy criteria are not met.

Prostate Cancer

There is enough research to show that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) may improve health outcomes for people with prostate cancer. Clinical guidelines based on research cautiously recommend SRS or SBRT for people with prostate cancer. Therefore, the use of SRS or SBRT for prostate cancer may be considered medically necessary.

For all other indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with prostate cancer. Therefore, SRS and SBRT for prostate cancer are considered investigational when policy criteria are not met.

Renal Cell Carcinoma

There is enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiotherapy (SBRT) may improve health outcomes for patients with inoperable primary renal cell carcinoma. Current clinical practice guidelines recommend SRS or SBRT as a treatment option for renal cell carcinoma in these scenarios. Therefore, SRS and SBRT for the treatment of renal cell carcinoma may be considered medically necessary when policy criteria are met.

For all other indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) improves health outcomes for patients with renal cell carcinoma. Therefore, the use of SRS and SBRT for renal cell carcinoma when policy criteria are not met are considered investigational.

Spinal and Vertebral Body Tumors (Primary or Metastatic)

There is enough research to show that stereotactic radiosurgery (SRS) and stereotactic body radiation therapy (SBRT) lead to improved net health outcomes in patients with spinal or vertebral body tumors and especially in patients that have received prior radiation therapy. In addition, there is expert clinical consensus on the benefits of SBRT in this population. Therefore, SRS and SBRT may be considered medically necessary for the treatment of primary and salvage treatment of local recurrence after previous irradiation when policy criteria are met.

Other Indications

For all other tumors or indications when policy criteria are not met, there is not enough research to show that stereotactic radiosurgery (SRS) or stereotactic body radiation therapy (SBRT) leads to improved health outcomes. Therefore, SRS and SBRT are considered investigational when policy criteria are not met.

CODES

NOTE: Coding for stereotactic radiosurgery typically consists of a series of CPT codes describing the individual steps required; medical radiation physics, clinical treatment planning, attachment of stereotactic head frame, treatment delivery and clinical treatment management.

The correct code to use for image fusion performed to provide enhanced delineation of target and normal critical structures is CPT code 77399 (Unlisted procedure, medical radiation physics, dosimetry and treatment devices, and special services); however, it is considered part of the treatment planning.

Treatment Planning Services:

Treatment delivered with LINAC based MLC may involve planning with the following codes.

Codes	Number	Description
CPT	77301	Intensity modulated radiotherapy plan, including dose volume histograms for target and critical structure partial tolerance specification
	77338	Multi-leaf collimator (MLC) device(s) for intensity modulated radiation therapy (IMRT), design and construction per IMRT plan

NOTE: Treatment delivery:

The codes used for treatment delivery will depend on the energy source used, typically either photons or protons.

Codes	Number	Description
CPT	32701	Thoracic target(s) delineation for stereotactic body radiation therapy (SRS/SBRT), (photon or particle beam), entire course of treatment
	77371	Radiation therapy delivery, stereotactic radiosurgery (SRS), complete course of treatment of cranial lesion(s) consisting of 1 session; multi-source Cobalt 60 based
	77372	Radiation therapy delivery, stereotactic radiosurgery (SRS), complete course of treatment of cranial lesion(s) consisting of 1 session; linear accelerator based
	77373	Stereotactic body radiation therapy, treatment delivery, per fraction to 1 or more lesions, including image guidance, entire course not to exceed 5 fraction
	77435	Stereotactic body radiation therapy, treatment management, per treatment course, to 1 or more lesions, including image guidance, entire course not to exceed 5 fractions

NOTE: Codes for treatment delivery primarily reflects the cost related to the energy source used, and not physician work.

Clinical treatment management:

Codes	Number	Description
CPT	77432	Stereotactic radiation treatment management of cerebral lesion(s) (complete course of treatment consisting of one session.)
	61796	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 simple cranial lesion
	61797	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional cranial lesion, simple (List separately in addition to code for primary procedure)
	61798	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 complex cranial lesion
	61799	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional cranial lesion, complex (List separately in addition to code for primary procedure)
	61800	Application of stereotactic headframe for stereotactic radiosurgery (List separately in addition to code for primary procedure)
	63620	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); 1 spinal lesion
	63621	Stereotactic radiosurgery (particle beam, gamma ray, or linear accelerator); each additional spinal lesion (List separately in addition to code for primary procedure)
		Stereotactic body radiation therapy, treatment delivery, per fraction to 1 or more lesions, including image guidance and real-time positron emissions-based delivery adjustments to 1 or more lesions, entire course not to exceed 5
	G0339	Image guided robotic linear accelerator-based stereotactic radiosurgery, complete course of therapy in one session, or first session of fractionated treatment.
	G0340	Image guided robotic linear accelerator-based stereotactic radiosurgery, delivery including collimator changes and custom plugging, fractionated treatment, all lesions, per session, second through fifth sessions, maximum five sessions per course of treatment

Hypoglossal Nerve Stimulation

Effective: January 1, 2024

Next Review: June 2024
Last Review: August 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

When patients with obstructive sleep apnea cannot tolerate positive airway pressure, or when continuous positive airway pressure (CPAP) treatment has failed, hypoglossal nerve stimulation may be considered.

MEDICAL POLICY CRITERIA

Note: Contract language takes precedent over medical policy. Some member contracts have specific benefit limitations for orthognathic surgery.

I. Hypoglossal nerve stimulation may be considered **medically necessary** in adults with obstructive sleep apnea when all of the criteria below (A.-E.) are met:

A. Has an AHI greater than or equal to 15 and less than or equal to 100 with less than 25% central apneas (see Policy Guidelines); and

B. Has PAP failure (residual AHI greater than or equal to 20 or failure to use CPAP greater than or equal to 4 hr per night for greater than or equal to 5 nights per week) or the patient is not an appropriate PAP candidate (see Policy Guidelines); and

C. Has a body mass index less than 35 kg/m^2; and

D. Has non-concentric retropalatal obstruction on drug-induced sleep endoscopy. Note: Concentric collapse decreases the success of hypoglossal nerve stimulation and is an exclusion criterion from the Food and Drug Administration.

E. One of the following is met:

1. Patient is 22 years of age or older; or
2. Patient is between 18 and 22 years of age and one of the following is met:
    a. Patient has had an adenotonsillectomy; or
    b. An adenotonsillectomy is contraindicated for the patient.

II. Hypoglossal nerve stimulation may be considered **medically necessary** in adolescents or young adults with Down syndrome and obstructive sleep apnea when all of the criteria below (A.-E.) are met:

A. Patient is age 10 to 21 years; and

B. Has an AHI greater than 10 and less than 50 with less than 25% central apneas after prior adenotonsillectomy (see Policy Guidelines); and

C. Have either tracheotomy or be ineffectively treated with PAP due to noncompliance, discomfort, un-desirable side effects, persistent symptoms despite compliance use, or refusal to use the device; and

D. Has a body mass index less than or equal to 95th percentile for age; and

E. Has non-concentric retropalatal obstruction on drug-induced sleep endoscopy. Note: Concentric collapse decreases the success of hypoglossal nerve stimulation and is an exclusion criterion from the Food and Drug Administration.

III. Revisions to an existing hypoglossal nerve stimulator may be considered **medically necessary** after the device has been placed.

IV. The replacement of all or part of an existing hypoglossal nerve stimulator and/or generator is considered **medically necessary** when the existing hypoglossal nerve stimulator and/or generator is malfunctioning, cannot be repaired, or is no longer under warranty.

V. Hypoglossal nerve stimulation is considered **not medically necessary** in adults with obstructive sleep apnea when Criterion I.C. is not met, including PAP refusal.

VI. The replacement of all or part of an existing hypoglossal nerve stimulator and/or generator is considered **not medically necessary** when Criterion IV. is not met.

VII. Hypoglossal nerve stimulation is considered **investigational** for all other indications including but not limited to when policy Criteria I. or II. are not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

There is divergence on scoring rules for hypopneas between the recommendations of the American Academy of Sleep Medicine (AASM) and the Center for Medicare Services (CMS), the latter being more restrictive.[1] Policy Criteria are based on apnea-hypopnea index (AHI)

scored with either the AASM or the CMS scoring rules,[2, 3] either of which are acceptable in this medical policy.

The most recent (2012) AASM rules define apnea in adults as a drop in the peak signal excursion by ≥ 90% of pre-event baseline using an oronasal thermal sensor (diagnostic study), positive airway pressure (PAP) device flow (titration study), or an alternative apnea sensor, for ≥ 10 seconds. Hypopnea in adults is scored when the peak signal excursions drop by ≥ 30% of pre-event baseline using nasal pressure (diagnostic study), PAP device flow (titration study), or an alternative sensor, for ≥ 10 seconds in association with either ≥ 3% arterial oxygen desaturation or an arousal.

The Center for Medicare Services (CMS) scoring rules state that apnea is defined as a cessation of airflow for at least 10 seconds. Hypopnea is defined as an abnormal respiratory event lasting at least 10 seconds with at least a 30% reduction in thorocoabdominal movement or airflow as compared to baseline, and with at least a 4% oxygen desaturation.

POSITIVE AIRWAY PRESSURE (PAP) – Continuous (CPAP), Bi-Level (BiPAP) or auto adjusting (APAP)

PAP failure: defined as AHI greater than 20 events per hour while using PAP.

Not an appropriate PAP candidate: defined as being unable to use PAP therapy for at least 4 hours per night for 5 nights or more per week, with reasonable attempts having been made to address any medical, mechanical, or psychological problems associated with PAP, e.g., adjustment of pressure settings, appropriate medication and humidification, refitting of the mask, trial of alternative pressure delivery systems such as auto-adjusting positive airway pressure or bi-level positive airway pressure.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Current symptomology
- Conservative medical therapies failed
- CPAP trial results
- Documentation that the patient is not an appropriate PAP candidate with clinical rationale, if applicable (See policy guidelines)
- Sleep Study results, including apnea-hypopnea index (AHI) scored either by the American Academy of Sleep Medicine (AASM) scoring rules or the Center for Medicare Services (CMS) scoring rules.
- Drug-induced sleep endoscopy (DISE) results
- If a replacement is being requested, documentation that the stimulator and/or generator is malfunctioning, cannot be repaired, or is no longer under warranty

BACKGROUND

OBSTRUCTIVE SLEEP APNEA (OSA)

Obstructive sleep apnea (OSA) is characterized by repetitive episodes of upper airway obstruction due to the collapse and obstruction of the upper airway during sleep. The hallmark symptom of OSA is excessive daytime sleepiness, and the typical clinical sign of OSA is snoring, which can abruptly cease and be followed by gasping associated with a brief arousal from sleep. The snoring resumes when the patient falls back to sleep, and the cycle of snoring/apnea/arousal may be repeated as frequently as every minute throughout the night.

Sleep fragmentation associated with the repeated arousal during sleep can impair daytime activity. For example, adults with OSA-associated daytime somnolence are thought to be at higher risk for accidents involving motorized vehicles (i.e., cars, trucks, heavy equipment). OSA in children may result in neurocognitive impairment and behavioral problems. In addition, OSA affects the cardiovascular and pulmonary systems. For example, apnea leads to periods of hypoxia, alveolar hypoventilation, hypercapnia, and acidosis. This, in turn, can cause systemic hypertension, cardiac arrhythmias, and cor pulmonale. Systemic hypertension is common in patients with OSA. Severe OSA is associated with decreased survival, presumably related to severe hypoxemia, hypertension, or an increase in automobile accidents related to overwhelming sleepiness.

There are racial and ethnic health disparities seen for OSA impacting the prevalence of disease and accessibility to treatment options, particularly affecting children. Black children are 4 to 6 times more likely to have OSA than white children.[4] Among young adults younger than 26 years, African American individuals are 88% more likely to have OSA compared to white individuals. Another study found that African American individuals 65 years of age and older were 2.1 times more likely to have severe OSA than white individuals of the same age group. These health disparities may affect accessibility of treatment for OSA and impact health outcomes. One analysis of insurance claims data, including over 500,000 patients with a diagnosis of OSA, found that increased age above the 18- to 29- year range ($p<0.001$) and Black race ($p=0.020$) were independently associated with decreased likelihood for receiving surgery for sleep apnea.[5] Lee (2022) found that Black men had a continuous mortality increase specifically related to OSA over the study period (1999 to 2019; annual percentage change 2.7%; 95% confidence interval, 1.2 to 4.2) compared to any other racial group.[6]

A polysomnogram performed in a sleep laboratory and, in adults, home sleep apnea testing with a technically adequate device, are considered the gold standard test used to diagnose OSA.[7] Objective measures of OSA are compiled using polysomnography monitors, which document the number of apneic (cessation or near cessation of airflow) and hypopneic (reductions in airflow associated with certain physiologica consequences) events per hour and combine them into the apnea-hypopnea index (AHI). AHI is a measure of severity of OSA. The American Academy of Sleep Medicine (AASM) provided an updated set of scoring rules in 2012.[2] Based on the 2012 AASM rules, apnea in adults is scored when there is a drop in the peak signal excursion by ≥ 90% of pre-event baseline using an oronasal thermal sensor (diagnostic study), positive airway pressure (PAP) device flow (titration study), or an alternative

apnea sensor, for ≥ 10 seconds. Hypopnea in adults is scored when the peak signal excursions drop by ≥ 30% of pre-event baseline using nasal pressure (diagnostic study), PAP device flow (titration study), or an alternative sensor, for ≥ 10 seconds in association with either ≥ 3% arterial oxygen desaturation or an arousal. The Center for Medicare Services (CMS) also published a set of scoring rules.[3] The CMS scoring rules state that apnea is defined as a cessation of airflow for at least 10 seconds. Hypopnea is defined as an abnormal respiratory event lasting at least 10 seconds with at least a 30% reduction in thorocoabdominal movement or airflow as compared to baseline, and with at least a 4% oxygen desaturation. The respiratory disturbance index (RDI) may be defined as the number of apneas, hypopneas and respiratory effort-related arousals (RERAs) per hour of sleep.

The final diagnosis of OSA rests on a combination of objective and subjective criteria (e.g. AHI or RDI and excessive daytime sleepiness) that seek to identify those levels of obstruction which are clinically significant. When sleep onset and offset are unknown (e.g., in home sleep studies) the AHI or RDI may be calculated based on the number of apneas, hypopneas, and/or RERAs per hour of recording time.

An increase in mortality is associated with an AHI greater than 15. More difficult to evaluate is the clinical significance of patients with mild sleep apnea. Mortality has not been shown to be increased in these patients, and frequently the most significant manifestations reported by the patient are snoring, excessive daytime sleepiness, witnessed breathing interruptions, awakenings due to gasping or choking, nocturia, morning headaches, memory loss, irritability, or hypertension.[8, 9] The hallmark clinical symptom of OSA is excessive snoring, although it is important to note that snoring can occur in the absence of OSA. Isolated snoring in the absence of medical complications, while troubling to the patient's bed partner, is not considered a medical problem requiring surgical intervention.

Table 1. Definitions of Terms for Obstructive Sleep Apnea

Terms	Definition
Apnea	The frequency of apneas and hypopneas is measured from channels assessing oxygen desaturation, respiratory airflow, and respiratory effort. In adults, apnea is defined as a drop in airflow by ≥90% of pre-event baseline for at least 10 seconds. Due to faster respiratory rates in children, pediatric scoring criteria define an apnea as ≥2 missed breaths, regardless of its duration in seconds.
Hypopnea	Hypopnea in adults is scored when the peak airflow drops by at least 30% of pre-event baseline for at least 10 seconds in association with either at least 3% oxygen desaturation or an arousal or at least 4% oxygen desaturation (depending on the scoring criteria). Hypopneas in children are scored by a ≥50% drop in nasal pressure and either a ≥3% decrease in oxygen saturation or an associated arousal.
Apnea/Hypopnea Index (AHI)	The average number of apneas or hypopneas per hour of sleep
Obstructive sleep apnea (OSA)	Repetitive episodes of upper airway obstruction due to the collapse and obstruction of the upper airway during sleep
Mild OSA	In adults: AHI of 5 to <15 In children: AHI ≥1 to <5
Moderate OSA	In adults: AHI of 15 to <30 In children: AHI ≥5 to <10
Severe OSA	Adults: AHI ≥30 Children: AHI of ≥10
Continuous	Positive airway pressure may be continuous (CPAP) or auto-adjusting (APAP)

Terms	Definition
positive airway pressure (CPAP)	or Bi-level (Bi-PAP). CPAP is a more familiar abbreviation and will refer to all types of PAP devices.
CPAP Failure	Usually defined as an AHI greater than 20 events per hour while using CPAP.
CPAP Intolerance	CPAP use for less than 4 h per night for 5 nights or more per week, or refusal to use CPAP. CPAP intolerance may be observed in patients with mild, moderate, or severe OSA

IMPLANTABLE HYPOGLOSSAL NERVE STIMULATORS

Hypoglossal nerve stimulation involves the surgical implantation of a subcutaneous generator in the upper chest and an electrode tunneled from the generator to the hypoglossal nerve. The patient uses a hand-held remote to activate the device just prior to sleep and to turn it off upon waking. Some have sensors detect inspiratory efforts and the hypoglossal nerve is stimulated in a synchronized fashion. This stimulation is intended to maintain muscle tone of the tongue base to prevent airway occlusion.

Stimulation systems such as the Inspire II Upper Airway Stimulation System include respiratory sensing leads that permit intermittent stimulation during inspiration. Stimulation parameters are titrated during an in-laboratory polysomnography and can be adjusted by the patient during home use. The device is turned on only during sleep periods.

REGULATORY STATUS

The Inspire® II Upper Airway Stimulation System (Inspire Medical Systems) received FDA approval in 2014 (P130008) for a subset of patients age 22 years and older with moderate to severe obstructive sleep apnea. Product code: MNQ. The original approval was for patients with an Apnea Hypopnea Index (AHI) of greater or equal to 20 and less than or equal to 65. In 2017, approval was granted to expand the AHI range to 15 to 65 events per hour (S021). In 2020, Inspire received approval to expand the indications to include adolescent patients age 18 to 21 with moderate to severe OSA (15≤ AHI ≤65) who:

- Do not have complete concentric collapse at the soft palate level
- Are contraindicated for, or not effectively treated by, adenotonsillectomy
- Have been confirmed to fail, or cannot tolerate, PAP therapy despite attempts to improve compliance
- Have followed standard of care in considering all other alternative/adjunct therapies

For this approval, existing adult clinical data and interim data from a pediatric feasibility study in patients with Down's syndrome were leveraged to support the reasonable assurance of safety and effectiveness of the proposed device in the pediatric sub-population of adolescents age 18 to 21.

In 2023 the FDA approved an expanded AHI for the Inspire Medical System for patients (18 and older) with an upper limit baseline AHI to 100 (increase from less than or equal to 65 to less than or equal to 100). Also, the FDA approved increasing the body mass index (BMI) warning to 40 kg/m^2 (increase from less than and equal to 32 to less than or equal to 40).[10]

There are hypoglossal nerve stimulation devices which have received an investigational device exemption (IDE) from the FDA. IDE allows the investigational device to be used in a clinical study in order to collect safety and effectiveness data, however, the device is still in the developmental phase and not considered to be in commercial distribution.

- In 2014, ImThera™ Medical received FDA approval for an IDE trial with the aura6000® hypoglossal nerve stimulator system.
- In 2011, Apnex Medical received FDA approval to conduct a randomized investigational device exemption (IDE) trial for the Hypoglossal Nerve Stimulation (HGNS®) System. The trial was terminated and Apnex Medical has ceased operations.
- In June 2020, the FDA approved an Investigational Device Exemption (IDE) trial for the Genio® system from Nyxoah. This is a battery-free, leadless and minimally invasive implanted hypoglossal nerve stimulator.

EVIDENCE SUMMARY

Continuous positive airway pressure (CPAP) is the most widely accepted medical therapy for treatment of obstructive sleep apnea (OSA) and improvement of primary health outcomes such as cardiovascular disease, type 2 diabetes, and overall mortality associated with OSA. Hypoglossal nerve stimulation (HNS), sometimes referred to as upper airway stimulation, is being proposed as a second line treatment for patients who have failed CPAP.

SYSTEMATIC REVIEWS

A systematic review (SR) with meta-analysis comparing outcomes of upper airway stimulation and other upper airway surgical procedures in the treatment of obstructive sleep apnea (OSA) was published by Neruntarat (2021).[11] Five articles (n= 990) were included in the review and analysis. Patients in the "Stim" group underwent hypoglossal nerve stimulation (HNS, n=660) with the Inspire implant, and patients in the surgical intervention "Surg" group (n=330) underwent various surgical interventions including uvulopalatoplasty (UPPP), transoral robotic surgery, expansion sphincter pharyngoplasty, and palatal or tongue base surgery. Studies by Huntley,[12-14] Shah,[15] and Yu[16] were included in the analysis. The follow-up time ranged from 2 to 13 months. The mean cure rates in the Stim group and the Surg group were 63% and 22%, respectively, and the mean success rates were 86% and 51% ($p < 0.001$). The apnea-hypopnea index (AHI) was significantly more reduced in the Stim group, -23.9 events/ hour (MD, 95% CI -25.53, -22.29) compared to the Surg group, -15.5 events/hour (MD, 95% CI -17.50, -13.45), $p < 0.001$. Oxygen saturation nadir improvement was 8.5% (MD 95% CI 7.05%, 9.92%) in the Stim group and 2.2% (MD 95% CI-0.22%, 4.58%) in the Surg group, which is significantly higher in the Stim group ($p < 0.001$). No significant difference in Epworth Sleepiness Scale (ESS) between groups was found. High risk of bias in multiple domains, including selective outcome reporting, incomplete outcome data, blinding, and participant selection was found for all included studies. Noted limitations in available data include retrospective study designs, limited follow-up times, and heterogeneity in patient characteristics.

Costantino (2020) published a SR with meta-analysis of studies evaluating the clinical outcomes of HNS in the treatment of moderate to severe OSA.[17] The SR included 12 prospective studies, excluding redundant cohorts of the same studies with varied follow-up lengths such as the STAR Trial[18-21] and the German Post-Market studies[22, 23] No randomized controlled trials comparing HNS to CPAP or other surgical interventions were identified. Of the 350 patients (median age 54.3 [IQR 53-56.25] years), 239 were implanted with the Inspire® system, 59 were implanted with the ImThera™ system, and 52 were implanted with the Apnex system. All of the studies were considered to be of generally high quality, having satisfied at least six of the eight NICE quality assessment tool items. In all studies, the American Academy of Sleep Medicine (AASM) apnea and hypopnea definitions[2] were used, except that a 4%

oxygen desaturation was required for a hypopnea to determine AHI. Analyses of long-term outcomes were conducted with data from the nine studies which had follow-up timepoints of six- and 12-months separately from the STAR trial data, which reported longer-term follow-up timepoints of 18-, 36-, and 60-months. At 12 months, the mean AHI difference was - 17.50 (Inspire; 95% CI: - 20.01 to - 14.98, p < 0.001), - 24.20 (ImThera™; 95% CI: - 37.39 to 11.01, p < 0.001), and - 20.10 (Apnex; 95% CI: - 29.62 to - 10.58, p < 0.001). The mean AHI reduction after five years was - 18.00 (Inspire®, - 22.38 to - 13.62, p < 0.001). The Epworth sleepiness scale (ESS) mean reduction was - 5.27 (Inspire®), - 2.90 (ImThera™), and - 4.20 (Apnex) at 12 months and - 4.40 (Inspire) at 60 months, respectively. Five-year serious device-related adverse events requiring surgical intervention in the STAR trial were 6% (8/126 patients), and the other studies included in the meta-analysis (n=195) reported a comparable complication rate at six and 12 months. Among the nine studies included in the meta-analysis, the overall success rate at 12 months (defined as a 50% reduction in AHI and overall AHI less than 20), was 72.4% (Inspire®, n=211), 76.9% (ImThera™, n=13), and 55% (Apnex, n=31).

A 2015 SR identified six case series with a total of 200 patients treated with HNS.[24] No controlled trials were identified. Two series were identified on the Inspire II System and included the STAR trial described below. Three series were identified with the HGNS system and included the study of 31 patients described above. One series of 13 patients was identified with the aura6000 System (ImThera Medical). When data were combined for meta-analysis, AHI and Oxygen Desaturation Index (ODI) improved by 50% (eg, AHI from 44 to 20, ODI from 21 to 10), and the ESS improved from 12 to 7. All of the included studies described minor complications such as tongue weakness, tongue soreness, pain/swelling at the neck incision, fever, and lack of tongue response to stimulation. Of the 200 patients, nine (4.5%) had serious device-related adverse events that led to removal of the stimulator.

RANDOMIZED CONTROLLED TRIALS

Schwartz (2023) published results from the ImThera Medical Targeted Hypoglossal Neurostimulation Study #3 (THN3), which investigated the efficacy and safety of targeted HNS of the proximal hypoglosal nerve in patients with moderate-to-severe OSA (AHI 20-60 events per hour).[25] This was a multicenter, randomized, open-label trial where all patients (n=138) were implanted with the HNS system (aura6000; ImThera Medical), and randomly assigned 2:1 to HNS device activation at 1 or 4 months after implant for the treatment and control groups, respectively. Efficacy was measured at month 4, as well as after 11 months of therapy (study months 12 and 15 for treatment and control groups, respectively). The study included mostly males (86.2%) and White individuals (91.3%). The results demonstrated that at month 4, the treatment group had significantly better outcomes compared to the control group for AHI and ODI scores. However, after 11 months of active therapy, the difference between the treatment and control groups was not statistically significant for AHI (relative risk [RR], -7.5; 95% CI, -16.0 to 1.4) but remained significant for ODI (RR, 10.4; 95% CI, 1.6 to 18.8). Limitations include homogeneity of the study population and difference in starting points for treatment between groups.

Heiser (2021) published the results of a multicenter, double-blind, randomized, sham-controlled, crossover trial to examine the effect of implanted hypoglossal nerve stimulation (Stim, n=45) or sham stimulation (Sham, n=44) using the Inspire HNS.[26] Inclusion criteria were moderate-to-severe OSA (AHI ≥ 15), CPAP intolerance, and the absence of complete concentric retropalatal collapse during drug-induced sleep endoscopy. The UAS devices implanted in the participants were programmed to the setting assigned to their respective

groups, i.e., Stim (continued therapeutic stimulation, average amplitude 1.6 V ± 0.7) and Sham (stimulation voltage set at 0.1 V as a subtherapeutic stimulation level and a deception for the patient). All participants received therapeutic stimulation during the first visit (baseline visit), and once randomized, the Stim–Sham group received therapeutic stimulation while the Sham–Stim group received sham stimulation for one week. Crossover occurred during the second week, in which the Stim–Sham group received sham stimulation while the Sham–Stim group received therapeutic stimulation. Primary outcome measures were the proportion of AHI responders (defined as AHI ≤ 15/h) between parallel randomized groups and self-reported sleepiness measure using the ESS questionnaire at the one-week visit. At one week, the AHI response rate was 76.7% with Stim and 29.5% with Sham, a difference of 47.2% (95% CI: 24.4 to 64.9, p < 0.001). The average ESS change from the Stim–Sham group was 0.4 ± 2.3 and from the Sham–Stim group was 5.0 ± 4.6, with a significant difference of 4.6 (95% CI of 3.1 to 6.1, p = 0.001). The change of AHI and ESS from the baseline to the one-week and two-week visits between the Stim–Sham and Sham–Stim groups and found no statistical evidence of a carryover effect for AHI (p = 0.55) or ESS (p = 0.23). The homogenous study population (81% male, 100% Caucasian) limits the generalizability of the study findings. In addition, the authors note that most participants randomized to the sham arm became aware of the group allocation, which may impact study outcomes. Longer-term outcomes are not reported. This study was funded by the device manufacturer (Inspire Medical Systems, Inc) and study authors received fees and/or other funding from the device manufacture and no clear attempt to mitigate potential bias is provided.

NONRANDOMIZED STUDIES

Observational Comparative Studies

Heiser (2023) published a study comparing HNS with positive airway pressure (PAP) treatment in 126 propensity matched patients in a real-world setting.[27] A clinically important symptom improvement was seen at 12 months in both cohorts, though there was a greater difference in the Epworth Sleepiness Scale (ESS) improvement in patients treated with HNS (8.0 ± 5.1 points vs. 3.9 ± 6.8 points; p = 0.042). In both groups, mean posttreatment AHI was significantly reduced (HNS: 8.1 ± 6.3/hour [h]; PAP: 6.6 ± 8.0/h; p < 0.001). Adherence after 12 months among patients treated with HNS was higher than in those receiving PAP therapy (5.0 ± 2.6 h/night; 4.0 ± 2.1 h/night) but not with statistical significance. Several of the study authors received fees and/or other funding from the device manufacture and no clear attempt to mitigate potential bias is provided.

Nonrandomized evidence consists of comparative studies that compared HNS with historical controls treated with UPPP or a variant of UPPP (expansion sphincter pharyngoplasty, see Table 2) and a study that compared HNS with transoral robotic surgery. AHI success by the Sher criteria ranged from 87% to 100% in the HNS group compared with 40% to 64% in the UPPP group (see Table 3). Posttreatment ESS was below 10 in both groups. It is not clear from some studies whether the patients in the historical control group were similar to the subset of patients in the HNS group, particularly in regard to the pattern of palatal collapse and from patients who did not return for postoperative PSG (see Tables 4 and 5).

Several comparative studies have addressed these concerns by only including patients who meet the criteria for HNS in the control group. Yu (2019) compared outcomes for patients who met the criteria for both HNS (non-concentric collapse on drug-induced sleep endoscopy) and transoral robotic surgery (retroglossal obstruction).[16] When patients with similar anatomic

criteria were compared, HNS led to significantly better improvements in AHI, cure rate (defined as AHI < 5), and the percentage of time that oxygen saturation fell below 90%. Huntley (2021) selected patients in the control group who met criteria for HNS (non-concentric collapse on drug-induced sleep endoscopy and body mass index [BMI] criteria) but had been treated at their institutions by single or multi-level palatal and lingual surgery.[12] There was no explanation of why the different treatments were given during the overlap period of 2010 to 2019, but the HNS patients were older and heavier. HNS resulted in a modestly greater decrease in AHI (HNS: -21.4 vs -15.9. p <.001), but not in ESS (HNS: -4.7 vs -5.8, p =.06). More patients in the HNS group achieved success by the Sher criteria (70% vs 48 to 49%) suggesting that there might be a clinical benefit for some patients.

Another report from the ADHERE registry investigators (Mehra 2020) compared outcomes from HNS patients with patients who met criteria but had been denied insurance coverage.[28] In a post-hoc multivariate analysis, previous use of PAP and prior surgical procedures were predictors of insurance approval. In the group of patients who received HNS, the average use downloaded from the device was 5.6 h/night and 92% of patients had usage greater than 20 h/week. Most of the comparator group (86%) were not using any therapy at follow-up. The remaining 14% were using PAP, an oral appliance, or underwent OSA surgery. The AHI decreased to 15 events/h (moderate OSA) on the night of the sleep test in patients with HNS, with only modest improvement in patients who did not receive HNS. The hours of use on the night of the post-operative sleep study was not reported, and the HNS patients may have been more likely to use their device on the test night. In addition, the use of a home sleep test for follow-up may underestimate the AHI. The ESS improved in the HNS group but worsened in the controls. This suggests the possibility of bias in this subjective measure in patients who were denied coverage.

Table 2. Summary of Observational Comparative Study Characteristics

Study	Study Type	Country	Dates	Participants	HNS	Traditional Surgery	Follow-Up
Mehra (2020)[28]	ADHERE registry	US, EU	2017-2019	OSA patients who were intolerant to CPAP and met HNS criteria of AHI 15 to 65, BMI < 35, and favorable pattern of palatal collapse[a]	250 registry patients treated with HNS	100 patients who qualified for HNS but were denied insurance coverage	6 to 24 months
Huntley (2021)[12]	ADHERE registry compared to retrospective controls	US, EU	• HNS 2010-2019 • Modified UPPP 2003-2019	OSA patients who were intolerant to CPAP and met HNS criteria of AHI 15 to 65, BMI < 35, and favorable pattern of palatal collapse[a]	465 registry patients treated with HNS who had 12 mo follow-up	233 patients who would have qualified for HNS and were treated by single level (68%) or multilevel (31%) surgery	173 days after surgery 383 days after HNS
Yu (2019)[16]	Retrospective series with historical controls	US	• HNS 2014-2016 • TORS 2011-NR	OSA patients with AHI >20 and <65, BMI ≤32, failed CPAP, favorable pattern of palatal collapse[a]	27 patients age 62 with retroglossal collapse amenable to TORS	20 patients age 53 y who would have qualified for HNS and were treated by TORS	NR
Shah (2018)[15]	Retrospective series with historical controls	US	HNS 2015-2016 UPPP 2003-2012	40 OSA patients with AHI >20 and <65, BMI ≤32, failed CPAP, favorable pattern of palatal collapse[a]	35% had previously had surgery for OSA	UPPP 50% of patients had additional surgical procedures	2-13 mo
Huntley (2018)[14]	Retrospective series with historical controls	US	HNS2014-2016 Modified UPPP 2011-2016	Retrospective review included treated patients who had a postoperative PSG	75 patients age 61.67 y with a favorable pattern of palatal collapse	33 patients age 43.48 y treated by ESP	To post-operative PSG

BMI: body mass index; CPAP: continuous positive airway pressure; ESP: expansion sphincter pharyngoplasty; HNS: hypoglossal nerve stimulation; OSA: obstructive sleep apnea; PSG: polysomnography; UPPP: uvulopalatopharyngoplasty.

[a] A favorable pattern of palatal collapse is not concentric retropalatal obstruction on drug-induced sleep endoscopy.

[f] Statistical key: 1. Intervention is not appropriate for outcome type: (a) continuous; (b) binary; (c) time to event; 2. Intervention is not appropriate for multiple observations per patient; 3. Confidence intervals and/or p values not reported; 4.Comparative treatment effects not calculated.

Prospective Single Arm Studies

Results of prospective single-arm studies show success rates in 66% to 68% of patients who had moderate-to-severe sleep apnea and a favorable pattern of palatal collapse (see Tables 6 and 7). Mean AHI was 31 to 32 at baseline, decreasing to 14 to 15 at 12 months. ESS scores decreased to 6.5 to 7.0. All improvements were maintained through 5 years of follow-up. Discomfort due to the electrical stimulation and tongue abrasion were initially common but were decreased when stimulation levels were reduced (see Table 8). In the post-market study, a normal ESS score (< 10) was obtained in 73% of patients. A FOSQ score of at least 19 was observed in 59% of patients compared to 13% at baseline. At the 12- month follow-up, 8% of bed partners regularly left the room due to snoring, compared to 75% of bed partners at baseline. The average use was 5.6 + 2.1 h per night. Use was correlated with the subjective outcomes, but not with AHI response. Two- and three-year follow-up of this study were reported by Steffen (2020)[31] but the percentage of patients at follow-up was only 68% at two years and 63% at 3 years, limiting conclusions about the longer-term efficacy of the procedure. A comparison of the populations who had 12-month versus two- or three-year results showed several differences between the patients who followed up and those who dropped out, including higher baseline AHI, higher baseline ODI, and trends towards lower usage per night and a lower responder rate at 12 months.

Table 6. Summary of Prospective Single-Arm Study Characteristics

Study	Country	Participants	Treatment Delivery	Follow-Up
STAR trial[18-21, 29, 30]	EU, US	126 patients with AHI >20 and <50, BMI ≤32 kg/m^2, failed CPAP, favorable pattern of palatal collapse[a]	Stimulation parameters titrated with full PSG	5 y

Down Syndrome

Liu (2022) published a systematic review investigating HNS in adolescents with Down Syndrome and OSA.[34] A total of nine studies were included with a follow up period ranging from two to 58 months; six studies had sample sizes fewer than 10 patients. The largest of the included studies was a prospective cohort study published by Yu (2022), which is summarized below. In an analysis that included 104 patients, AHI scores were significantly reduced in patients after HNS (mean AHI reduction, 17.43 events/h; 95% CI, 13.98 to 20.88 events/h; p<0.001). Similarly, in an analysis that included 88 patients, OSA-18 survey scores were significantly reduced after HNS (mean OSA-18 reduction, 1.67; 95% CI, 1.27 to 2.08; p<0.001).

Yu (2022) reported on the safety and effectiveness of HNS in 42 adolescents with Down Syndrome and severe OSA (AHI of 10 events/h or greater).[35] This was a single-group, multicenter, cohort study with a one-year follow-up that included non-obese (BMI <95%) children and adolescents aged 10 to 21 years who were refractory to adenotonsillectomy and unable to tolerate CPAP. Patients who were included had an AHI between 10 and 50 on baseline PSG; the mean baseline AHI was 23.5 (SD, 9.7). All patients included tolerated HNS without any intraoperative complications. The most common complication was tongue or oral discomfort or pain, which occurred in 5 (11.9%) patients and was temporary, lasting weeks or rarely, months. Four patients (9.5%) had device extrusion resulting in readmissions to replace the extruded device. At 12 months, there was a mean decrease in AHI of 12.9 (SD, 13.2) events per hour (95% CI, -17.0 to -8.7 events/h). At the 12-month PSG, 30 of 41 patients (73.2%) had an AHI of less than 10 events/h, 14/41 patients (34.1%) had an AHI of less than five events/h, and 3/41 patients (7.3%) had an AHI of less than two events/h. There was also a significant improvement in quality-of-life outcomes. The mean improvement in the OSA-18 total score was 34.8 (SD, 20.3; 95% CI, -42.1 to -27.5) and the ESS improved by 5.1 (SD, ,6.9; 95% CI, -7.4 to -2.8).

Caloway (2020) reported a safety study of HNS in 20 children with Down Syndrome and severe OSA (AHI of 10 or greater) treated at three tertiary care centers.[36] Included were non-obese (BMI < 95%) children and adolescents aged 10 - 21 years who were refractory to tonsillectomy and either unable to tolerate CPAP or dependent on a tracheostomy. Patients who were included had an AHI between 10 and 50 on baseline PSG; the median baseline AHI

was 24.15 (interquartile range [IQR] of 19.88 to 35.10). All of the patients tolerated the stimulation, and at two months after implantation, the median AHI was 3.56 (IQR 2.61 to 4.40). Success, defined as an AHI of 5 or less (mild) with HNS, was achieved in 14 of 20 patients (70%). The median percent reduction in AHI was 85% with a median usage of 9.21 h (IQR: 8.29 to 9.50) per night. The OSA-18 score improved by 1.15 (IQR: 0.02 to 1.97), indicating a moderate but clinically significant change. There were two adverse events related to extrusion or connectivity of the stimulation or sensation leads, which were both corrected with wound exploration surgery. Study in a larger population of children with Down Syndrome is ongoing.

Registry

A retrospective review of the US Food and Drug Administration (FDA) Manufacturer and User Facility Device Experience (MAUDE) database, a publicly available voluntary reporting system, was published by Bellamkonda in 2021.[37] This search was specific to the Inspire system and for adverse events reported between May 2014 and September 2019. Over the five-year period, 132 patient reports containing 134 adverse events were identified, including 32 device revision procedures and 17 device explantations. Complications noted to have not been reported in large-scale clinical trials included pneumothorax, pleural effusion, and lead migration into the pleural space.

Kent (2019) pooled data from the ADHERE registry plus data from three other studies to evaluate factors predicting success.[38] Over 80% of the 584 patients were men, and most were overweight. Seventy-seven percent of patients achieved treatment success, defined as a decrease in AHI by at least 50% and below 20 events/per hour. AHI decreased to below 5 in 41.8% of patients. Greater efficacy was observed in patients with a higher preoperative AHI, older patient age, and lower BMI. A report of data from the ADHERE registry by Thaler (2020) included 640 patients with 6-month follow-up and 382 with 12-month follow-up.[39] AHI was reduced from 35.8 at baseline to 14.2 at 12 months ($p < 0.001$), although the number of hours of use during the sleep test was not reported and home sleep studies may underestimate AHI. ESS was reduced from 11.4 at baseline to 7.2 at 12 months ($p < 0.001$), and patient satisfaction was high. In a multivariate model, only female sex (odds ratio: 3.634, $p = 0.004$) and lower BMI (odds ratio: 0.913, $p = 0.011$) were significant predictors of response according to the Sher criteria. In sensitivity analysis, higher baseline AHI was also found to be a negative predictor of success.

Boon (2018) reported results from 301 patients in the multicenter Adherence and Outcome of Upper Airway Stimulation for OSA International Registry (ADHERE).[40] The ADHERE registry included both retrospective and prospectively collected data from the U.S. and Germany between October 2016 and September 2017. Data were collected from PSG prior to implantation and between 2 and 6 months after implantation, or from home sleep tests which were often performed at 6 and 12 months after implantation as part of routine care. Mean AHI decreased from 35.6 (SD: 15.3) to 10.2 (SD: 12.9) post-titration with 48% of patients achieving an AHI of 5 or less. ESS decreased from 11.9 (5.5) to 7.5 (4.7) ($p < 0.001$).

Body Mass Index

Apublication by Sarber (2020) reported on outcomes of 18 patients implanted with HNS as a salvage procedure despite being outside of FDA trial data.[41] Of these patients, 12 had a BMI >32 kg/m^2 (range 32.1–39.1). Positive outcomes across the 18 subjects were found, with (83.3%) patients achieving surgical success (decrease in AHI >50% and AHI <20 events/hour). This study is limited by the retrospective design and very small sample size. In addition, a

retrospective analysis by Huntley (2018) found patients with a BMI of greater than 32 (n=40) did not have lower success rates than patients with a BMI less than 32 (n=113).[13] Only patients who had palpable cervical landmarks and carried most of their weight in the waist and hips were offered HNS.

PRACTICE GUIDELINE SUMMARY

AMERICAN ACADEMY OF OTOLARYNGOLOGY - HEAD AND NECK SURGERY

In a position statement, the American Academy of Otolaryngology - Head and Neck Surgery (2019) supported hypoglossal nerve stimulation as an effective second-line treatment of moderate-to-severe obstructive sleep apnea in patients who are intolerant or unable to achieve benefit with positive pressure therapy.[42]

AMERICAN ACADEMY OF SLEEP MEDICINE

The American Academy of Sleep Medicine (AASM, 2021) published practice guideline on when to refer patients for surgical modifications of the upper airway for OSA.[43] These guidelines replaced the 2010 practice parameters for surgical modifications.[44] The AASM guidelines note that positive airway pressure (PAP) is the most efficacious treatment for OSA, but effectiveness can be compromised when patients are unable to adhere to therapy or obtain adequate benefit, which is when surgical management may be indicated. The AASM guideline recommendations are based on a systematic review and meta-analysis of 274 studies of surgical interventions, including procedures such as uvulopalatopharyngoplasty (UPPP), modified UPPP, MMA, tongue base suspension, and hypoglossal nerve stimulation.[45] The systematic review deemed most included data of low quality, consisting of mostly observational data. The AASM strongly recommend that clinicians discuss referral to a sleep surgeon with adults with OSA and body mass index (BMI) <40 kg/m^2 who are intolerant or unaccepting of PAP. Clinically meaningful and beneficial differences in nearly all critical outcomes, including decrease in excessive sleepiness, improved quality of life (QOL), improved Apnea/Hypopnea Index (AHI) or respiratory disturbance index (RDI), and sleep quality, were demonstrated with surgical management in patients who are intolerant or unaccepting of PAP. The AASM makes a conditional recommendation that clinicians discuss referral to a sleep surgeon with adults with OSA, BMI <40 kg/m^2, and persistent inadequate PAP adherence due to pressure-related side effects, as available data (very low-quality) suggests that upper airway surgery has a moderate effect in reducing minimum therapeutic PAP level and increasing PAP adherence. In adults with OSA and obesity (class II/III, BMI >35) who are intolerant or unaccepting of PAP, the AASM strongly recommends discussion of referral to a bariatric surgeon, along with other weight loss strategies.

SUMMARY

Evidence for hypoglossal nerve stimulation (HNS) as a treatment of obstructive sleep apnea (OSA) is limited. However, HNS has become generally accepted in medical practice, and is recommended as an effective second-line treatment in a consensus statement by the American Academy of Otolaryngology - Head and Neck Surgery. Therefore, hypoglossal nerve stimulation may be considered medically necessary for some patients with OSA when policy criteria are met.

A hypoglossal nerve stimulation device may require revision after it has been placed. In these cases, revision may be medically appropriate to allow for the proper functioning of the device. Therefore, revision(s) to an existing hypoglossal nerve stimulation device may be considered medically necessary after the device has been placed.

In certain situations, a hypoglossal nerve stimulation device may no longer be able to perform its basic function due to damage or wear. When a stimulator is out of its warranty period and cannot be repaired adequately to meet the patient's medical needs, replacement of the device may be medically appropriate. Therefore, replacement of all or part of a hypoglossal nerve stimulation device and/or generator may be considered medically necessary when device replacement Criteria are met.

When a hypoglossal nerve stimulation device is in its warranty period or can be repaired or adapted adequately to meet the patient's medical needs, replacement of the device is not medically appropriate. Therefore, replacement of all or part of a hypoglossal nerve stimulation device and/or generator is considered not medically necessary when device replacement Criteria are not met.

Clinical practice guidelines recommend positive airway pressure (PAP) as the most efficacious treatment for obstructive sleep apnea (OSA) and hypoglossal nerve stimulation (HNS) may be considered in some patients who are unable to adhere to therapy or obtain adequate benefit. Therefore, HNS is considered **not medically necessary** when there is PAP therapy refusal in adults with OSA.

There is not enough research to know if or how well hypoglossal nerve stimulation (HNS) works to treat people when policy criteria are not met. This does not mean that it does not work, but more research is needed to know. No clinical guidelines based on research address HNS for indications other than for those listed in the policy criteria. Therefore, hypoglossal nerve stimulation is considered investigational when policy criteria are not met.

Medical Policy Manual Surgery, Policy No. 216

Responsive Neurostimulation

Effective: March 1, 2024

Next Review: September 2024
Last Review: January 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Responsive neurostimulation (RNS) provides cortical stimulation in response to detection of specific seizure-related electrical signals. RNS shares some features with deep brain stimulation but is differentiated by its use of direct cortical stimulation and by its use in both monitoring and stimulation. RNS is used in individuals with refractory focal epilepsies to provide a treatment option that is an alternative to or an improvement on existing therapies.

MEDICAL POLICY CRITERIA

I. Responsive neurostimulation may be considered **medically necessary** for patients with focal epilepsy who meet ALL of the following criteria:

   A. 18 years or older; and

   B. Device is FDA approved (PMA or 510k only); and

   C. Diagnosis of focal seizures with 1 or 2 localized seizure foci identified; and

   D. Average of 3 or more disabling seizures (e.g., motor focal seizures, complex focal seizures, or secondary generalized seizures) per month for 3 consecutive months; and

   E. Failed greater than or equal to 2 antiepileptic medications; and

F. Not a candidate for focal resective epilepsy surgery (e.g., have an epileptic focus near the eloquent cerebral cortex; have bilateral temporal epilepsy); and

G. Do not have any of the following contraindications for responsive neurostimulation device placement:

1. 3 or more specific seizure foci
2. Presence of primary generalized epilepsy
3. Presence of a rapidly progressive neurologic disorder

II. Responsive neurostimulator revision(s) or replacement(s) may be considered **medically necessary** after the device has been placed.

III. Responsive neurostimulation is considered **investigational** for all other indications, including but not limited to patients with focal epilepsy who do not meet the above Criteria.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical exam, including requirements as outlined by the policy criteria
- Number of seizure foci
- Documentation of seizure occurrence over the prior 3 months
- Clinical documentation demonstrating medicine-refractory symptoms
- Clinical documentation demonstrating that the patient is not a candidate for focal resective epilepsy surgery
- Presence of other conditions, such as a neurological disorder

BACKGROUND

Focal seizures (previously referred to as partial seizures) arise from a discrete area of the brain and can cause a range of symptoms, depending on the seizure type and the brain area involved.

Note that the term focal seizure in older literature may be referred to as “partial seizure.” A position paper from the International League Against Epilepsy (2017) outlined updated terminology for seizure and epilepsy subtypes.[1] For example, focal-onset seizures are subdivided based on the associated level of consciousness, and subsequently into whether they are motor or non-motor-onset.

Seizure disorders may be grouped into epileptic syndromes based on a number of factors, including the types of seizures that occur and their localization, the age of onset, patterns on electroencephalogram, associated clinical or neuroimaging findings, and genetic factors. Temporal lobe epilepsy is the most common syndrome associated with focal seizures. Of those with focal seizures, 30% to 40% have intractable epilepsy, defined as a failure to control seizures after two seizure medications have been appropriately chosen and used.[2]

EPILEPSY TREATMENT

Medical Therapy for Seizures

Standard therapy for seizures, including focal seizures, includes treatment with one or more of various antiepileptic drugs (AEDs), which include newer AEDs, like oxcarbazepine, lamotrigine, topiramate, gabapentin, pregabalin, levetiracetam, tiagabine, and zonisamide.[2] Currently, response to AEDs is less than ideal: one systematic review comparing newer AEDs for refractory focal epilepsy reported an overall average responder rate in treatment groups of 34.8%.[2] As a result, a substantial number of patients do not achieve good seizure control with medications alone.

Surgical Therapy for Seizures

When a discrete seizure focus can be identified, seizure control may be achieved through resection of the seizure focus (epilepsy surgery). For temporal lobe epilepsy, a randomized controlled trial has demonstrated that surgery for epilepsy was superior to prolonged medical therapy in reducing seizures associated with impaired awareness and in improving quality of life.[3] Surgery for refractory focal epilepsy (excluding simple focal seizures) is associated with five-year freedom from seizure rates of 52%, with 28% of seizure-free individuals able to discontinue AEDs.[4] Selection of appropriate patients for epilepsy surgery is important, because those with nonlesional extratemporal lobe epilepsy have worse outcomes after surgery than those with nonlesional temporal lobe epilepsy.[5] Some patients are not candidates for epilepsy surgery if the seizure focus is located in an eloquent area of the brain or other region that cannot be removed without risk of significant neurologic deficit.

Neurostimulation for Neurologic Disorders

Electrical stimulation at one of several locations in the brain has been used as therapy for epilepsy, either as an adjunct to or as an alternative to medical or surgical therapy. Vagus nerve stimulation (VNS) has been widely used for refractory epilepsy, following Food and Drug Administration (FDA) approval of a VNS device in 1997 and two randomized controlled trials evaluating VNS in epilepsy.[6] Although the mechanism of action for VNS is not fully understood, VNS is thought to reduce seizure activity through activation of vagal visceral afferents with diffuse central nervous system projections, leading to a widespread effect on neuronal excitability.

Stimulation of other locations in the neuroaxis has been studied for a variety of neurologic disorders. Electrical stimulation of deep brain nuclei (deep brain stimulation [DBS]) involves the use of chronic, continuous stimulation of a target. It has been most widely used in the treatment of Parkinson disease and other movement disorders, and has been investigated for treating epilepsy. DBS of the anterior thalamic nuclei was studied in a randomized control trial, the Stimulation of the Anterior Nucleus of the Thalamus for Epilepsy trial, but DBS is not currently approved by FDA for stimulation of the anterior thalamic nucleus.[7] Stimulation of the

cerebellar and hippocampal regions and the subthalamic, caudate, and centromedian nuclei have also been evaluated for the treatment of epilepsy.[6]

Responsive Neurostimulation for Epilepsy

Responsive neurostimulation (RNS) shares some features with DBS but is differentiated by its use of direct cortical stimulation and by its use in both monitoring and stimulation. The RNS system provides stimulation in response to detection of specific epileptiform patterns, while DBS provides continuous or intermittent stimulation at preprogrammed settings.

Development of the RNS system arose from observations related to the effects of cortical electrical stimulation for seizure localization. It has been observed that electrical cortical stimulation can terminate induced and spontaneous electrographic seizure activity in humans and animals.[8] Patients with epilepsy may undergo implantation of subdural monitoring electrodes for the purposes of seizure localization, which at times have been used for neurostimulation to identify eloquent brain regions. Epileptiform discharges that occur during stimulation for localization can be stopped by a train of neighboring brief electrical stimulations.[9]

In tandem with the recognition that cortical stimulation can stop epileptiform discharges was development of fast pre-ictal seizure prediction algorithms. These algorithms interpret electrocorticographic data from detection leads situated over the cortex. The RNS process thus includes electrocorticographic monitoring via cortical electrodes, analysis of data through a proprietary seizure detection algorithm, and delivery of electrical stimulation via both cortical and deep implanted electrodes in an attempt to halt a detected epileptiform discharge.

One device, the NeuroPace RNS System, is currently approved by FDA and is commercially available.

RNS FOR SEIZURE MONITORING

Although the intent of the electrocorticography component of the RNS system is to provide input as a trigger for neurostimulation, it also provides continuous seizure mapping data (chronic unlimited cortical electrocorticography) that may be used by practitioners to evaluate patients' seizures. In particular, the seizure mapping data have been used for surgical planning of patients who do not experience adequate seizure reduction with RNS placement. Several studies have described the use of RNS in evaluating seizure foci for epilepsy surgery[10] or for identifying whether seizure foci are unilateral.[11, 12]

This review does not further address use of RNS exclusively for seizure monitoring.

REGULATORY STATUS

In November 2013, the NeuroPace RNS® System (NeuroPace) was approved by FDA through the premarket approval process for the following indication[13]:

"The RNS® System is an adjunctive therapy in reducing the frequency of seizures in individuals 18 years of age or older with partial onset seizures who have undergone diagnostic testing that localized no more than two epileptogenic foci, are refractory to two or more antiepileptic medications, and currently have frequent and disabling seizures (motor partial seizures, complex partial seizures and/ or secondarily generalized seizures). The RNS® System has demonstrated safety and effectiveness in patients who average three or more

disabling seizures per month over the three most recent months (with no month with fewer than two seizures), and has not been evaluated in patients with less frequent seizures."

FDA product code: PFN.

EVIDENCE SUMMARY

RNS FOR TREATMENT OF REFRACTORY FOCAL EPILEPSY

The body of evidence addressing whether RNS is associated with improved health outcomes for patients with focal epilepsy includes an industry-sponsored RCT, which was used for the device's U.S. Food and Drug Administration (FDA) approval, as well as several published follow-up analyses.

Pivotal Trial

RNS for epilepsy was evaluated in the RNS System Pivotal Trial, a multicenter, double-blinded, sham-controlled trial that served as the basis of FDA's approval of the device.[14] Published by Morrell (2011), this RCT included 191 patients with medically intractable focal epilepsy who were implanted with the RNS device and randomized to treatment or sham control after a one-month postimplant period during which time no subjects had the device activated. Eligible patients were adults with focal seizures whose epilepsy had not been controlled with at least two trials of antiepileptic drugs (AEDs), who had at least three disabling seizures (motor focal seizures, complex focal seizures, or secondary generalized seizures) per month on average, and who had standard diagnostic testing that localized one or two epileptogenic foci. Thirty-two percent of those implanted had prior epilepsy surgery, and 34% had a prior vagal nerve stimulator.

Patients were randomized to active stimulation (n=97) or sham stimulation (n=94). After the four-week postoperative period, patients received either sham or active stimulation according to group assignment. There was a four-week stimulation optimization period, followed by a three-month blinded evaluation period. In the evaluation period, all outcome data were gathered by a physician blinded to group assignment, and the neurostimulator was managed by a nonblinded physician. One patient in each group did not complete the stimulus optimization period (one due to subject preference in the active stimulation group; one due to death in the sham stimulation group). An additional patient in each group did not complete the blinded evaluation phase due to emergent explant of the device. After the three-month blinded evaluation period, all patients received active stimulation during an open-label follow-up period. At the time of the Morrell publication, 98 subjects had completed the open-label period and 78 had not. Eleven patients did not complete the open-label follow-up period (five due to death, two to emergent explant, four to study withdrawal).

The trial's primary effectiveness objective was to demonstrate a significantly greater reduction in the frequency of total disabling seizures in the treatment group compared with the sham group during the blinded evaluation period relative to baseline (preimplant). The mean preimplant seizure frequency per month in the treatment group was 33.5 (range 3 to 295) and 34.9 (range, 3-338) in the sham group.[13] Mean seizure frequency modeled using generalized estimating equations was significantly reduced in the treatment group compared with the sham group (p=0.012). During the blinded evaluation period, the mean seizure frequency in the treatment group was 22.4 (range 0.0 to 227) and 29.8 (range 0.3 to 447) in the sham group. The treatment group experienced a -37.9% change in seizure frequency (95% confidence

interval [CI] -46.7% to -27.7%), while the sham group experienced a -17.3% change in seizure frequency (95% CI -29.9% to -2.3%).

By the third month of the blinded evaluation period, the treatment group had 27% fewer days with seizures while the sham group experienced 16% fewer days (p=0.048). There were no significant differences between groups over the blinded evaluation period for secondary end points of responder rate (proportion of subjects who experienced a ≥50% reduction in mean disabling seizure frequency vs the preimplant period), change in average frequency of disabling seizures, or change in seizure severity.

During the open-label period, subjects in the sham group demonstrated significant improvements in mean seizure frequency compared with the preimplant period (p=0.04). For all subjects (treatment and sham control), the responder rate at one-year postimplant was 43%. Overall quality of life scores improved for both groups compared with baseline at one year (p=0.001) and two years postimplant (p=0.016).

For the study's primary safety end point, the significant adverse event rate over the first 28 days postimplant was 12%, which did not differ significantly from the prespecified literature-derived comparator of 15% for implantation of intracranial electrodes for seizure localization and epilepsy surgery. During the implant period and the blinded evaluation period, the significant adverse event rate was 18.3%, which did not differ significantly from the prespecified literature-derived comparator of 36% for implantation and treatment with deep brain stimulation for Parkinson disease. The treatment and sham groups did not differ significantly in terms of mild or serious adverse events during the blinded evaluation period. Intracranial hemorrhage occurred in 9 (4.7%) of 191 subjects; implant or incision site infection occurred in 10 (5.2%) of 191 subjects, and the devices were explanted from 4 of these subjects.

Follow-Up Analyses to the Pivotal Trial Subjects

In a follow-up to the RNS System Pivotal Trial, Heck (2014) compared outcomes at one and two years postimplant with baseline for patients in both groups (sham and control) who had the RNS stimulation device implanted during the RNS System Pivotal Trial.[15] Of the 191 subjects implanted, 182 subjects completed follow-up to one year postimplant and 175 subjects completed follow-up to two years postimplant. Six patients withdrew from the trial, four underwent device explantation due to infection, and five died, with one due to sudden unexplained death in epilepsy. During the open-label period, at two years of follow-up, median percent reduction in seizures was 53% compared with the preimplant baseline (p<0.001), and the responder rate was 55%.

Loring (2015) analyzed one of the trial's prespecified safety end points (neuropsychologic function) during the trial's open-label period.[16] Neuropsychological testing focused on language and verbal memory, measured by the Boston Naming Test and the Rey Auditory Verbal Learning Test. One hundred seventy-five subjects had cognitive assessment scores at baseline and at one or two years or both and were included in this analysis. The authors used reliable change indices (RCIs) to identify patients with changes in test scores beyond that attributed to practice effects or measurement error in the test-retest setting, with 90% RCIs used for classification. Overall, no significant group-level declines in any neuropsychological outcomes were detected. On the Boston Naming Test, 23.5% of subjects demonstrated RCI improvements while 6.7% had declines; on the Rey Auditory Verbal Learning Test, 6.9% of subjects demonstrated RCI improvements and 1.4% demonstrated declines.

Meador (2015) reported on quality of life and mood outcomes for individuals in the RNS pivotal trial.[17] At the end of the blinded study period, both groups reported improvements in Quality of Life in Epilepsy Inventory-89 (QOLIE-89) scores, with no statistically significant differences between groups. In analysis of those with follow-up to two years post-enrollment, implanted patients had statistically significant improvements in QOLIE-89 scores from enrollment to one- and two-year follow-up. Mood, as assessed by the Beck Depression Inventory and the Profile of Mood States, did not worsen over time.

Nair (2020) published a long-term prospective open-label study that included patients who participated in the two-year feasibility or pivotal studies of the RNS® System between 2004 and 2018.[18] Patients were followed for an additional seven years. Overall, 230 patients enrolled in the study and 162 completed all nine years of follow-up, providing a total of 1,895 patient-implantation years. Among 68 patients who discontinued the study, four experienced emergent explant, five were lost to follow up, nine were deceased, and 50 withdrew (five transferred care to a non-study center, seven were noncompliant, eight experienced insufficient efficacy, 10 pursued other treatments, and 20 chose not to replace neurostimulator). The mean follow-up period was 7.5 years. At nine years, the median percent reduction in seizure frequency was 75% ($p<0.0001$), 73% of patients were considered responders, and 35% had a ≥90% reduction in seizure frequency. Overall, 18.4% of patients experienced at least one year free of seizures. Overall scores for quality of life and epilepsy-targeted and cognitive domains of the Quality of Life in Epilepsy-89 (QOLIE-89) inventory remained significantly improved at year nine ($p<0.05$). The only device-related serious adverse events that were reported in ≥ 5% of patients were implantation site infection and elective explantation of the neurostimulator, leads, or both. Overall, serious device-related implantation site infection occurred in 12.1% of patients. No serious adverse events occurred related to stimulation.

Section Summary: RNS for Treatment of Refractory Focal Epilepsy

The most direct and rigorous evidence related to the effectiveness of RNS in the treatment of refractory focal seizures is from the RNS System Pivotal Trial, in which patients who had focal epilepsy refractory to at least two medications and received RNS treatment demonstrated a significantly greater reduction in their rates of seizures compared with sham-control patients. Although this single RCT was relatively small (97 patients in the treatment group), it was adequately powered for its primary outcome and all patients were treated with the device during the open-label period (97 in the original treatment group, 94 in the original sham group) and demonstrated a significant improvement in seizure rates compared with baseline. However, there were no differences in the percentage of patients who responded to RNS, and no difference on most of the other secondary outcomes. Follow-up has been reported to five years postimplantation, without major increases in rates of adverse events.

Adverse Events with the RNS System

As a surgical procedure, implantation of the RNS system is associated with the risks that should be balanced against the risks of alternative treatments, including AEDs and other invasive treatments (vagal nerve stimulator and epilepsy surgery), and the risks of uncontrolled epilepsy. During the RNS System Pivotal Trial, rates of serious adverse events were relatively low: 3.7% of patients had implant site infections, 6% had lead revisions or damage, and 2.1% percent had intracranial hemorrhages during initial implantation.[15]

FDA's summary of safety and effectiveness data for the RNS system summarized deaths and adverse events. As reported in the safety and effectiveness data, as of October 24, 2012, there were 11 deaths in the RNS System trials, including the pivotal trial and the ongoing long-term treatment study. Two of the deaths were suicides (one each in the pivotal and LTT studies), one due to lymphoma and another to complications of status epilepticus, and seven were attributed to possible, probable, or definite sudden unexplained death in epilepsy. With 1195 patient implant years, the estimated sudden unexplained death in epilepsy rate is 5.9 per 1000 implant years, which is comparable with the expected rate for patients with refectory epilepsy.[13]

The Long-Term Treatment (LTT) Study was a seven-year, multicenter, prospective, open-label study to evaluate the RNS system's long-term efficacy and safety in individuals who participated in device's feasibility or pivotal trials. Bergey (2015) reported on follow-up for 191 participants in the LTT Study (of a total of 230 originally enrolled in the LTT Study) for a median 5.4 years.[19] Of those who discontinued, three were lost to follow-up, 28 patients withdrew (nine to pursue other treatments, five due to insufficient efficacy, five decided not to replace the RNS system after expected battery depletion, five after infection resolved, three for noncompliance, one for elective explant, one due to ongoing suicidality/noncompliance), four underwent emergent explant, and four died. For follow-up at years three and six, the median percent reductions in seizures were 60% and 66%, respectively. Statistically significant quality of life improved at four years, with a trend toward improvement at five years. The most common adverse events were implant site infection (n=24 [9.4%]) and increase in complex focal seizures (n=20 [7.8%]).

Summary of Evidence

For individuals who have refractory focal epilepsy who receive RNS, the evidence includes an industry-sponsored RCT, which was used for Food and Drug Administration approval of the NeuroPace RNS System, as well as case series. Relevant outcomes are symptoms, morbid events, quality of life, and treatment-related mortality and morbidity. The pivotal trial was well-designed and well-conducted; it reported that RNS is associated with improvements in mean seizure frequency in patients with refractory focal epilepsy, with an absolute difference in change in seizure frequency of about 20% between groups, though the percentage of treatment responders with at least a 50% reduction in seizures did not differ from sham control. Overall, the results suggested a modest reduction in seizure frequency in a subset of patients. The number of adverse events reported in the available studies is low, although the data on adverse events were limited because of small study samples. Generally, patients who are candidates for RNS are severely debilitated and have few other treatment options, so the benefits are likely high relative to the risks. In particular, patients who are not candidates for resective epilepsy surgery and have few treatment options may benefit from RNS. The evidence is sufficient to determine that the technology results in an improvement in the net health outcome.

PRACTICE GUIDELINE SUMMARY

The American Academy of Neurology has published guidelines on specific treatments for epilepsy, which were reaffirmed in 2019.[20] It has not published any guidelines with recommendations regarding responsive neurostimulation.

SUMMARY

It appears that in patients with refractory focal epilepsy, responsive neurostimulation (RNS) may improve health outcomes, including a reduction in seizure frequency in some patients. In particular, patients who are not candidates for resective epilepsy surgery and have few treatment options may benefit from RNS. Therefore, RNS may be considered medically necessary in patients with medication-refractory focal epilepsy when criteria are met.

In certain situations, a responsive neurostimulation device may no longer be able to perform its basic function due to damage or wear. When a stimulator is out of its warranty period and cannot be repaired adequately to meet the patient's medical needs, replacement of the device may be medically appropriate. Therefore, responsive neurostimulator revision(s) or replacement(s) may be considered medically necessary after the device has been placed.

There is not enough research to show that responsive neurostimulation (RNS) improves health outcomes for all other indications not meeting the criteria, including but not limited to patients with focal epilepsy who do not meet the criteria. Therefore, RNS is considered investigational when criteria are not met.

Medical Policy Manual Surgery, Policy No. 217

Leadless Cardiac Pacemakers

Effective: January 1, 2024

Next Review: September 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Pacemakers are intended to be used as a substitute for the heart's intrinsic pacing system to correct cardiac rhythm disorders. Conventional pacemakers consist of two components: a pulse generator and electrodes (or leads). Some patients are medically ineligible for conventional pacemakers due to lack of venous access and recurrent infection. Leadless pacemakers are single-unit devices that are implanted in the heart via femoral access.

MEDICAL POLICY CRITERIA

Notes: See Policy Guidelines for contraindications for leadless pacemaker systems.

I. A single-chamber transcatheter leadless cardiac pacing system may be considered **medically necessary** in patients when all the Criteria (A. – C.) . below are met:

   A. The device is approved by the Food and Drug Administration (FDA).

   B. The patient has one or more of the following:

      1. Symptomatic paroxysmal or permanent high-grade atrioventricular (AV) block; or

      2. Symptomatic bradycardia-tachycardia syndrome; or

3. Sinus node dysfunction (sinus bradycardia or sinus pauses).

C. The patient has a significant contraindication precluding placement of conventional single-chamber ventricular pacemaker leads, including but not limited to a history or high risk of infection, limited venous access, or presence of a bioprosthetic tricuspid valve.

II. A single-chamber transcatheter leadless pacing system is considered **investigational** for all other indications when Criterion I. is not met.

III. The initial insertion or replacement of a dual chamber leadless pacemaker is considered **investigational.**

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

MICRA™ SYSTEM CONTRAINDICATIONS[1]

Devices

As per the FDA label, the Micra™ Model MC1VR01 pacemaker is contraindicated for patients who have the following types of devices implanted:

- An implanted device that would interfere with the implant of the Micra™ device in the judgment of the implanting physician
- An implanted inferior vena cava filter
- A mechanical tricuspid valve
- An implanted cardiac device providing active cardiac therapy which may interfere with the sensing performance of the Micra™ device

Conditions

As per the FDA label, the Micra™ Model MC1VR01 pacemaker is also contraindicated for patients who have the following conditions:

- Femoral venous anatomy unable to accommodate a 7.8 mm (23 French) introducer sheath or implant on the right side of the heart (for example, due to obstructions or severe tortuosity)
- Morbid obesity that prevents the implanted device to obtain telemetry communication within <12.5 cm (4.9 in)
- Known intolerance to titanium, titanium nitride, parylene C, primer for parylene C, polyether ether ketone, siloxane, nitinol, platinum, iridium, liquid silicone rubber, silicone medical adhesive, and heparin or sensitivity to contrast medical which cannot be adequately premedicated

Other Contraindications

As per the FDA label, the Micra™ Model MC1VR01 pacemaker should not be used in patients for whom a single dose of 1.0 mg dexamethasone acetate cannot be tolerated because the device contains a molded and cured mixture of dexamethasone acetate with the target dosage

of 272 µg dexamethasone acetate. It is intended to deliver the steroid to reduce inflammation and fibrosis.

For the MRI contraindications for patients with a Micra™ MRI device, refer to the Medtronic MRI Technical Manual.

AVEIR™ SYSTEM CONTRAINDICATIONS[2]

Aveir™ DR Leadless System

As per the FDA label, the Aveir™ Leadless Pacemaker System is contraindicated in the following situations:

- Use of any pacemaker is contraindicated in patients with a co-implanted ICD because high-voltage shocks damage the pacemaker, and the pacemaker could reduce shock effectiveness.
- Single-chamber ventricular demand pacing is relatively contraindicated in patients who have demonstrated pacemaker syndrome, have retrograde VA conduction, or suffer a drop in arterial blood pressure with the onset of ventricular pacing.
- Programming of rate-responsive pacing is contraindicated in patients with intolerance of high sensor-driven rates.
- Use is contraindicated in patients with an implanted vena cava filter or mechanical tricuspid valve because of interference between these devices and the delivery system during implantation.
- Persons with known history of allergies to any of the components of this device may suffer an allergic reaction to this device. Prior to use on the patient, the patient should be counseled on the materials (listed in IFU Product Materials) contained in the device and a thorough history of allergies must be discussed.
- For the MRI contraindications for patients implanted with Aveir™ Leadless Pacemaker, refer to the MRI Procedure Manual.
- There are no contraindications for use of the Aveir™ Link Module.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Documentation of symptoms, associated diagnoses and treatments
- Name of FDA-approved leadless device
- Documentation that supports contraindication of placement of conventional single-chamber ventricular pacemaker leads

BACKGROUND

CONVENTIONAL PACEMAKERS

Pacemakers are intended to be used as a substitute for the heart's intrinsic pacing system to correct cardiac rhythm disorders. By providing an appropriate heart rate and heart rate response, cardiac pacemakers can reestablish effective circulation and more normal hemodynamics that are compromised by a slow heart rate. Pacemakers vary in system complexity and can have multiple functions as a result of the ability to sense and/or stimulate both the atria and the ventricles.

Transvenous pacemakers or pacemakers with leads (hereinafter referred as conventional pacemakers) consist of two components: a pulse generator (i.e., battery component) and electrodes (i.e., leads). The pulse generator consists of a power supply and electronics that can provide periodic electrical pulses to stimulate the heart. The generator is commonly implanted in the infraclavicular region of the anterior chest wall and placed in a pre-pectoral position; in some cases, a subpectoral position is advantageous. The unit generates an electrical impulse, which is transmitted to the myocardium via the electrodes affixed to the myocardium to sense and pace the heart as needed.

Conventional pacemakers are also referred to as single-chamber or dual-chamber systems. In single-chamber systems, only one lead is placed, typically in the right ventricle. In dual-chamber pacemakers, tow leads are placed: one in the right atrium and the other in the right ventricle. Single-chamber ventricular pacemakers are more common.

As of 2015, approximately 200,000 pacemakers are implanted in the United States and one million worldwide, annually.[3] Implantable pacemakers are considered life-sustaining, life-supporting class III devices for patients with a variety of bradyarrhythmias. Pacemaker systems have matured over the years with well-established, acceptable performance standards. As per the Food and Drug Administration (FDA), the early performance of conventional pacemaker systems from implantation through 60 to 90 days has usually demonstrated acceptable pacing capture thresholds and sensing. Intermediate performance (90 days through more than five years) has usually demonstrated the reliability of the pulse generator and lead technology. Chronic performance (5 to 10 years) includes a predictable decline in battery life and mechanical reliability, but a vast majority of patients receive excellent pacing and sensing free of operative or mechanical reliability failures.

Even though the safety profile of conventional pacemakers is excellent, they are associated with complications particularly related to leads. Most safety data on the use of conventional pacemakers comes from registries from Europe, particularly from Denmark where all pacemaker implants are recorded in a national registry. These data are summarized in Table 1. It is important to recognize that valid comparison of complication rates is limited by differences in definitions of complications, which results in a wide variance of outcomes, as well as by the large variance in follow-up times, use of single-chamber or dual-chamber systems, and data reported over more than two decades.[4] As such, the following data are contemporary and limited to single-chamber systems when reported separately.

In many cases when conventional pectoral approach is not possible, alternate approaches such as epicardial pacemaker implantation and trans-iliac approaches have been used[5]. Cohen (2001) reported outcomes from a retrospective analysis of 123 patients who underwent 207 epicardial lead implantations[6]. Congenital heart disease was present in 103 (84%) of the patients. Epicardial leads were followed for 29 months (range 1 to 207 months). Lead failure was defined as the need for replacement or abandonment due to pacing or sensing problems, lead fracture, or phrenic/muscle stimulation. The one-, two-, and five-year lead survival was

96%, 90%, and 74%, respectively. Epicardial lead survival in those placed by a subxiphoid approach was 100% at one year and at 10 years, by the sternotomy approach (93.9% at one year and 75.9% at 10 years) and lateral thoracotomy approach (94.1% at one year and 62.4% at 10 years).

Doll (2008) reported results of a randomized trial comparing epicardial implantation to conventional pacemaker implantation in 80 patients with indications for cardiac resynchronization therapy.[7] The authors reported that the conventional pacemaker group had significantly shorter intensive care unit stay, less blood loss, and shorter ventilation times while the epicardial group had less exposure to radiation and less use of contrast medium. The left ventricular pacing threshold was similar in the two groups at discharge but longer in the epicardial group during follow-up. Adverse events were also similar in the two groups. The following events were experienced by one (3%) patient each in the epicardial group: pleural puncture, pneumothorax, wound infection, acute respiratory distress syndrome, and hospital mortality.

As a less invasive alternate to epicardial approach, trans-iliac approach has also been utilized. Data using trans-iliac approach is limited. Multiple other studies with smaller sample size report a wide range of lead longevity.

Harake (2018) reported a retrospective analysis of five patients who underwent a transvenous iliac approach (median age 26.9 years)[8]. Pacing indications included AV block in three patients and sinus node dysfunction in two patients. After a median follow-up of 4.1 years (range 1.0 -16.7 years), outcomes were reported for four patients. One patient underwent device revision for lead position-related groin discomfort; a second patient developed atrial lead failure following a Maze operation and underwent lead replacement by the iliac approach. One patient underwent heart transplantation six months after implant with only partial resolution of pacing-induced cardiomyopathy.

Tsutsumi (2010) reported a case series of four patients from Japan in whom conventional pectoral approach was precluded due to recurrent lead infections (n=1), superior vena cava obstruction following cardiac surgery (n=2) and a postoperative dermal scar (n=1). The mean follow-up was 24 months and authors concluded iliac vein approach was satisfactory and less invasive alternative to epicardial lead implantation. However, the authors reported that incidence of atrial lead dislodgement using this approach in the literature ranged from 7% to 21%. Experts who provided clinical input reported that trans-iliac or surgical epicardial approach require special expertise and long term performance is suboptimal.[9]

Table 1. Reported Complication Rates with Conventional Pacemakers

Complications	Rates, %[10-12]a
Traumatic complications	
RV perforation	0.2-0.8
RV perforation with tamponade	0.07-0.4
Pneumo(hemo)thorax	0.7-2.2
Pocket complications	
Including all hematomas, difficult to control bleeding, infection, discomfort, skin erosion	4.75
Including only those requiring invasive correction or reoperation	0.66-1.0
Lead-related complications	
Including lead fracture, dislodgement, insulation problem, infection, stimulation threshold problem, diaphragm or pocket stimulation, other	1.6-3.8

Complications	Rates, %[10-12]a
All system related infections requiring reoperation or extraction	0.5-0.7

Adapted from Food and Drug Administration executive summary memorandum (2016).[13]

[a] Rates are for new implants only and ventricular single-chamber devices when data were available. Some rates listed in this column are for single- and dual-chamber devices when data were not separated in the publication. Note that Micra™ transcatheter pacing system is a single-chamber device.

POTENTIAL ADVANTAGES OF LEADLESS CARDIAC PACEMAKERS OVER CONVENTIONAL PACEMAKERS

The potential advantages of leadless pacemakers fall into three categories: avoidance of risks associated with intravascular leads in conventional pacemakers, avoidance of risks associated with pocket creation for placement of conventional pacemakers, and an additional option for patients who require a single-chamber pacer.[14]

Lead complications include lead failure, lead fracture, insulation defect, pneumothorax, infections requiring lead extractions and replacements that can result in a torn subclavian vein or tricuspid valve. In addition, there are risks of venous thrombosis and occlusion of the subclavian system from the leads. Use of a leadless system eliminates such risks with the added advantage that a patient has vascular access preserved for other medical conditions (e.g., dialysis, chemotherapy).

Pocket complications include infections, erosions, and pain that can be eliminated with leadless pacemakers. Further, a leadless cardiac pacemaker may be more comfortable and appealing because, unlike conventional pacemakers, patients are unable to see or feel the device or have an implant scar on the chest wall.

Leadless pacemakers may also be a better option than surgical endocardial pacemakers for patients with no vascular access due to renal failure or congenital heart disease.

SINGLE CHAMBER LEADLESS CARDIAC PACEMAKERS IN CLINICAL DEVELOPMENT

Leadless pacemakers are self-contained in a hermetically sealed capsule. The capsule houses a battery and electronics to operate the system. Similar to most pacing leads, the tip of the capsule includes a fixation mechanism and a monolithic controlled-release device. The controlled-release device elutes glucocorticosteroid to reduce acute inflammation at the implantation site. Leadless pacemakers have rate-responsive functionality, and current device longevity estimates are based on bench data. Estimates have suggested that these devices may last over 10 years, depending on the programmed parameters.[13]

Three systems are currently being evaluated in clinical trials: (1) the Micra™ Transcatheter Pacing System (Medtronic), (2) the Aveir™ VR leadless pacemaker (Abbot; formerly Nanostim, St. Jude Medical); and (3) the WiCS Wireless Cardiac Stimulation System (EBR Systems). The first two devices are free-standing capsule-sized devices that are delivered via femoral venous access using a steerable delivery sheath. However, the fixing mechanism differs between the two devices. In the Micra™ Transcatheter Pacing System, the fixation system consists of four self-expanding nitinol tines, which anchor into the myocardium; for the Aveir™ device, there is a screw-in helix that penetrates into the myocardium. In both devices, the cathode is steroid eluting and delivers pacing current; the anode is located in a titanium case. The third device, WiCS system differs from the other devices; this system requires implanting a pulse generator subcutaneously near the heart, which then wirelessly transmits ultrasound energy to a receiver electrode implanted in the left ventricle. The receiver electrode

converts the ultrasound energy and delivers electrical stimulation to the heart sufficient to pace the left ventricle synchronously with the right.[13]

Of these three, only the Micra™ and Aveir™ single-chamber transcatheter pacing systems are approved by FDA and commercially available in the United States. Multiple clinical studies of the Aveir™ predecessor device, the Nanostim, have been published[3, 15-19] but trials have been halted due to the migration of the docking button in the device and premature battery depletion. These issues have since been addressed with the Aveir™ device.[20] Aveir™ has a unique mapping capability to assess correct positioning prior to placement and is specifically designed to be retrieved when therapy needs evolve or the device needs to be replaced.[21]

The Micra™ is about 26 mm in length and introduced using a 23 French catheter via the femoral vein to the right ventricle. It weighs about two grams and has an accelerometer-based rate response.[22]

The Aveir™ is about 42 mm in length and introduced using a 25 French catheter to the right ventricle. It also weighs about three grams and uses a temperature-based rate response sensor.[23]

REGULATORY STATUS

Micra™ leadless pacing system (Medtronic)

In April 2016, the Micra™ transcatheter pacing system (Medtronic) was approved by FDA through the premarket approval process for use in patients who have experienced one or more of the following conditions:

- symptomatic paroxysmal or permanent high-grade AV block in the presence of atrial fibrillation
- paroxysmal or permanent high-grade AV block in the absence of atrial fibrillation, as an alternative to dual-chamber pacing, when atrial lead placement is considered difficult, high risk, or not deemed necessary for effective therapy
- symptomatic bradycardia-tachycardia syndrome or sinus node dysfunction (sinus bradycardia or sinus pauses), as an alternative to atrial or dual-chamber pacing, when atrial lead placement is considered difficult, high risk, or not deemed necessary for effective therapy.

In January 2020, the Micra AV Transcatheter Pacing System Model MC1AVR1 and Application Software Model SW044 were approved as a PMA supplement (S061) to the Micra system described above. The Micra AV includes an enhanced algorithm to provide AV synchronous pacing.

In November 2021, the U.S. FDA issued a letter to health care providers regarding the risk of major complications related to cardiac perforation during implantation of leadless pacing systems.[24] Specifically, the FDA states that "real-world use suggests that cardiac perforations associated with Micra leadless pacemakers are more likely to be associated with serious complications, such as cardiac tamponade or death, than with traditional pacemakers."

Aveir™ DR Leadless Pacemaker system (Abbott)

In March 2022, the Aveir™ VR Leadless Pacemaker was approved by the U.S. FDA through the premarket approval process for use in patients with bradycardia and:

- normal sinus rhythm with only rare episodes of A-V block or sinus arrest
- chronic atrial fibrillation
- severe physical disability.

Rate-modulated pacing is indicated for patients with chronotropic incompetence, and for those would benefit from increased stimulation rates concurrent with physical activity.

In June 2023, the Aveir™ DR Leadless Pacemaker system was approved by the FDA through the premarket approval process. The device is indicated for management of one or more of the following permanent conditions:

- syncope
- pre-syncope
- fatigue
- disorientation.

The device has multiple pacing functions including rate-modulated pacing, atrial pacing, ventricular pacing and dual chamber pacing. Each function has specific indications:

Rate-Modulated Pacing is indicated for patients with chronotropic incompetence, and for those who would benefit from increased stimulation rates concurrent with physical activity.

Atrial Pacing is indicated for patients with:

- Sinus node dysfunction and normal AV and intraventricular conduction systems

Ventricular Pacing is indicated for patients with:

- Significant bradycardia and normal sinus rhythm with only rare episodes of AV block or sinus arrest
- Chronic atrial fibrillation
- Severe physical disability

Dual-Chamber Pacing is indicated for patients exhibiting:

- Sick sinus syndrome
- Chronic, symptomatic second- and third-degree AV block
- Recurrent Adams-Stokes syndrome
- Symptomatic bilateral bundle branch block when tachyarrhythmia and other causes have been ruled out.

MR Conditional: The Aveir Leadless Pacemaker is conditionally safe for use in the MRI environment and according to the instructions in the MRI-Ready Leadless System Manual.

EVIDENCE SUMMARY

Conventional pacemaker systems have been in use for over 50 years and current technology has matured with significant similarities in designs across models. Extensive bench testing

data with conventional pacemakers and a good understanding of operative and early postimplant safety and effectiveness are available, which limits the need for clinical data collection to understand their safety and effectiveness with regard to implantation, tip fixation, electrical measures, and rate response. As such, a randomized controlled trial comparing the leadless pacemakers with conventional pacemakers was not required by the Food and Drug Administration (FDA).

VENTRICULAR PACING FOR INDIVIDUALS WHO ARE MEDICALLY ELIGIBLE FOR A CONVENTIONAL PACING SYSTEM

Micra™ Leadless Pacemaker

Pivotal Trial

The pivotal investigational device exemption (IDE) trial was a prospective single cohort study enrolled 744 patients with a class I or II indications for implantation of a single-chamber ventricular pacemaker based on national guidelines. Details on the design[25], and results of the IDE trial have been published.[26-28] Trial characteristics and results at six months are summarized in Tables 2 and 3, respectively. System performance from the pivotal trial has been published,[29] but results are not discussed further.

Of the 744 patients enrolled, implantation of the Micra™ transcatheter pacing system was successful in 719 (99.2%) of the 725 patients who underwent the procedure. The demographics of the trial population were typical for a single-chamber pacemaker study performed in the U. S., with 42% being female and the average age was 76 years. Sixty-four percent had a pacing indication associated with persistent or permanent atrial arrhythmias, 72.6% had any atrial fibrillation at baseline, and 27.4% did not have a history of atrial fibrillation. Among those 27.4% (n =199) without atrial fibrillation, 16.1% (n =32) had a primary indication of sinus bradycardia and 3.5% (n =7) had a primary indication of tachycardia-bradycardia.[28]

The IDE trial had two primary endpoints related to safety and efficacy. The trial would meet its safety endpoint if the lower bound of the 95% confidence interval (CI) for the rate of freedom from major complications related to the Micra™ transcatheter pacing system or implantation procedure exceeded 83% at six months. Major complications were defined as those resulting in any of the following; death, permanent loss of device function due to mechanical or electrical dysfunction of the device (e.g., pacing function disabled, leaving device abandoned electrically), hospitalization, prolonged hospitalization by at least 48 hours, or system revision (reposition, replacement, explant).[1] The trial would meet its efficacy endpoint if the lower bound of the 95% CI for the proportion of patients with adequate pacing capture thresholds (PCT) exceeded 80% at six months. PCT as an effectiveness objective is a common electrical measure of pacing efficacy and is consistent with recent studies. Pacing capture threshold measured in volts is defined as the minimum amount of energy needed to capture the myocardial tissue electrically. Unnecessary high pacing output adversely shortens the battery life of the pacemaker and is influenced by physiologic and pharmacologic factors.[1] As per the FDA, demonstrating that “PCT is less than 2 Volts for the vast majority of subjects will imply that the Micra™ system will have longevity similar to current pacing systems since Micra’s capture management feature will nominally set the safety margin to 0.5 Volts above the PCT with hourly confirmation of the PCT.”[1]

Safety and efficacy results of the IDE trial are summarized in Table 3. At six months, the trial met both of its efficacy and safety primary endpoints including freedom from major complications related to the system or procedure in 96.0% of the patients (95% CI 93.9% to 97.3%), compared with a performance goal of 83%, and an adequate pacing capture threshold in 98.3% of the patients (95% CI 96.1% to 99.5%), compared with a performance goal of 80%.[28]

Quality of life results of the IDE trial were published in 2018. At baseline and 12 months, 702 (98%) and 635 (88%) participants completed the 36-Item Short Form questionnaire, respectively.[27] The mean 36-Item Short Form Physical Component Scale at baseline was 36.3 (standard deviation [SD] 9.0) and the mean 36-Item Short Form Mental Component Scale was 47.3 (SD 12.5); the general population mean for both scores is 50. Both the Physical Component Scale and Mental Component Scale improved at 12 months post-implant to a mean Physical Component Scale score of 38.6 (SD 9.4, $p< 0.001$) and a mean Mental Component Scale score of 50.7 (SD 12.2, $p< 0.001$) compared with baseline.

IDE trial results were compared post hoc with a historical cohort of 2,667 patients generated from six previous pacemaker studies, conducted between 2005 and 2012 by Medtronic, that evaluated the performance requirement at six months postimplant of right ventricle pacing leads (single-chamber rates obtained by excluding any adverse events only related to the right atrial lead from the analysis). The Micra™ device was associated with fewer complications than the historical control (4.0% vs 7.4%, hazard ratio [HR], 0.49, 95% CI 0.33 to 0.75, p=0.001).[28] Because there were differences in baseline patient characteristics between the two cohorts (patients in the historical cohort were younger and had a lower prevalence of coexisting conditions vs the IDE trial), an additional propensity-matched analysis was conducted. It showed similar results (HR 0.46, 95% CI 0.28 to 0.74). As per the FDA, the lower rate of major complications with the Micra™ device was driven by reductions in access site events (primarily implant site hematoma and implant site infections), pacing issues (primarily device capture and device pacing issues), and fixation events (there was no device or lead dislodgements in the Micra™ IDE trial).[13]

While the overall rate of complications was low, the rate of major complications related to cardiac injury (i.e., pericardial effusion or perforation) was higher in the Micra™ IDE trial than in the six reference Medtronic pacemaker studies (1.6% vs. 1.1%, p=0.288).[13] Thus, there appears to be a trade-off between types of adverse events with the Micra™ transcatheter pacing system and conventional pacemakers. While adverse events related to leads and pocket are eliminated or minimized with the Micra™ device, certain adverse events (e.g., groin vascular complications, vascular or cardiac bleeding) occur at a higher frequency or are additive (new events) compared with conventional pacemakers. Of these, procedural complications (e.g., acute cardiac perforations) that were severe enough to result in tamponade and emergency surgery were most concerning.[13]

In addition to lack of adequate data on long-term safety, effectiveness, reliability, and incidence of late device failures and battery longevity, there is also inadequate clinical experience with issues related to devices that have reached end-of-life, including whether to extract or leave the device in situ and possible device-device interactions.[30] There are limited data on device-device interactions (both electrical and mechanical) that may occur when there is a deactivated Micra™ device alongside another leadless pacemaker or when a leadless pacemaker and transvenous device are both present. Even though there have only been few device retrievals and very limited experience with the time course of encapsulation of these devices in humans,

it is highly likely that these devices will be fully encapsulated by the end of its typical battery life, and therefore device retrieval is unlikely.[30] Current recommendations for end-of-device-life care for a Micra™ device may include the addition of a replacement device with or without explantation of the Micra™ device, which should be turned off.[31]

Grubman (2017) reported on system revisions including patients from the IDE study (n=720) and the Micra Transcatheter Pacing System Continued Access Study (n=269).[32] The Continued Access study was conducted to allow for continued access of the Micra™ in the same centers as the IDE study while the device was pending the FDA approval. The mean follow-up duration was 13 months (16 months in the IDE patients and two months in the continued access patients). There were 11 system revisions in 10 patients, corresponding to a 1.4% (95% CI 0.7% to 2.6%) actuarial rate of revisions through 24 months. Micra™ was disabled and left in situ in 7 of 11 revisions including five patients in which there was no retrieval attempt, one patient in which retrieval was aborted because of fluoroscopy failure, and one patient in which retrieval was unsuccessful because of inability to dislodge the device. There were three percutaneous retrievals and one retrieval during surgical valve replacement. There were no complications associated with retrievals. The report indicates that there when a transvenous system was implanted with a deactivated Micra™, there were no reported interactions between the two systems, although it is not clear how often this occurred. In the historical controls from the IDE study, there were 123 revisions in 117 patients through 24 months (actuarial rate 5.3%, 95% CI 4.4% to 6.4%). Using propensity score matching, the reduction in system revisions for Micra™ compared to historical controls was significant (HR 0.27, 95% CI 0.14 to 0.54, p<0.001).

Micra™ Post-approval Experience

Three year outcomes from the Micra Coverage with Evidence Development study were published by Crossley (2023).[33] Patients implanted with leadless pacemakers had a 32% lower rate of chronic complications (HR, 0.68; 95% CI, 0.59 to 0.78; p<.001) and a 41% lower rate of any reinterventions compared to patients receiving a transvenous pacemaker (HR, 0.59; 95% CI, 0.44 to 0.78; p=.0002). Use of a leadless system was also associated with a 49% lower rate (p=.01) of upgrades to a dual-chamber system and a 35% lower rate (p=.002) of upgrades to cardiac resynchronization therapy. Heart failure hospitalizations at three years were slightly, but significantly lower in adjusted time-to-event models (HR, 0.90; 95% CI, 0.83 to 0.97; p=.005) in patients receiving a leadless system. All-cause mortality rates at three years between leadless and transvenous systems were not significantly different after accounting for differences in baseline characteristics (HR, 0.97; 95% CI, 0.92 to 1.03; p=.32). No significant differences in the composite endpoint of time to heart failure hospitalization or death were observed for the original full cohort (p = 0.28) or in a subgroup of patients without a history of heart failure (p = 0.98).

Boveda (2023) published a study comparing clinical outcomes between leadless pacemakers (leadless-VVI) and transvenous ventricular pacemakers (transvenous ventricular permanent-VVI) in subgroups of patients at higher risk of pacemaker complications. [34] This study is based on the Micra Coverage with Evidence Development (CED) study. Patients from the Micra CED study were considered in a high-risk subgroup if they had a diagnosis of chronic kidney disease Stages 4-5 (CKD45), end-stage renal disease, malignancy, diabetes, tricuspid valve disease (TVD), or chronic obstructive pulmonary disease (COPD) 12 months prior to pacemaker implant. A pre-specified set of complications and reinterventions were identified using diagnosis and procedure codes. Competing risks models were used to compare

reinterventions and complications between leadless-VVI and transvenous-VVI patients within each subgroup; results were adjusted for multiple comparisons. A post hoc comparison of a composite outcome of reinterventions and device complications was conducted. Out of 27 991 patients, 9858 leadless-VVI and 12 157 transvenous-VVI patients have at least one high-risk comorbidity. Compared to transvenous-VVI patients, leadless-VVI patients in four subgroups [malignancy, HR 0.68 (0.48-0.95); diabetes, HR 0.69 (0.53-0.89); TVD, HR 0.60 (0.44-0.82); COPD, HR 0.73 (0.55-0.98)] had fewer complications, in three subgroups [diabetes, HR 0.58 (0.37-0.89); TVD, HR 0.46 (0.28-0.76); COPD, HR 0.51 (0.29-0.90)) had fewer reinterventions, and in four subgroups (malignancy, HR 0.52 (0.32-0.83); diabetes, HR 0.52 (0.35-0.77); TVD, HR 0.44 (0.28-0.70); COPD, HR 0.55 (0.34-0.89)] had lower rates of the combined outcome. ClinicalTrials.gov ID NCT03039712.

The FDA approval of the Micra™ transcatheter pacing system was contingent on multiple post-approval studies to provide reasonable assurance of continued safety and effectiveness of the device. Among these, the Micra Transcatheter Pacing System Post-Approval Study, a global, prospective, observational, multicenter study, enrolled 1,830 patients to collect data on 1,741 patients to estimate the acute complication rate within 30 days of the implant, 500 patients to estimate the nine-year complication-free survival rate, and a minimum of 200 patients with a Micra™ device revision for characterizing device end of service.[1] As per the protocol, if a subsequent device is placed and the Micra™ is deactivated or explanted, Medtronic would contact the implanting center and request the patient's clinical data concerning the revision. All such data would be summarized, including the type of system revision, how the extraction was attempted, success rate, and any associated complications.[30]

Study characteristics and results at one year (reported in the FDA documents and published) are summarized in Table 2 and 3, respectively. The post-approval study completed enrollment in early March 2018. The definition of a major complication in the post-approval study was the same as the Micra IDE trial. Although some patients who participated in the IDE study consented to also participate in the PAR study, the publication excludes those patients from analysis and therefore includes an independent population. Results summarized in Table 3 summarize the data at 30 days published by Roberts (2017)[35] and El-Chami (2018),[36, 37] with a mean follow-up of 6.8 months for 1,817 patients, of whom 465 patients had a follow-up for more than one year.

At 30 days, the major complication rate was 1.51% (95% CI 0.78 to 2.62%). The major complication rate was lower in the post-approval study than in the IDE trial (odds ratio, 0.58, 95% CI 0.27 to 1.25) although this did not reach statistical difference. The lower rate of major complications was associated with a decrease in events that led to hospitalization, prolonged hospitalization, or loss of device function in the post-approval study compared with the IDE trial.[35] A subsequent subgroup analysis of patients who did not receive perioperative anticoagulation treatment, who received interrupted anticoagulation treatment, or who received continuous anticoagulation treatment did not find a significant difference in rates of acute major complications according to anticoagulation strategy (3.1%, 2.6%, and 1.5%, respectively, p=0.29). The most common major complication was pacing problems, including elevated threshold and device capturing issues.[38] A subgroup analysis of patients treated with and without atrioventricular node ablation (AVNA) at the time of Micra™ implantation identified a significantly higher risk of major complications at both 30 days (7.3% versus 2.0%, p<0.001) and 36 months (HR 3.81, 95% CI 2.33 to 6.23, p<0.001) in the AVNA group versus those without AVNA.[39]

After a mean follow-up of 6.8 months, the estimated major complication rate at 12 months was 2.7% (95% CI 2.0% to 3.7%), corresponding to 46 major complications in 41 patients, the majority of which (89%) occurred within 30 days of implantation. The major complications included 14 device pacing issue events, 11 events at the groin puncture site, eight cardiac effusion/perforation events, three infections, one cardiac failure event, one cardiomyopathy event, and one pacemaker syndrome event. Authors compared these results with the same historical cohort of 2,667 patients used in the IDE trial and reported a 63% reduction in the risk for major complications through 12 months with the Micra™ transcatheter pacing system relative to conventional pacemakers (HR 0.37, 95% CI 0.27 to 0.52). Additionally, the risk for major complications was lower in the Micra™ post-approval study than in the IDE trial but it was a statistically significant difference (HR 0.71, 95% CI 0.44 to 1.1).[36] The reduction in major complications compared to historical controls was primarily driven by a significant 74% (95% CI 54 to 85, p=0.0001) relative risk reduction in system revisions and 71% (95% CI 51 to 83, p=0.0001) relative risk reduction in hospitalizations. The reduction in risk compared to the IDE trial was driven by significantly lower pericardial effusion rates in the post-approval study.

Piccini (2021) published initial data from the ongoing Longitudinal Coverage with Evidence Development Study on Micra Leadless Pacemakers (Micra CED).[40] Patients implanted between March 2017 and December 2018 were identified and included from a fee-for-service population with at least 12 continuous months of Medicare enrollment prior to device implantation. A total of 5,746 patients with single-chamber leadless Micra™ pacemakers and 9,662 patients with transvenous pacemakers were analyzed. Patients with a Micra™ pacemaker were more likely to have end-stage kidney disease (p<0.001) and a higher mean Charlson Comorbidity Index score (5.1 versus 4.6, p<0.001). The unadjusted acute 30-day complication rate was higher in the Micra™ subgroup (8.4% versus 7.3%, p=0.02), but no significant difference was found following adjustment for patient characteristics (p=0.49). Pericardial effusion and/or perforation within 30 days of implantation was significantly higher in the Micra™ population in the adjusted model (0.8% versus 0.4%, p=0.004). Patients with Micra™ pacemakers had a 23% lower risk of complications at six months compared to patients receiving a transvenous pacemaker (HR 0.77, 95% CI 0.62 to 0.96, p=0.02) and a 37% reduction in rates of device revision after adjustment for patient baseline characteristics. The 30-day all-cause mortality rate was not significantly different between groups in both unadjusted (p=0.14) and adjusted analyses (p=0.61). The study is ongoing with an estimated study completion date of June 2025. Study characteristics and results are summarized in Tables 2 and 3.

El-Chami (2022) subsequently compared reinterventions, chronic complications, and all-cause mortality at two years in patients implanted with the Micra™ leadless pacemaker or a transvenous pacemaker in the Micra™ Coverage with Evidence Development study.[41] Patients implanted with leadless (n=6,219) or transvenous pacemakers (n=10,212) were identified from Medicare claims data and compared contemporaneously. Patients receiving leadless pacemakers had higher rates of end-stage renal disease (12.0% versus 2.3%) and a higher Charlson comorbidity index (5.1 versus 4.6). Patients with leadless pacemakers received 37% fewer reinterventions (adjusted HR 0.62, 95% CI 0.45 to 0.85, p =0.003), defined as system revision lead revision or replacement, system replacement, system removal, or system switch or upgrade to an alternative device. Patients implanted with leadless pacemakers also experienced fewer chronic complications (2.4% versus 4.8%, adjusted HR 0.69, 95% CI 0.60 to 0.81, p<0.0001). However, patients receiving leadless pacemakers experienced significantly more other complications, driven by higher rates of pericarditis (adjusted, 1.6% versus 0.8%, p<0.0001). Adjusted all-cause mortality at two years was not

significantly different between groups (adjusted HR 0.97, 95% CI 0.91 to 1.04, p=0.37) despite the higher comorbidity index in patients implanted with a Micra™ device. Study interpretation is limited by reliance on claims data. It is unclear whether all patients receiving leadless devices were considered medically eligible for transvenous devices. Study characteristics and results are summarized in Tables 2 and 3.

Hauser (2021) analyzed the Food and Drug Administration's Manufacturers and User Facility Device Experience (MAUDE) database to capture major adverse clinical events (MACE) associated with the Micra™ device compared to the Medtronic CapSureFix transvenous pacing system.[42] In a search of reports from 2016 through 2020, 363 MACE and 960 MACE were identified for the Micra™ and CapSureFix devices, respectively. For the Micra™ device, significantly higher rates of death (26.4% versus 2.4%, p<0.001)), cardiac tamponade (79.1% versus 23.4%; p<.001), and rescue thoracotomy (27.3% versus 5.2%; p<.001) were reported. Micra™ patients were more likely to require cardiopulmonary resuscitation (21.8% versus 1.1%) and to suffer hypotension or shock (22.0% versus 5.8%) compared to CapSureFix recipients (p<0.001). While the overall incidence of myocardial and vascular perforations and tears that may result in cardiac tamponade and death in Micra™ recipients is estimated to be low (<1%), the authors note that Micra™ patients were more likely to survive these events if they received surgical repair (p=0.014). In a subsequent analysis of the MAUDE database focused on rates of Micra™ perforations from 2016 to 2021, Hauser (2022) identified 563 perforations reported within 30 days of implant, resulting in 150 deaths (27%), 499 cardiac tamponades (89%), and 64 pericardial effusions (11%).[43] Emergency surgery was required in 146 patients (26%). Half all perforations were associated with 139 device problems (25%), 78 operator use problems (14%), and 62 combined device and operator use problems (11%). The most common device problem leading to redeployment were non-capture or inadequate electrical values that required implantable pulse generator recapture and reimplantation or replacement. No device or operator use problems were identified for the remaining 282 perforations (50%), but these were associated with 78 deaths, 245 tamponades, and 57 emergency surgeries. The authors concluded that Micra™ implantation should be confined to specialized centers capable of managing emergency complications and that a risk score for perforation should be developed and validated. Importantly, these analyses are limited by the passive nature of the FDA's post-market device surveillance system, which may not capture all voluntary reports from health care professionals, consumers, and patients. Such analyses carry a high risk of ascertainment bias which may lead to overestimation of the true prevalence of adverse events.

Three year outcomes from the Micra Coverage with Evidence Development study were published by Crossley (2023).[44] Patients implanted with leadless pacemakers had a 32% lower rate of chronic complications (HR, 0.68; 95% CI, 0.59 to 0.78; p<.001) and a 41% lower rate of any reinterventions compared to patients receiving a transvenous pacemaker (HR, 0.59; 95% CI, 0.44 to 0.78; p=.0002). Use of a leadless system was also associated with a 49% lower rate (p=.01) of upgrades to a dual-chamber system and a 35% lower rate (p=.002) of upgrades to cardiac resynchronization therapy. Heart failure hospitalizations at 3 years were slightly, but significantly lower in adjusted time-to-event models (HR, 0.90; 95% CI, 0.83 to 0.97; p=.005) in patients receiving a leadless system. All-cause mortality rates at 3 years between leadless and transvenous systems were not significantly different after accounting for differences in baseline characteristics (HR, 0.97; 95% CI, 0.92 to 1.03; p=.32). No significant differences in the composite endpoint of time to heart failure hospitalization or death were observed for the original full cohort (p=.28) or in a subgroup of patients without a history of

Aveir™ Leadless Pacemaker

Pivotal Trial

The pivotal investigational device exemption (IDE) trial of the Aveir™ leadless pacemaker (LEADLESS II - Phase 2) was a multicenter, prospective single cohort study enrolling 200 patients with a guidelines-based indication for single-chamber pacing.[23] Primary results from the IDE trial have been summarized in a published research correspondence[20] and FDA documents.[23] Trial characteristics and results through six months are summarized in Tables 2 and 3, respectively.

Implantation of the Aveir™ leadless pacing system was successful in 196/200 (98%) trial subjects (mean age 75.6 years, 37.5% female). The primary indication for pacing was chronic atrial fibrillation with 2nd or 3rd degree atrioventricular block (52.5%). The trial had two primary endpoints related to safety and efficacy. The trial would meet its safety endpoint if the lower bound of the 97.5% CI for the complication-free rate exceeded 86% at six weeks. A complication was defined as a device-or-procedure-related serious adverse event, including those that prevented initial implantation. The trial would meet its efficacy endpoint if the lower bound of the 97.5% CI for the composite success rate exceeded 85% at six weeks. The confirmatory effectiveness endpoint was considered met if the pacing threshold voltage is ≤ 2.0 V at 0.4 ms and the sensed R-wave amplitude is either ≥ 5.0 mV at the six-week visit or ≥ the value at implant.

Safety and efficacy results of the Aveir™ IDE trial are summarized in Table 3. At six weeks, the trial met both of its confirmatory safety and efficacy endpoints, including freedom from device-or-procedure-related complications in 96% of patients (95% CI 92.2% to 98.2%), compared with a performance goal of 86%, and a composite success rate of 95.9% of patients (95% CI 92.1% to 98.2%), compared with a performance goal of 85%. The six-month complication-free rate was 94.9% (95% CI 90.0% to 97.4%). The most frequent complications included three cardiac tamponade events and three premature deployment events. The rate of cardiac perforation/tamponade/pericardial effusion was 1.5%. No dislodgement events were reported in the Aveir™ cohort.

Confirmatory secondary endpoints included assessment of an appropriate and proportional rate-response during a Chronotropic Assessment Exercise Protocol (CAEP) exercise protocol and an estimated two-year survival rate. The CAEP assessment was initiated in 23 subjects, of which 17 were considered analyzable. The rate-response slope was 0.93 (95%CI 0.78 to 1.08), which fell within the prespecified range of 65% to 135%. The estimated two-year survival rate based on the Nanostim Phase 1 cohort (n=917) was 85.3% (95% CI 82.7% to 87.4%), which exceeded the performance goal of 80%.[44]

Table 2. Summary of Key Nonrandomized Trial Characteristics

Study; Trial	Study; Type	Country	Dates	1. Participants	Treatment	Follow-Up, mo

Aveir™ Postapproval Experience

Continued FDA approval of the Aveir™ pacing system is contingent on the results of the Aveir VR Real-World Evidence Study.[46] This post-approval study is designed to evaluate the long-term safety of the Aveir™ device in a real-world sample of 2,100 participants. Both acute and long-term safety will be evaluated as post implant complication-free rates at 30-days and 10-years. Ten-year reports are due in March 2032.

Reddy (2023) published the 1-year outcomes from the LEADLESS II IDE trial. [44] Safety and efficacy endpoints at one year were reported. Freedom from device-or-procedure-related complications was reported in 93.2% of patients (95% CI, 88.7% to 95.9%), compared with a performance goal of 83%, and a composite success rate of 95.1% (95% CI, 91.2% to 97.6%), compared with a performance goal of 80%. Most complications (11 of 15) were reported within the first three days post-implantation (four cardiac tamponade events, three premature deployments with or without device migration, two access site bleeding events, one pulmonary embolism, and one case of deep vein thrombosis. Four long-term complications were reported between 3.8 and 9.5 months post-implantation (two cases of heart failure and two cases of pacemaker-induced cardiomyopathy. The investigators estimated the mean device battery longevity is 17.6 ± 6.6 years (95% CI, 16.6 to 18.6).

Garg (2023) published evaluated the safety profile and assessed the complications of the Aveir™ leadless pacing system.[47] A MAUDE database search was conducted for reports received post-FDA approval to capture all adverse events. A total of 64 entries were included. The most commonly encountered problem was high threshold/noncapture (28.1%, 18 events), followed by stretched helix (17.2%, 11 events) and device dislodgement (15.6%, ten events-5 intraprocedural, while five in the postoperative Day 1). Other reported events included high impedance (14.1%, nine events), sensing issues (12.5%, eight events), bent/broken helix (7.8%, five events), premature separation (4.7%, three events), interrogation problem (3.1%, two events), low impedance (3.1%, two events), premature battery depletion (1.6%, one event) and inadvertent MRI mode switch (1.6%, one event) and miscellaneous (15.6%, n = 10). There were eight serious patient injury events-pericardial effusion requiring pericardiocentesis (7.8%, five events) due to cardiac perforation that resulted in two deaths (3.1%) followed by sustained ventricular arrhythmias (4.6%, n = 3).

Tokavanich (2023) published a retrospective case study review comparing the implant efficiency and clinical performance of the Aveir™ VR Leadless Pacemaker (LP) compared to the Micra™ VR LP.[48] A total of 67 patients were included in the study. The Micra™ VR group had shorter time in the electrophysiology lab (41 ± 12 vs. 55 ± 11.5 min, $p = 0.008$) and shorter fluoroscopic time (6.5 ± 2.2 vs. 11.5 ± 4.5 min, $p < 0.001$) compared to the Aveir™ VR group. The Aveir™ VR group had a significantly higher implant pacing threshold compared to the Micra™ VR group (0.74 ± 0.34 mA vs. 0.5 ± 0.18 mA at pulse width 0.4 ms, $p < 0.001$), but no difference was found at three and six months. There was no significant difference in the R-wave sensing and impedance and pacing percentage at implantation, three and six months. Complications of the procedure were rare. The mean projected longevity of the Aveir™ VR group was longer than the Micra™ VR group (18.8 ± 4.3 vs. 7.7 ± 0.75 years, $p < 0.001$). The authors conclude that Implantation of the Aveir™ VR required longer laboratory and

fluoroscopic time, but showed longer longevity at six months follow-up, compare to the Micra™ VR. Limitations include retrospective study design at a single site, small sample size and lack of long-term data.

Shantha (2023) published a retrospective case study review to compare effectiveness and safety between the Aveir-VR and Micra-VR.[49] The first patients (n= 25) to undergo Aveir-VR implant at our institution between June and November 2022, were compared to 25 age- and sex-matched patients who received MICRA-VR implants. In both groups, mean age was 73 years and 48% were women. Leadless pacemaker implant was successful in 100% of patients in both groups. Single attempt deployment was achieved in 80% of AVEIR-VR and 60% of Micra-VR recipients ($p = 0.07$). Fluoroscopy, implant, and procedure times were numerically longer in the Aveir-VR group ($p > 0.05$). No significant periprocedural complications were noted in both groups. Incidence of ventricular arrhythmias were higher in the Aveir-VR group (20%) compared to the Micra-VR group (0%) ($p = 0.043$). At two and eight weeks follow-up, device parameters remained stable in both groups with no device dislodgements. The estimated battery life at 8 weeks was significantly longer in the Aveir-VR group (15 years) compared to the Micra-VR group (8 years) ($p = 0.047$). The authors reported that it took three to four Aveir-VR implants for the learning curve for successful implantation to reach steady state.The authors conclude that the initial experience with Aveir-VR show that it has comparable effectiveness and safety to Micra-VR. Limitations include retrospective study design at a single site, small sample size and lack of long-term data.

The current evidence on the use of the Aveir™ device remains limited by a lack of adequate data on quality of life, long-term safety, effectiveness, reliability, and incidence of late device failures. The Aveir™ pivotal prospective cohort study primary safety and efficacy outcomes at six weeks exceeded performance goals for complication-free rate and composite success rate (96.0% and 95.9%, respectively). Results at six months were similar and at one year were 93.2% and 91.5%, respectively. Incidence of major complications at one year was 6.7% compared to 4.0% in the Micra pivotal trial. The two-year survival estimate of 85.3% is based on Phase 1 performance with the predecessor Nanostim device. While the device is designed to be retrieved when therapy needs evolve or the device needs to be replaced, there is currently inadequate clinical experience with issues related to devices that have reached end-of-life. Two small retrospective case study reports comparing the Aveir device with the Micra device. Both reported fluoroscopy, implant, and procedure times were longer for the Aveir device. Other outcomes were similar. Through six months follow-up , device parameters remained stable in both groups with no device dislodgements. Long term survival data for the currently marketed version of the Aveir™ device has not been reported.

Section Summary: Ventricular Pacing for Individuals Who Are Medically Eligible for a Conventional Pacing System

The evidence for use of the Micra™ transcatheter pacing system consists of a pivotal prospective cohort study, a post-approval prospective cohort study, a Medicare registry, and a retrospective FDA database analysis. Results at six months and one year for the pivotal study reported high procedural success (>99%) and device effectiveness (pacing capture threshold met in 98% patients). Most of the system- or procedural-related complications occurred within 30 days. At one year, the incidence of major complications did not increase substantially from six months (3.5% at six months vs 4% at one year). Results of the post-approval study were consistent with a pivotal study and showed a lower incidence of major complications up to 30 days post-implantation and one year (1.5% and 2.7%, respectively). In both studies, the point

estimates of major complications were lower than the pooled estimates from six studies of conventional pacemakers used as a historical comparator. Results of the CMS study indicated that acute complication rates were similar for the Micra™ and transvenous pacemakers, after adjustment for baseline and encounter differences, and there was a slightly lower six-month complication rate for the leadless system. While the Micra™ transcatheter pacing system eliminates adverse events associated with lead and pocket issue, its use results in additional complications related to the femoral access site (groin hematomas, access site bleeding) and implantation and release of the device (traumatic cardiac injury). Initial data from a Medicare registry found a significantly higher rate of pericardial effusion and/or perforation within 30 days in patients with the leadless Micra™ pacemaker compared to patients who received a transvenous device; overall six-month complications rates were significantly lower in the Micra™ group in the adjusted analysis (p=0.02). In a real-world study of Medicare patients, 41% lower rate of reinterventions and a 32% lower rate of chronic complications compared with transvenous pacing, with no significant difference in adjusted all-cause mortality at 3 years despite the higher comorbidity index for patients implanted with a Micra device. However, patients receiving the Micra device experienced significantly more other complications, driven by higher rates of pericarditis. No significant differences were noted in the composite endpoint of time to heart failure hospitalization or death for the full cohort (p=.28) or the subgroup without a history of heart failure (p=.98) It is also unclear whether all patients were considered medically eligible for a conventional pacing system. A 2021 analysis of the FDA Manufacturer's and User Facility Device Experience (MAUDE) database revealed significantly higher rates of death, cardiac tamponade, and rescue thoracotomy in Micra™ recipients compared to patients implanted with a transvenous pacemaker (p<0.001), although this study is limited by potential risk of ascertainment bias. A single-arm study of the Micra AV device reported that 85.2% of individuals with complete AV block and normal sinus rhythm successfully achieved a >70% resting AV synchrony (AVS) rate at 1 month postimplant and that AVS rates could be further enhanced with additional device programming. However, clinically meaningful rates of AVS are unknown. Longer-term device characterization is planned in the Micra AV Post-Approval Registry through 3 years.

The evidence for the use of the Aveir™ transcatheter leadless pacing system consists of a pivotal prospective cohort study. Primary safety and efficacy outcomes at six weeks exceeded performance goals for complication-free rate and composite success rate (96.0% and 95.9%, respectively). Results at six months were similar and at one year were 93.2% and 91.5%, respectively. Incidence of major complications was comparable to rates observed in the Micra™ pivotal trial (4.0%). The two-year survival estimate of 85.3% is based on Phase 1 performance with the predecessor Nanostim device.

Considerable uncertainties and unknowns remain in terms of the durability of the devices and end-of-life device issues. Early and limited experience with the Micra™ device has suggested that retrieval of these devices is unlikely because in due course of time, the devices will be encapsulated. There are limited data on device-device interactions (both electrical and mechanical), which might occur when there is a deactivated Micra™ device alongside another leadless pacemaker or when a leadless pacemaker and transvenous device are both present. While the Aveir™ device is specifically designed to be retrieved when therapy needs evolve or the device needs to be replaced, clinical experience with device retrieval has not yet been reported.

OTHER INDICATIONS

Atrioventricular Synchronous pacing

Micra-AV

Wu (2023) published a systematic review and meta-analysis to examine the efficacy and safety of leadless pacemakers for atrioventricular synchronous pacing.[50] The primary efficacy outcome was atrioventricular synchrony after implantation, whereas the secondary efficacy outcome was the change in cardiac output represented by the left ventricular outflow tract velocity time integral (LVOT-VTI). The primary safety outcome was major complications related to the procedures and the algorithm. Eight published studies (464 participants) were included in the qualitative analysis. The pooled atrioventricular synchrony proportion was 78.9% (95% CI 71.9-86.0%), and a further meta-regression did not screen factors that contributed significantly to the heterogeneity. Additionally, a significant increase in atrioventricular synchrony of 11.3% (95% CI 7.0-15.7%, p < 0.01) was achieved in patients experiencing programming optimization. LVOT-VTI was significantly increased by 1.9 cm (95% CI 1.2-2.6, p < 0.01), compared with the VVI pacing mode. The overall incidence of complications was approximately 6.3%, with major complications related to the algorithm being extremely low. The authors conclude that the leadless pacemakers with atrioventricular synchronous pacing demonstrated favorable safety and efficacy. Future data on long-term performance are required.

Chinitz (2022) conducted a prospective, single-arm study (AccelAV) at 20 sites in the United States and Hong Kong to assess the efficacy of the Micra AV leadless pacemaker in promoting atrioventricular synchrony (AVS) in adults with a history of atrioventricular (AV) block (n=157).[51] This device uses an accelerometer and detection algorithm to mechanically sense atrial contractions to facilitate VDD pacing (ventricle pacing chamber, both atrium and ventricle are sensing chamber and mode of operation is dual (inhibited and triggered) and AVS in individuals with normal sinus function. Micra AV implantation and completion of the 1-month study visit was achieved by 139 individuals, of which 54 (mean age, 77 years; 55.6% female) comprised the intended use population with a predominant heart rhythm of complete AV block with normal sinus rhythm. The primary endpoint was the rate of AVS during a 20-minute resting period at 1 month postimplant in these patients. Atrioventricular synchronous pacing was defined as a ventricular marker preceding a P wave within 300 ms, regardless of the underlying cardiac rhythm. Secondary endpoints included stability of AVS during rest between one and three months, percent AVS during a 24-hr ambulatory period at one months, and change in stroke volume. Quality of life was also measured with the EQ-5D-3L health status assessment. At one month, AVS percentage at rest was 85.4% (95% CI, 81.1% to 88.9%; median, 90.0%) during VDD pacing, with 85.2% of patients achieving >70% resting AVS. At the 3-month visit, 37/54 remained in the same rhythm. Among these subjects, no significant change in AVS synchrony was detected (p=.43) between the 3-month (mean, 84.1%; 95% CI, 78.3% to 88.6%) and 1-month visits (mean, 84.1%; 95% CI, 81.2% to 89.9%). At the 1 month visit, average 24-hour ambulatory AVS was 74.5% (95% CI, 70.4% to 78.2%). EQ-5D-3L health status scores significantly improved by 0.07 points between baseline and 3 months (p = 0.031) among patients with complete AV block and normal sinus function. Ambulatory AVS percentage significantly increased from 71.9% to 82.6% (p < 0.001) in twenty patients who participated in a substudy at a mean follow-up of 9.5 months designed to characterize the impact of optimized device programming. Improvement in AVS was most evident during elevated sinus rates between 80 and 110 bpm. In the safety cohort (n=152), there were 14 major complications, including four pericardial effusions and two heart failure events. One pericardial effusion resulted in perforation and death in a 92-year-old woman with high

baseline risk. A second death was reported in an 83-year-old man at 127 days postimplant but was not considered system- or procedure-related. No device upgrades and one device explantation and replacement was reported during follow-up. Study interpretation is limited by lack of a comparator group and short duration of follow-up. The ongoing Micra AV Post-Approval Registry (NCT04253184) has follow-up planned through three years. The investigators also noted that the AVS percentage required to maintain a clinical benefit over time is unknown, but likely is not 100%.

VENTRICULAR PACING FOR INDIVIDUALS WHO ARE MEDICALLY INELIGIBLE FOR A CONVENTIONAL PACING SYSTEM.

Nonrandomized Controlled Trials

No studies that exclusively enrolled patients who were medically ineligible to receive a conventional pacing system were identified.

Micra™ Leadless Pacemaker

In the IDE trial, 6.2% or 45 patients received the Micra™ transcatheter pacing system because they were medically ineligible for a conventional pacing system due to compromised venous access, the need to preserve veins for hemodialysis, thrombosis, a history of infection, or the need for an indwelling venous catheter. A stratified analysis of these 45 patients was not presented in the published paper[28] or the FDA documents.[1, 13, 22, 30]

In the postapproval registry as an abstract, the authors reported stratified results for 105 of 1,820 patients who had previous cardiac implantable electronic device (CIED) infection.[36, 52] Of these, 83 patients (79%) were classified as medically ineligible to receive a conventional pacemaker in the opinion of the physician. A stratified analysis of these 83 patients was not presented in the publication. Trial characteristics and results are summarized in Tables 4 and 5, respectively. In this cohort of patients with CIED infection, the Micra™ device was implanted successfully in 104 patients and the previous CIED was explanted the same day as the Micra™ device was implanted in 37% of patients. Major complications were reported in 3.8% of patients with an average follow-up of 8.5 months. Ten deaths were reported (14% at 12 months) but none were related to the Micra™ transcatheter pacing system or the implantation procedure.

Garg (2020) performed a post-hoc, stratified analysis of data from the Micra™ clinical trials (Micra Post-Approval Registry, Micra Continued Access [CA] Study, Micra Transcatheter Pacing Study, Medtronic Product Surveillance Registry) based on whether the patient was deemed to be ineligible to receive a conventional pacemaker by the implanter.[53] Of the 2,817 patients that underwent an attempted implantation of a Micra™ device, 546 (19%) were considered to be precluded from receiving a transvenous permanent pacemaker, for reasons that included venous access issues or previous device infections. Compared with individuals that were not precluded from a transvenous device, the precluded patients had significantly higher acute mortality and total mortality at 36 months (2.75% vs 1.32%, p=0.022; and 38.1% versus 20.6%, p<0.001, respectively). The major complication rate was not significantly different between the groups. The majority of medically ineligible patients were enrolled in the CA and Post-Approval Registry studies, which unlike the IDE study, did not exclude patients with a life expectancy <12 months.

Table 4. Summary of Key Nonrandomized Trial Characteristics in Patients Ineligible for a Conventional Pacing System and/or Previous CIED Infection

Section Summary: Ventricular Pacing for Individuals Who Are Medically Ineligible for a Conventional Pacing System

No studies that exclusively enrolled patients who were medically ineligible for a conventional pacing system were identified. However, a subgroup of patients in whom the use of conventional pacemakers was precluded was enrolled in the pivotal and the postapproval trials of the Micra™ device. Information on the outcomes in these subgroups of patients from the postapproval study showed that Micra™ was successfully implanted in 98% of cases and safety outcomes were similar to the original cohort. Even though the evidence is limited, and long-term effectiveness and safety are unknown, the short-term benefits may outweigh the risks in the context of the life-saving potential of pacing systems in patients that are ineligible for conventional pacing systems.

USE OF LEADLESS PACEMAKERS EMERGENTLY

Systematic Reviews

Noor (2023) published a SR evaluating the feasibility and outcomes of emergency implantation of LPM in patients referred for urgent PM implantation.[54] In a total of four studies (1276 patients) of which 114 patients (8.9%) were implanted with leadless pacemakers (LPM) and the rest were implanted with either conventional PMs or some other alternatives. In the included studies, 468 (36.6%) patients were males. All four included studies were prospective cohort studies. The authors reported that LPM implantation demonstrated low procedural times, hospital stay, and fluoroscopy time but one study demonstrated more procedure time in an urgent setting, and pacing parameters were comparable in both comparison with other cardiac implantable electronic devices and elective LPM implantation. Quantative analysis was limited by the heterogeneity of studies and the small number of studies included. Other limitations included experience of the operators, possible selection bias. They conclude that randomized controlled trials are needed to evaluate safety and efficacy of LPMs in emergency settings.

DUAL CHAMBER LEADLESS PACEMAKERS

The Aveir DR i2i ™ is currently being evaluated in an open label prospective, multicenter, international, single-arm, pivotal investigational study designed to evaluate the clinical safety and efficacy of the Aveir DR leadless pacemaker in patients who were indicated for a dual-chamber bradycardia pacing pacemaker that stimulates the appropriate chamber of the heart when necessary or DDD(R).[55] The study was initiated February 2, 2022 and is estimated to be complete by November 2025. The primary completion date is September 2023. The study plan is to enroll up to 550 patients from up to 82 sites in the U.S., Canada, Europe and Asia-Pacific, and all patients will be followed for a minimum of 12 months post-implant. (ClinicalTrials.gov identifier NCT05252702).

Knop (2023) published a prospective, multicenter, single-group study to evaluate the safety and performance of a dual-chamber leadless pacemaker system.[56] Patients with a conventional indication for dual-chamber pacing were eligible for participation. The primary safety end point was freedom from complications (i.e., device- or procedure-related serious adverse events) at 90 days. The first primary performance end point was a combination of adequate atrial capture threshold and sensing amplitude at three months. The second primary performance end point was at least 70% atrioventricular synchrony at three months while the patient was sitting. Among the patients (n = 300) enrolled, 190 (63.3%) had sinus-node dysfunction and 100 (33.3%) had atrioventricular block as the primary pacing indication. The implantation procedure was successful (i.e., two functioning leadless pacemakers were implanted and had established implant-to-implant communication) in 295 patients (98.3%). A total of 35 device- or procedure-related serious adverse events occurred in 29 patients. The primary safety end point was met in 271 patients (90.3%; 95% confidence interval [CI], 87.0 to 93.7), which exceeded the performance goal of 78% ($p < 0.001$). The first primary performance end point was met in 90.2% of the patients (95% CI, 86.8 to 93.6), which exceeded the performance goal of 82.5% ($p < 0.001$). The mean (±SD) atrial capture threshold was 0.82 ± 0.70 V, and the mean P-wave amplitude was 3.58±1.88 mV. Of the 21 patients (7%) with a P-wave amplitude of less than 1.0 mV, none required device revision for inadequate sensing. At least 70% atrioventricular synchrony was achieved in 97.3% of the patients (95% CI, 95.4 to 99.3), which exceeded the performance goal of 83% ($p < 0.001$). This study was (Funded by Abbott Medical; Aveir DR i2i ClinicalTrials.gov number, NCT05252702.).

Section Summary

There is not enough evidence to support the use of dual chamber leadless pacemakers for any indication.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF CARDIOLOGY FOUNDATION, AMERICAN HEART ASSOCIATION, AND HEART RHYTHM SOCIETY

The American College of Cardiology Foundation, American Heart Association, and Heart Rhythm Society's (2012) focused update on device-based therapy of cardiac rhythm abnormalities incorporated into their joint 2008 guidelines for device-based therapy of cardiac rhythm abnormalities does not include recommendations on leadless cardiac pacemakers.[57]

In 2020, the Heart Rhythm Society (HRS), along with the International Society for Cardiovascular Infectious Diseases (ISCVID) and several other Asian, European and Latin American societies, endorsed the European Heart Rhythm Association (EHRA) international consensus document on how to prevent, diagnose, and treat cardiac implantable electronic device infections.[58] The consensus states that for patients at high risk of device-related infections, avoiding a transvenous system, and implanting an epicardial system, may be preferential. It makes the following statements regarding leadless pacemakers:

- "There is hope that 'leadless' pacemakers will be less prone to infection and can be used in a similar manner [as epicardial systems] in high-risk patients."
- "In selected high-risk patients, the risk of infection with leadless pacemakers appears low. The device also seems safe and feasible in patients with pre-existing CIED infection and after extraction of infected leads."

The Heart Rhythm Society and American College of Cardiology Foundation (2012) expert consensus statement on pacemaker device and mode selection did not include recommendations on leadless cardiac pacemakers.[59]

SUMMARY

There is enough research to show that Micra™ single-chamber transcatheter pacing system may improve health outcomes for patients with a guidelines-based indication for a ventricular pacing system who are medically ineligible for a conventional pacing system. Although evidence is limited and long-term effectiveness and safety are unknown, the short-term benefits may outweigh the risks, in the context of the life-saving potential of this pacing system for patients who are ineligible for conventional pacing systems. Therefore, this pacemaker system may be considered medically necessary for patients who meet the policy criteria.

There is not enough research to show that a leadless pacing system can improve health outcomes for patients who do not meet medical necessity criteria, including the use of the Aveir™ system or a non-FDA-approved system, or in patients who are eligible for a conventional pacing system. There is little evidence regarding the durability of devices, device end-of-life issues, and device-device interactions (both electrical and mechanical), which may occur when there is a deactivated leadless device alongside another leadless pacemaker or when a leadless pacemaker and transvenous device are both present. Therefore, a leadless pacemaker is considered investigational when criteria are not met.

There is not enough evidence to show that dual chamber leadless pacing systems can improve health outcomes for patients. There are currently no FDA approved dual chamber leadless pacemaker devices.

Last Review: March 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Lymphedema is an accumulation of fluid due to disruption of lymphatic drainage. Lymphedema can be caused by congenital or inherited abnormalities in the lymphatic system (primary lymphedema) but is most often caused by acquired damage to the lymphatic system (secondary lymphedema). Lipedema is a rare condition where increased fat tissue accumulates under the skin which causes non-pitting, bilateral swelling in the extremities.

MEDICAL POLICY CRITERIA

Note: Member contracts for covered services vary. Member contract language takes precedence over medical policy.

I. Liposuction or lipectomy to treat lipedema of the extremities may be considered **medically necessary** when all of the following are met (A.-G.):

   A. Surgical interventions are performed by hospital credentialed, board certified plastic surgeon; and

   B. The individual has a diagnosis of lipedema including all of the following clinical exam findings:

      1. Bilateral symmetric adiposity that is disproportionately affecting the

extremities with minimal involvement of the hands and feet; and

2. Non-pitting edema; and
3. Pain and tenderness on palpation of the affected areas; and
4. Negative Stemmer sign; and
5. Submission of photographs documenting the affected extremities requested for treatment and are consistent with the diagnosis of lipedema; and

C. There is documentation of significant physical functional impairment (e.g., difficulty ambulating or performing activities of daily living); and

D. The individual has not responded to at least three consecutive months of optimal medical management including complex decongestive therapy and compression therapy; and

E. For individuals with BMI greater than 35 kg/m^2, there has been a lack of effect on lipedema-affected areas of weight loss measures as documented in the medical records through nutrition and/or medical interventions with clinic visits over three consecutive months; and

F. The plan of care postoperatively is to continue to wear compression garments as instructed to maintain the benefits of treatment; and

G. The area requested to be treated has not previously been treated with liposuction or lipectomy.

II. Liposuction or lipectomy to treat lipedema for areas other than extremities (e.g., trunk or back) or when Criterion I. is not met is considered **investigational.**

III. Lymphatic physiologic surgery with or without a microscope performed during nodal dissection (e.g. axillary or groin) or breast reconstruction to prevent lymphedema (including, but not limited to, the Lymphatic Microsurgical Preventing Healing Approach) in individuals who are being treated for breast cancer is considered **investigational**.

IV. Liposuction or lipectomy to treat lymphedema (including, but not limited to, lipectomy, suction-assisted protein lipectomy, lipisuction, and lymph-sparing liposuction) is considered **investigational.**

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF DOCUMENTATION

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Documentation that surgery will be performed by hospital credentialed, board certified plastic surgeon

- Documentation supporting diagnosis of lipedema as defined by the policy criterion I.B.
- Documentation of specific significant physical functional impairment(s) including specific ADLs (e.g., walking, feeding, dressing/grooming, toileting, bathing, transferring).
- Documentation of no response to a minimum of three months of conservative therapy including compression therapy and complex decongestive therapy (CDT), which combines several approaches including manual lymph drainage (a massage technique), compression therapy, and physical mobilization.
- If the individual has a BMI greater than 35 kg/m^2, documentation of lack of effect of weight loss on lipedema-affected areas through nutrition and/or medical interventions with clinic visits over three consecutive months.
- Documentation of post-operative plan to include compression therapy.

BACKGROUND

LYMPHEDEMA

A diagnosis of secondary lymphedema is based on history (e.g., cancer treatment, trauma) and physical examination (localized, progressive edema and asymmetric limb measurements) when other causes of edema can be excluded. Imaging, such as magnetic resonance imaging, computed tomography, ultrasound, or lymphoscintigraphy, may be used to differentiate lymphedema from others causes of edema in diagnostically challenging cases.

Breast Cancer-Related Lymphedema

Breast cancer treatment is one of the most common causes of secondary lymphedema. Both the surgical removal of lymph nodes and radiotherapy are associated with development lymphedema in patients with breast cancer.

In a systematic review of 72 studies (N=29,612 women), DiSipio (2013) reported that approximately 1 in 5 women who survive breast cancer will develop arm lymphedema.[1] Reviewers reported that risk factors for development of lymphedema that had a strong level of evidence were extensive surgery (i.e., axillary-lymph-node dissection, greater number of lymph nodes dissected, mastectomy) and being overweight or obese.

Management and Treatment

Early and ongoing treatment of lymphedema is necessary. Conservative therapy may consist of several features depending on the severity of the lymphedema. Patients are educated on the importance of self-care including hygiene practices to prevent infection, maintaining ideal body weight through diet and exercise, and limb elevation. Compression therapy consists of repeatedly applying padding and bandages or compression garments. Manual lymphatic drainage is a light pressure massage performed by trained physical therapists or by patients designed to move fluid from obstructed areas into functioning lymph vessels and lymph nodes. Complete decongestive therapy is a multiphase treatment program involving all of the previously mentioned conservative treatment components at different intensities. Pneumatic compression pumps may also be considered as an adjunct to conservative therapy or as an alternative to self-manual lymphatic drainage in patients who have difficulty performing self-

manual lymphatic drainage. In patients with more advanced lymphedema after fat deposition and tissue fibrosis has occurred, palliative surgery using reductive techniques such as liposuction may be performed.

LIPEDEMA

Lipedema is a rare condition primarily seen in women where increased fat tissue accumulates under the skin which causes non-pitting, bilateral swelling typically seen in the lower extremities. Lipedema can also be seen in the upper extremities. The condition usually worsens gradually, although in some cases minor lipedema may stabilize. Lipedema is often painful and may be accompanied by easy bruising and joint problems. There is no known cause for lipedema.

Management and Treatment

Management of lipedema is complex and distinct from lymphedema. The proposed main conservative treatment is complete or complex decongestive therapy (CDT). CDT combines several approaches including manual lymph drainage (a massage technique), compression therapy, and physical mobilization. Liposuction has been proposed as an alternative treatment option for lipedema.

EVIDENCE SUMMARY

SURGICAL TREATMENT FOR LYMPHEDEMA

The purpose of physiologic microsurgery treatments and liposuction for lymphedema is to provide a treatment option that is an improvement on existing therapies such as conservative therapy with compression garments or bandages, manual lymph drainage or pneumatic pumps, and decongestive therapy. Both surgical treatment and radiotherapy for breast cancer can lead to lymphedema and is one of the most common causes of secondary peripheral lymphedema.

Multiple Techniques

Systematic Reviews

Meuli (2023) published an updated systematic review which included 150 studies with 6496 patients who received LVA or LVNT.[2] A qualitative summary was conducted initially to determine the three most frequently reported outcomes for which a pooled analysis was then conducted. The authors reported an overall pooled change in excess limb circumference of -35.6%, change in excess volume of -32.7%, and a change in the number of cutaneous infection episodes per year of -1.9. Although the authors reported positive findings in reducing volume, circumference, and infection, the included studies suffer from significant quality and study design limitations. There exists significant heterogeneity in sampling, outcomes, and staging in the included studies which further limits possible conclusions.

Coriddi (2020) reported on a systematic review of PROs following surgical treatment of lymphedema, including lymphovenous bypass and vascularized lymph node transfer (VLNT).[3] Overall, 32 studies were identified (details regarding study design were not reported) with follow-up ranging from approximately 4 months to 43 months. The number of patients with breast cancer-related lymphedema was not described. The study reported findings for both validated and non-validated instruments assessing quality of life; however, only 18 studies

(n=717 patients) reported individual patient data to permit quantitative assessment of the proportion of patients experiencing quality of life improvements. All studies showed an improvement in QOL ranging from 50% to 100%. Only one study used a validated instrument which demonstrated a 50% improvement in QOL.

Markkula (2019) published a Cochrane systematic review to assess and compare the efficacy of surgical interventions for the prevention of the development of lymphedema (LE) in the arm after breast cancer treatment and to assess and compare the efficacy of surgical interventions for the treatment of established LE in the arm after breast cancer treatment.[4] Reductive and reconstructive techniques were considered including liposuction, lymphaticovenular anastomoses (LVA), lymphatico-lymphatic bypass (LLB), and vascularized lymph node transfer (VLNT). Three studies which included two studies assessing the effectiveness of LVA as part of preventive management protocols in the prevention of breast cancer-related lymphedema and one study addressing the effectiveness of VLNT in the treatment of established breast cancer-related lymphedema. The authors concluded that there is not enough evidence to support the widespread adoption of liposuction, LVA, or VLNT techniques and that high-quality RCTs are needed.

A 2019 systematic review by Tyker aimed to evaluate the efficacy of a variety of surgical treatments for patients with lymphedema following head and neck cancer therapy.[5] 26 studies met the inclusion criteria including 14 cohort studies, seven case reports, two RCTs, two systematic reviews, and one narrative review. Manual lymph drainage had the largest number of studies and participants and there was limited evidence evaluating the efficacy of liposuction and microsurgery techniques. The authors concluded that there is limited data from high-quality studies including RCTs and that more research is needed to understand the long-term efficacy of other treatment modalities.

A 2017 systematic review by Carl aimed to develop a treatment algorithm based on highest-quality lymphedema research.[6] The SR addressed lymphovenous anastomosis (LVA), vascularized lymph node transfer (VLNT), liposuction, excision, and combination surgical approaches for the treatment of lymphedema. Sixty-nine articles met inclusion criteria and were included in the review. In studies measuring excess volume reduction, the mean reduction was 96.6% for liposuction, 33.1% for LVA, and 26.4% for VLNT. Included excision articles did not report excess volume reduction. The authors stated that further studies with a focus on follow up after treatment will improve the validity of lymphedema surgery research. There was significant heterogeneity of the included studies in terms of lymphedema stage and etiology, method of assessing surgical outcomes, and inconsistent reporting of complications and quality of life outcomes. Additional trials are needed that compare surgical treatments to conservative therapies which may help define the most appropriate interventions for patients according to their clinical stage.

Additional single-arm studies have been published on liposuction for the treatment of lymphedema.[7, 8] However, these studies suffer from the same limitations as the studies included in the systematic reviews and do not capture longer periods of follow up and/or larger populations than the existing studies. Therefore, they are not discussed further.

Surgeries That Reconstruct or Bypass Using Donor Lymph Vessels

Leung (2015) reported on a systematic review of the surgical management of breast cancer-related lymphedema.[9] The search included studies reporting on the efficacy of surgical techniques used for the prevention or treatment of breast cancer-related lymphedema

published between 2000 and 2014. Only one study on lymphatico-lymphatic bypass was identified and published since 2000. The study included seven patients followed for 2.6 years. One patient had "complete recovery" as measured by the circumference of the affected limb and the remaining six patients had a "reasonable outcome". Postsurgery complications were cellulitis, donor-site lymphorrhea, and transient edema of donor leg.

Surgeries That Reconstruct or Bypass Using the Venous System

Systematic Reviews

Several systematic reviews specifically evaluating microsurgical procedures using the venous system (lymphaticovenular anastomosis [LVA], lymphovenous bypass) have been reported.[10, 11] Two broader systematic reviews of treatments for lymphedema including several microsurgical procedures have also been reported.[6, 9] Corneilissen (2018) and Leung (2015) were limited to studies of breast cancer-related lymphedema but the remaining reviews were not.

Chang (2021) reported on a systematic review and meta-analysis of LVA and vascularized lymph node transfer (VLNT) for treatment of lymphedema.[12] Overall, 66 total studies were included, with 16 studies included on LVA. Follow-up ranged from approximately 6 to 68 months. The number of patients with breast cancer-related lymphedema was not described. In addition, studies evaluating use of these procedures for both upper and lower extremity lymphedema were included. The results of the study showed both a reduction in limb circumference and a reduction in the number of cellulitis infections before and after surgery.

Cornelissen (2018) reported on a systematic review assessing the effect of LVA in breast cancer-related lymphedema.[10] Fifteen observational studies were identified (11 prospective, 4 retrospective) with follow-up times ranging from two months to eight years. Although LVA surgery was performed in the included studies, the technical procedure differed among studies: six studies used only end-to-end anastomoses; four studies used both end-to-end and end-to-side anastomoses; one study used the ‘‘Octopus technique''; and four studies did not report the LVA technique used. Only two studies included a control group (bandaging, decongestive therapy).

Scaglioni (2017) reported on a systematic review of LVA for the treatment of lymphedema.[11] Reviewers noted significant variations in surgical techniques, numbers of anastomoses, and supplementary interventions (i.e., compressive therapy, additional debulking surgery). Nine studies included secondary lymphedema alone, while eight studies included patients with both primary and secondary lymphedemas. The number of patients with breast cancer-related lymphedema was not described. As mentioned, the Carl (2017) and Leung (2015) reviews included multiple surgical techniques. Leung (2015) was limited to breast cancer-related lymphedema while Carl (2017) was not.

Basta (2014) published a systematic review which included 27 studies evaluating the efficacy and safety of microsurgical treatments for lymphedema.[13] Lymphovenous shunt procedures were used in 22 studies and lymph node transfer was used in the remaining five studies. The primary endpoint was reduction in excess volume or circumference. The authors reported an excess circumference reduction of 48.8% and an absolute circumference reduction of 3.3 cm. The studies that reported excess volume reduction show a reduction of 56.6%. The rate of no improvement in the included studies was 11.8% and complications included infection, lymphorrhea, reexploration for flag congestion, and reoperation.

Randomized Controlled Trials

No RCTs were identified.

Nonrandomized Studies

Maruccia (2019) published a retrospective study comparing vascularized lymph node transfer (VLNT) to combined VLNT and axillary scar release.[14] Thirty-nine patients were included and all had stage II or III breast cancer-related lymphedema. Primary outcomes were limb circumference and lymphedema-related quality of life. A significant difference between the circumference reduction rates at above elbow level was observed at three and six months of follow-up comparing the two groups, with higher values in the combined treatment group than VLNT alone. No significant difference was detected comparing reduction rate values at above and below elbow at 12 and 24 months postoperatively. Quality of life metrics showed significantly better scores in all domains at all follow-up appointments in the combined group.

Agko (2018) published a nonrandomized, noncomparative prospective study including 12 patients with lymphedema who received vascularized lymph node transfer followed by lipectomy.[15] The primary outcomes were limb size and number of infectious episodes in addition to an evaluation of compression garment utilization. The authors reported a limb circumference reduction rate of 37.9% after the VLNT procedure and this was increased to a reduction rate of 96.4% after the lipectomy procedure. Only one patient reported an infectious episode after either of the treatments. It was noted that all patients were able to eventually discontinue the use of compression garments. Limitations of this study include the lack of a comparator group, small sample size, and no long-term follow-up.

Additional single-arm studies have been published since the systematic reviews.[16] However, these studies suffer from the same limitations as the studies included in the systematic reviews and do not capture longer periods of follow-up and/or larger populations than the existing studies. Therefore, they are not discussed further.

Subsection Summary: Surgeries That Reconstruct or Bypass Using the Venous System

No controlled trials were identified evaluating the physiologic microsurgeries using techniques such as lymphovenous bypass or LVA that reconstruct or bypass the obstructed lymphatic vessels using the venous system. Systematic reviews have indicated that most of the available evidence for these procedures comes from uncontrolled studies including fewer than 40 participants each, most of which lack adequate descriptions of how patients were selected for inclusion. Surgical technique, the severity of lymphedema, outcomes metrics, and follow-up times varied across studies making it difficult to synthesize the evidence. Surgical complications have been inconsistently reported but appear to be rare. RCTs of physiologic microsurgeries that bypass the obstructed lymphatic vessels using the venous system plus conservative therapy vs conservative therapy alone are needed.

SURGERIES THAT TRANSFER LYMPH TISSUE

Systematic Reviews

Systematic reviews evaluating microsurgical procedures that transfer lymph tissue (autologous lymph node transfer, vascularized lymph node transfer [VLNT]) have been reported. Ozturk (2016) reported on a systematic review of VLNT for treatment of lymphedema.[17] They included treatment for both primary and secondary lymphedema and as such comprised a

heterogeneous population. However, 191 of 305 of the surgeries were for breast cancer-related lymphedema. Eighteen studies were identified (3 prospective, 15 retrospective). For breast cancer-related lymphedema, VLNT with a skin island or VLNT with an autologous flap was used. There was inconsistent reporting of the staging of lymphedema. Reviewers did not state whether any of the studies included a control group. Two systematic reviews of various surgical methods previously described also included a review of lymph node transfer.[6, 9]

In addition to the systematic reviews of efficacy, Demiri (2018) reported on a systematic review of donor-site complications following autologous lymph node transfer for breast cancer-related lymphedema.[18]

Risk of bias was assessed in Ozturk (2016) using a checklist from the American Society of Plastic Surgeons guidelines for therapeutic studies. A summary of the assessment follows:

- 12 of 18 studies did not report whether patients were selected consecutively and one did not include consecutive patients;
- 13 of 18 studies had insufficient information on the surgical team;
- 3 of 18 studies had an insufficient follow-up to observe outcomes (ie, <1 year).

Randomized Controlled Trials

Dionyssiou (2016) reported on an RCT that evaluated VLNT plus physical therapy vs physical therapy alone for lymphedema in 36 women with stage II breast cancer-related lymphedema.[19] At 18 months, the reduction in the excess volume of the affected limb as a percentage of the intact limb was 57% in the VLNT group and 18% in the physical therapy group (treatment effect not reported, p<0.001). The mean number of lymphedema-related infections per patient per year was lower in the VLNT group (0.28 vs 1.16; treatment effect not reported, p=0.001). The trial had several limitations described in Tables 9 and 10. Notably, there was no description of allocation concealment and the trial was not blinded, possibly introducing both selection and ascertainment bias. The reporting did not describe the power calculations or justify a clinically important difference for the reported outcomes. The trial was not registered, so selective reporting cannot be ruled out.

Nonrandomized Studies

Additional single-arm studies have been published since the systematic reviews.[20-25] However, these studies suffer from the same limitations as the studies included in the systematic reviews and do not capture longer periods of follow-up and/or larger populations than the existing studies. Therefore, they are not discussed further.

Subsection Summary: Surgeries That Transfer Lymph Tissue

One RCT with 36 participants was identified evaluating VLNT that uses lymph tissue transfer in patients with breast cancer-related lymphedema. The trial reported reductions in the excess volume of the affected limb and rates of lymphedema-related infections for VLNT plus physical therapy compared with physical therapy alone. Systematic reviews have indicated that most of the remaining available evidence for these procedures comes from uncontrolled studies including fewer than 50 participants each, most of which lacked adequate descriptions of how patients were selected for inclusion. Surgical techniques, the severity of lymphedema, outcomes metrics, and follow-up times varied across studies. Although surgical complications were inconsistently reported, a systematic review of complications estimated that donor-site lymphedema occurs in approximately 2% of surgeries and seroma occurs in approximately

4%. Additional RCTs of physiologic microsurgeries that use lymph tissue transfer with conservative therapy vs conservative therapy alone are needed.

PHYSIOLOGIC MICROSURGERY TO PREVENT LYMPHEDEMA

The purpose of lymphatic physiologic microsurgery simultaneous to lymphadenectomy for breast cancer (e.g., the Lymphatic Microsurgical Preventing Healing Approach [LYMPHA]) is to prevent lymphedema in individuals who are being treated for breast cancer. While recommendations on preventive measures for lymphedema exist, such as avoiding needle sticks, limb constriction, and air travel, most recommendations are based on clinical opinion. A systematic review of preventive measures for lymphedema by Cemal (2011) found strong scientific evidence only for the recommendations to maintain a normal body weight or avoid weight gain and to participate in a supervised exercise regimen.[26]

LYMPHA is a preventive LVA procedure performed during nodal dissection or reconstructive surgery that involves anastomosing arm lymphatics to a collateral branch of an axillary vein.

Systematic Reviews

Jorgensen (2017) reported on a systematic review of prophylactic LVA and shunts for preventing cancer-related lymphedema, not limited to breast cancer.[27] Twelve articles were included in the qualitative analysis (5 specific to breast cancer) and four of those studies (2 specific to breast cancer) were included in a meta-analysis. Jorgensen (2017) performed a meta-analysis of the incidence of lymphedema that included 4 studies (2 specific to breast cancer) with a control group consisting of patients without prophylactic LVA. The relative risk for incident lymphedema was 0.33 (95% CI, 0.19 to 0.56) favoring prophylactic LVA vs control; however, because the incidence of lymphedema varies over time and the follow-up times varied across studies, it is not clear whether it would be appropriate to pool the risk including all time points.

Jorgensen (2017) also performed a risk of bias assessment of the included studies. They noted the following:

- None of the studies had allocation concealment or blinding;
- Only 1 study was randomized;
- None of the studies were registered;
- Only 4 studies had a control group. Selection of the control groups was unclear or a potential source of bias in all 4 controlled studies.

Randomized Controlled Trials

Boccardo (2011) reported on results of an RCT including 46 women referred for axillary dissection for breast cancer treatment between 2008 and 2009 who were randomized to LYMPHA or no preventive surgery (control).[28] All LVA procedures were performed by the same surgeon, reported to be skilled in lymphatic microsurgery. The LVA surgeon was not the same surgeon who performed lymph node dissection. The same axillary dissection treatment was performed in the 2 treatment groups. Lymphedema was diagnosed as a difference in excess volume of at least 100 mL compared with preoperative volume measurements. Lymphedema was diagnosed in 1 (4%) woman in the LYMPHA group and 7 women (30 %) in the control group by 18 months of follow-up. The change in volume with respect to baseline was reportedly higher in the control group than in the LYMPHA group at 1, 3, 6, 12, and 18 months (all $p<0.01$). The trial had several limitations described in Tables 15 and 16. Notably,

the follow-up duration was only 18 months. Methods of randomization and allocation concealment were not described and there was no justification of the sample size. The patients and investigators were not blinded (ie, no sham procedure was performed) and there was no discussion of whether outcome assessors were blinded.

Nonrandomized Studies

Additional single-arm studies have been published since the systematic reviews.[29] However, these studies suffer from the same limitations as the studies included in the systematic reviews and do not capture longer periods of follow up and/or larger populations than the existing studies. Therefore, they are not discussed further.

Section Summary: Physiologic Microsurgery to Prevent Lymphedema

One RCT was identified evaluating LYMPHA to prevent lymphedema in 49 patients referred for axillary dissection for breast cancer. The trial reported that lymphedema developed in 4% of women in the LYMPHA group and 30% in the control group by 18 months of follow-up. Longer follow-up is needed to observe incident lymphedema occurring after 18 months and assess the durability of the procedure. The trial had limitations that could have introduced bias: methods of randomization and allocation concealment were not described, and there was no sham procedure or blinding. Systematic reviews have indicated that most of the remaining available evidence for LYMPHA comes from uncontrolled studies, although two controlled observational studies in women with breast cancer have been performed. Selection of the control group was identified as a potential source of bias in both controlled studies. Outcomes metrics and follow-up times varied across studies. Additional RCTs of LYMPHA are needed and 1 such trial is underway (see NCT03428581).

SURGICAL TREATMENT FOR LIPEDEMA

The purpose of liposuction treatments for lipedema is to provide a treatment option that is an improvement on existing therapies such as complete decongestive therapy.

Systematic Reviews

The Canadian Agency for Drugs and Technology in Health (CADTH) published a rapid response report summarizing the evidence on liposuction for the treatment of lipedema.[30]

The report consists of five nonrandomized, uncontrolled studies that suggest liposuction may be effective in reducing extremity size and complaints related to lipedema. Complaints related to lipedema included spontaneous pain, easy bruising, sensitivity to pressure, impairment in quality of life, restrictions to mobility, edema, feeling of tension, and general impairment. Outcome data was collected via patient self-assessment using tools that have not been validated for lipedema related complaints. Additionally, all studies included were noncomparative, nonrandomized studies and did not include long-term follow up.

Randomized Controlled Trials

No RCTs were identified.

Nonrandomized Studies

Baumgartner (2021) reported the results of a single center study of 60 patients to monitor the 12-year success of liposuction for treating lipedema from the patients' perspective using self-

reported outcomes.[31] Prior to liposuction, 18 patients had Stage I lipedema, and 42 had Stage II. Self-reported outcomes included responses from patients that were asked to indicate to what extent they are currently experiencing the following: spontaneous pain, sensitivity to pressure, edema, bruising, restriction of movement, cosmetic impairment, reduction in quality of life. The results showed significant improvement in scores across all indicators, as well as overall impairment score. There were 37 of the 60 patients that underwent combined decongestive therapy (CDT) with manual lymph drainage (MLD) plus compression garments before surgery. A subgroup analysis was conducted on these patients in order to assess treatment success, and the results showed seven patients required fewer conservative treatments and 10 no longer needed conservative treatment. The authors concluded that these results demonstrate a permanent improvement in lipedema symptoms for patients with Stage I and II lipedema. This study did not include Stage III lipedema patients and relies exclusively on self-reported outcomes.

Section Summary: Surgical Treatment for Lipedema

The existing literature addressing liposuction techniques for the treatment of lipedema only includes nonrandomized, uncontrolled studies with no comparator group. The evidence is lacking and further research with longer-term outcomes and patient selection criteria are needed. High quality randomized trials or comparative studies are needed.

PRACTICE GUIDELINE SUMMARY

NATIONAL LYMPHEDEMA NETWORK

The National Lymphedema Network published a position paper on the diagnosis and treatment of lymphedema in 2011.[32] The paper stated the following on microsurgical procedures:

"Microsurgical and supramicrosurgical (much smaller vessels) techniques have been developed to move lymph vessels to congested areas to try to improve lymphatic drainage. Surgeries involve connecting lymph vessels and veins, lymph nodes and veins, or lymph vessels to lymph vessels. Reductions in limb volume have been reported and a number of preliminary studies have been done, but there are no long-term studies of the effectiveness of these techniques."

INTERNATIONAL SOCIETY OF LYMPHOLOGY

International Society of Lymphology published a consensus document on the diagnosis and treatment of peripheral lymphedema in 2016.[33] The document stated the following on lymphaticovenous (or lymphovenous) anastomoses (LVA):

"LVA are currently in use at multiple centers around the world. These procedures have undergone confirmation of long-term patency (in some cases more than 20 years) and some demonstration of improved lymphatic transport (by objective physiologic measurements of long-term efficacy)."

NATIONAL CANCER INSTITUTE

The NCI Health Professional Version on lymphedema states:[34]

> “Surgery is rarely performed on patients who have cancer-related lymphedema. The primary surgical method for treating lymphedema consists of removing the

subcutaneous fat and fibrous tissue with or without creation of a dermal flap within the muscle to encourage superficial-to-deep lymphatic anastomoses. These methods have not been evaluated in prospective trials, with adequate results for only 30% of patients in one retrospective review. In addition, many patients face complications such as skin necrosis, infection, and sensory abnormalities. The oncology patient is usually not a candidate for these procedures. Other surgical options include the following: Microsurgical lymphaticovenous anastomoses in which the lymph is drained into the venous circulation or the lymphatic collectors above the area of lymphatic obstruction; liposuction; superficial lymphangiectomy; fasciotomy".

SUMMARY

There is enough research to show that liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) to treat lipedema may improve health outcomes in certain populations. Therefore, liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) may be considered medically necessary when policy criteria are met.

There is not enough research to show that liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) to treat lipedema improves health outcomes when policy criteria are not met. Therefore, liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) is considered investigational for patients with lipedema when policy criteria are not met.

There is not enough research to show that physiologic microsurgeries including, but not limited to, lymphatico-lymphatic bypass, lymphatic-venous-lymphatic plasty, lymphovenous bypass, lymphaticovenous anastomosis, autologous lymph node transplantation, and vascularized lymph node transfer improve health outcomes for people with lymphedema. Therefore, physiologic microsurgeries including, but not limited to, lymphatico-lymphatic bypass, lymphatic-venous-lymphatic plasty, lymphovenous bypass, lymphaticovenous anastomosis, autologous lymph node transplantation, and vascularized lymph node transfer is considered investigational for all indications, including but not limited to lymphedema.

There is not enough research to show that lymphatic physiologic microsurgery performed during nodal dissection or breast reconstruction to prevent lymphedema (including, but not limited to, the Lymphatic Microsurgical Preventing Healing Approach) in individuals who are being treated for breast cancer improves health outcomes. Therefore, lymphatic physiologic microsurgery performed during nodal dissection or breast reconstruction to prevent lymphedema (including, but not limited to, the Lymphatic Microsurgical Preventing Healing Approach) in individuals who are being treated for breast cancer is considered investigational.

There is not enough research to show that liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) to treat lymphedema improves health outcomes. No clinical guidelines based on research recommend liposuction for the treatment of lymphedema. Therefore, liposuction (including, but not limited to, lipectomy, suction-assisted protein lipectomy, and lymph-sparing liposuction) is considered investigational for patients with lymphedema.

Ablation for the Treatment of Chronic Rhinitis

Effective: January 1, 2024

Next Review: October 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Ablation therapy is proposed as an alternative to medical management for patients with chronic rhinitis symptoms. Ablation therapy includes cryoablation (also known as cryosurgical ablation, cryosurgery, or cryotherapy), radiofrequency ablation, and laser ablation. Ablation therapy is thought to correct the imbalance of autonomic input to the nasal mucosa, thereby reducing nasal antigen responses and vascular hyperreactivity.

MEDICAL POLICY CRITERIA

Cryoablation, radiofrequency ablation, and/or laser ablation for chronic rhinitis (allergic or nonallergic) are considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

Cryosurgical ablation (known as cryosurgery) is proposed as an alternative to medical management for patients with chronic rhinitis symptoms. The procedure involves ablation of tissue in the posterior nasal nerve region, using nitrous oxide to freeze the nasal tissue and cause nerve damage. The procedure is thought to correct the imbalance of autonomic input to the nasal mucosa thereby reducing nasal antigen responses and vascular hyperreactivity.

Medical management is the standard of care for chronic rhinitis. Surgical options such as vidian nerve resection have been investigated for patients with chronic rhinitis refractory to multiple medical therapies, and cryoablation is proposed as a less invasive alternative. Vidian neurectomy has not been widely adopted however, due to the need for general anesthesia, risk of serious adverse events (e.g., dry eyes in up to 25% of patients), and uncertainty about the procedure's long-term benefits.[1]

REGULATORY STATUS

In February 2019, the Clarifix® device was cleared for use in adults with chronic rhinitis through the 510(k) process (K190356).[2] Clearance was based on substantial equivalence to the predicate device, ClariFix (K162608). The only modification to the subject device was an update to the indications for use to include adults with chronic rhinitis.

EVIDENCE SUMMARY

CRYOABLATION

SYSTEMATIC REVIEWS

Desai (2023) published a systematic review of eight studies including 472 patients receiving cryoablation for the treatment of chronic rhinitis.[3] The results of the review indicated a significant reduction in post-treatment scores in all eight included studies. This review included a single RCT and seven additional non-randomized, non-comparative studies, several of which had small sample sizes of 30 or less.

Kompelli (2018) conducted a systematic review of cryoablation for chronic rhinitis, identifying 15 nonrandomized studies enrolling a total of 1266 patients.[4] Across all of the studies, 63% to 95.7% of patients noted improvement in overall symptoms, and no serious adverse events were reported. The authors concluded that although the procedure appeared to be safe and efficacious, methodological weaknesses and heterogeneity limited the strength of conclusions that could be drawn from this body of evidence. In addition to their uncontrolled design, most studies were outdated, published between 1977 and 1997. Only one study, reported by Hwang (2017) used an FDA-cleared device and a validated outcome measure.[5] This study is discussed in detail, along with other recent nonrandomized studies, in the following section.

RANDOMIZED CONTROLLED TRIALS

Stolovitsky (2021) conducted an RCT comparing radiofrequency ablation using the RhinAer device with sham treatment.[6] The trial enrolled 117 adults (age, 18 to 85 years; mean age, 57

years) with chronic rhinitis. Use of medication to treat chronic rhinitis was allowed in both groups. Based on an intention to treat analysis that accounted for all randomized participants, after 3-months follow-up, the proportion of participants with a ≥30% improvement in rTNSS score was higher in the active radiofrequency ablation group (66.7%; 95% CI, 55.1% to 76.9%) than in the sham group (41.0%; 95% CI, 25.6% to 57.9%; p=.01). A similar number of participants in the active (9.1% [7/77]) and sham (12.8% [5/39]) groups increased their medication use during the study (Table 12). The study was unblinded at 3 months, and individuals in the control group were allowed to crossover to the active intervention group.

Takashima (2022) reported 12-month follow-up for patients (n=77) initially randomized to the active intervention group. Study results for the active intervention group at 6- and 12-months are reported in Table 12. Treatment response and mean change from baseline remained stable through 12 months in the active intervention group, while concomitant medication use increased. The study is ongoing, with planned 3-year follow-up.

NONRANDOMIZED STUDIES

Three recent single arm, nonrandomized studies including 149 patients, reported in four publications, have evaluated cryoablation for patients with chronic rhinitis. The largest study (N = 98) was reported by Chang (2020)[7], with 2-year follow-up data on a subset of patients (n = 62) reported by Ow (2021)[8]. Scores on the rTNSS improved significantly over baseline at one month, three months, six months, and nine months, and improvements were sustained for up to two years among those patients who enrolled in the follow-up study. Smaller single-arm studies reported by Hwang (2017)[5] and Gerka Stuyt (2021)[9] also reported improvements in symptoms from baseline. Chang (2020) reported two serious procedure-related adverse events: severe epistaxis occurring on posttreatment day 19 due to a pledget inadvertently left in the nasal cavity from the day of treatment, and one case of mild epistaxis occurring on post-treatment day 36 which resolved with in-office cautery. Of 72 patients completing a telephone questionnaire about procedure-related discomfort, 56 (77.8%) experienced some degree of pain or discomfort. Seventeen patents reported severe headache, five reported severe nasal pain, and two reported severe sinus pain.[7] No serious adverse events were reported in the other studies.

Key limitations of these studies include no comparison groups, nonrandomization, and small sample size. A major limitation was their uncontrolled, open-label design. Additionally, loss to follow-up was high and MCID were not pre-specified for important outcome measures. Randomized controlled trials are needed to confirm improvements in symptom scores observed in nonrandomized studies.

SUMMARY OF EVIDENCE

For individuals with chronic rhinitis who receive cryoablation, the evidence includes nonrandomized studies and a systematic review of nonrandomized trials. Relevant outcomes are symptoms, change in disease status, quality of life, and treatment-related morbidity. Three single-arm, open-label studies enrolling a total of 149 patients reported improvements from baseline in patient-reported symptom scores up to one year. Sustained improvement for up to two years was observed in one study, however only 62 of 98 patients enrolled in the longer-term follow-up phase. In the largest study, there were two serious procedure-related adverse events (2.0%), and 77.8% of patients who responded to a post-procedure questionnaire reported some degree of pain or discomfort. Study limitations, including lack of a control group

and high loss to follow-up, preclude drawing conclusions from this body of evidence. Randomized controlled trials are needed to confirm improvements reported in nonrandomized studies. A systematic review of 15 nonrandomized studies reported improvements with cryoablation; however, only one study used an approved device and validated outcome measuring, limiting conclusions from this systematic review. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

RADIOFREQUENCY ABLATION

RANDOMIZED CONTROLLED TRIALS

Stolovitsky (2021) conducted an RCT comparing radiofrequency ablation using the RhinAer device with sham treatment.[9,] The trial enrolled 117 adults (age, 18 to 85 years; mean age, 57 years) with chronic rhinitis. Use of medication to treat chronic rhinitis was allowed in both groups (Table 11). Based on an intention to treat analysis that accounted for all randomized participants, after 3-months follow-up, the proportion of participants with a ≥30% improvement in rTNSS score was higher in the active radiofrequency ablation group (66.7%; 95% CI, 55.1% to 76.9%) than in the sham group (41.0%; 95% CI, 25.6% to 57.9%; p=.01). A similar number of participants in the active (9.1% [7/77]) and sham (12.8% [5/39]) groups increased their medication use during the study (Table 12). The study was unblinded at 3 months, and individuals in the control group were allowed to crossover to the active intervention group.

Takashima (2022) reported 12-month follow-up for patients (n=77) initially randomized to the active intervention group.[10] Study results for the active intervention group at 6- and 12-months were shown to be different across treatment and sham groups. Treatment response and mean change from baseline remained stable through 12 months in the active intervention group, while concomitant medication use increased. Follow-up is only reported for the treatment group in this study and excludes the sham group. Additional long-term follow-up with appropriate comparators, such as carefully controlled medical management, are needed.

NONRANDOMIZED STUDIES

The effectiveness of radiofrequency ablation with the RhinAer device has been assessed in two industry-sponsored, nonrandomized, uncontrolled, open-label studies. Both studies included patients with chronic rhinitis. Lee (2022) enrolled 129 patients and reported outcomes of radiofrequency ablation up to 6 months.[11] Ehmer (2021) enrolled 50 patients, 47 of whom had 1-year follow-up; 2-year results were subsequently reported in an extension study of 34 patients.[12, 13] Both studies found symptom response rates and the proportion of responders durable at time points ranging from 3 months to 2 years. Lee et al reported quality of life outcomes using the miniRQLQ, a validated measure with an established MCID of 0.4 points. At 3 and 6 months post-treatment, the mean change in miniRQLQ scores from baseline was -1.6 and -1.8, respectively, indicating clinically important improvement in symptom-related quality of life. These studies are limited by nonrandomized, open-label designs and lack of control groups.

LASER ABLATION

NONRANDOMIZED STUDIES

Krespi (2020) conducted a nonrandomized study evaluating laser ablation for treatment of chronic rhinitis.[14] The study enrolled 32 adults treated with an endoscopic diode laser in an outpatient setting. Duration of follow-up was 3 months. Mean rTNSS was reduced from 6.0 (standard deviation [SD], 0.7) at baseline to 2.3 (SD, 0.4) at 3-month follow-up. Adverse events were not reported. The study had multiple limitations, including the small sample size, uncontrolled design, and duration of follow-up less than 6 months. Randomized studies comparing laser ablation with medical management and with longer follow-up are needed to determine efficacy and safety.

PRACTICE GUIDELINE SUMMARY

No practice guidelines were identified.

SUMMARY

There is not enough research to show that cryoablation, radiofrequency ablation, or laser ablation for chronic rhinitis improves health outcomes. In addition, no practice guidelines recommend cryoablation, radiofrequency ablation, or laser ablation for chronic rhinitis. Therefore, cryoablation, radiofrequency ablation, or laser ablation for chronic rhinitis is considered investigational.

Devices for Treatment of Benign Prostatic Hyperplasia, Urethral Stricture, and Urethral Stenosis

Effective: January 1, 2024

Next Review: March 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Temporarily implanted nitinol devices (e.g., iTind) have been proposed as a minimally invasive alternative to transurethral resection of the prostate (TURP) to treat symptomatic benign prostatic hyperplasia. The device is temporarily implanted into the obstructed prostatic urethra to facilitate tissue reshaping and improve urine outflow. The implant is typically removed after five to seven days.

Drug-coated balloon catheter systems (e.g., Optilume®) have been proposed as minimally invasive alternatives to TURP, endoscopic management, and urethroplasty to treat obstructive urinary tract symptoms associated with benign prostatic hyperplasia or urethral stricture. The devices utilize balloon catheters to dilate the urethra or prostate lobes and deliver paclitaxel indicated to prevent future obstructive urinary symptoms.

MEDICAL POLICY CRITERIA

I. The use of a temporarily implanted nitinol device (e.g., iTind) is considered **investigational** for all indications, including treatment of lower urinary tract symptoms due to benign prostatic hyperplasia.

II. The use of a drug-coated balloon catheter system (e.g., Optilume® BPH Catheter System) is considered **investigational** for all indications, including treatment of obstructive urinary symptoms associated with benign prostatic hyperplasia.

III. The use of a drug-coated balloon catheter system (e.g., Optilume® Urethral Drug Coated Balloon) is considered **investigational** for all indications, including treatment of obstructive urinary symptoms associated with anterior urethral stricture.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

1. Transurethral Water Vapor Thermal Therapy and Transurethral Water Jet Ablation (Aquablation) of the Prostate, Surgery Policy No. 210

BACKGROUND

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is a common disorder among older individuals that results from hyperplastic nodules in the periurethral or transitional zone of the prostate. The clinical manifestations of BPH include increased urinary frequency, nocturia, urgency or hesitancy to urinate, and a weak stream when urinating. The urinary tract symptoms often progress with worsening hypertrophy and may lead to acute urinary retention, incontinence, renal insufficiency, and/or urinary tract infection. BPH prevalence increases with age and is present in more than 80% of individuals age 70 to 79 years.[1]

Two scores are widely used to evaluate BPH-related symptoms: the American Urological Association Symptom Index (AUASI) and the International Prostate Symptom Score (IPSS). The AUASI is a self-administered seven-item questionnaire assessing the severity of various urinary symptoms.[2] Total AUASI scores range from 0 to 35, with overall severity categorized as mild (≤7), moderate (8-19), or severe (20-35). The IPSS incorporates questions from the AUASI and a quality of life question or a "Bother score."[3]

Benign prostatic hyperplasia does not necessarily require treatment. The decision on whether to treat BPH is based on an assessment of the impact of symptoms on quality of life along with the potential side effects of treatment. For patients with moderate-to-severe symptoms (e.g., an AUASI score of ≥8), bothersome symptoms, or both, a discussion about medical therapy is reasonable. Benign prostatic hyperplasia should generally be treated medically first. Available medical therapies for BPH-related lower urinary tract dysfunction include α-adrenergic blockers (e.g., alfuzosin, doxazosin, tamsulosin, terazosin, silodosin), 5α-reductase inhibitors (e.g., finasteride, dutasteride), combination α-adrenergic blockers and 5α-reductase inhibitors, anti-muscarinic agents (e.g., darifenacin, solifenacin, oxybutynin), and phosphodiesterase-5 inhibitors (e.g., tadalafil).[1] In a meta-analysis of both indirect comparisons from placebo-controlled studies (n=6333) and direct comparative studies (n=507), Djavan (1999) found that the IPSS improved by 30% to 40% and the Qmax score (mean peak urinary flow rate) improved by 16% to 25% in individuals assigned to α-adrenergic blockers.[4] Combination therapy using an α-adrenergic blocker and 5α-reductase inhibitor has been shown to be more effective for improving IPSS than either treatment alone, with median scores improving by more than 40% over one year and by more than 45% over four years.

Patients who do not have sufficient response to medical therapy, or who are experiencing significant side effects with medical therapy, may be referred for surgical or ablative therapies. The American Urological Association (AUA) recommends surgical intervention for patients who have "renal insufficiency secondary to BPH, refractory urinary retention secondary to BPH, recurrent urinary tract infections (UTIs), recurrent bladder stones or gross hematuria due to BPH, and/or with lower urinary tract symptoms (LUTS) attributed to BPH refractory to and/or unwilling to use other therapies."[5] Transurethral resection of the prostate (TURP) is generally considered the reference standard for comparisons of BPH procedures.[6] In the perioperative period, TURP is associated with risks of any operative procedure (e.g., anesthesia risks, blood loss). Although short-term mortality risks are generally low, a large prospective study with 10,654 patients by Reich (2008) reported the following short-term complications: "failure to void (5.8%), surgical revision (5.6%), significant urinary tract infection (3.6%), bleeding requiring transfusions (2.9%), and transurethral resection syndrome (1.4%)."[7] Incidental carcinoma of the prostate was diagnosed by histologic examination in 9.8% of patients. In the longer term, TURP is associated with an increased risk of sexual dysfunction and incontinence.

The use of the iTind temporarily implanted nitinol device has been investigated as a minimally invasive treatment for lower urinary tract symptoms associated with BPH. With the use of a rigid cystoscope, the device is temporarily implanted into the obstructed prostatic urethra where three double intertwined nitinol struts configured in a tulip shape gradually expand.[8] The resulting circumferential force facilitates tissue reshaping via ischemic necrosis of the mucosa, resulting in urethral expansion and prostatic incisions that function as longitudinal channels to improve urine outflow.[9] The implant is typically removed after five to seven days of treatment. A distal nylon wire facilitates device retrieval which may be approached using a snare to pull the device into either a cystoscope sheath or an open-ended silicone catheter (20-22 French units [Fr]).[10] The first-generation TIND device had one extra strut and a pointed tip covered by a soft plastic material.

The Optilume® BPH Catheter System is a drug and device combination that consists of two catheters: a non-drug coated catheter for pre-dilation (Optilume® BPH Prostatic Pre-dilation Catheter) and a paclitaxel coated catheter (Optilume® BPH Prostatic Dilation Drug Coated Balloon Catheter).[11] The Pre-dilation Catheter is used to initiate a commissurotomy between the lateral lobes of the prostate. The Drug Coated Balloon Catheter further dilates and completes the commissurotomy then transfers paclitaxel to the pre-dilated prostatic urethra and anterior commissure. The increase in cross-sectional area of the prostatic urethra from the anterior commissurotomy permits increased urine flow. Transfer of the paclitaxel from the balloon surface to the dilated area inhibits cell proliferation and maintains urethral patency.

URETHRAL STRICTURE AND STENOSIS

Urethral stricture is the chronic fibrosis and narrowing of the urethral lumen caused by acute injury, inflammatory conditions, and interventions including urethral instrumentation, surgery, and prostate cancer treatment.[12] Urethral stricture is the preferred term for abnormal narrowing of the anterior urethra, and narrowing of the posterior urethra is referred to as stenosis. Urethral stricture symptoms are often non-specific and overlap with other common conditions including LUTS and UTI. Patients with urethral stricture most often present with decreased urinary stream and incomplete bladder emptying but may also have UTI, epididymitis, rising post-void residual, decreased ejaculation force, urinary spraying, or dysuria. In high income countries, the most common cause of urethral stricture is idiopathic (41%)

followed by medical treatments (35%). In low- and middle-income countries, trauma is the most common cause of urethral stricture (36%).

Initial management of urethral stricture includes assessing patient medical history, physical examination, and urinalysis.[12] A combination of patient reported measures, uroflowmetry, and ultrasound post-void residual assessment are recommended for initial evaluation of suspected urethral stricture. Urethro-cystoscopy, retrograde urethrography, voiding cystourethrography, or ultrasound urethrography are recommended for diagnosis of urethral stricture. For urgent management of urethral stricture, urethral endoscopic management (e.g., urethral dilation, direct visual internal urethrotomy [DVIU]) or immediate suprapubic cystostomy are recommended. For non-urgent strictures, the length and location of the stricture should be determined to guide treatment. For initial treatment of short (less than two centimeters [cm]) bulbar urethral strictures, urethral dilation, DVIU, or urethroplasty are recommended.

Urethroplasty, instead of repeated endoscopic management, is recommended for management of recurrent anterior urethral strictures following failed dilation or DVIU. Urethral dilation and DVIU are also recommended for recurrent bulbar urethral strictures that are less than three cm in length. Urethral dilation and DVIU have similar long-term outcomes, with success ranging from 35-70% for short strictures. These endoscopic treatments have high success rates for strictures less than one cm but very low success rates for strictures over two cm. Urethroplasty has a higher long-term success rate than endoscopic treatment (80-95%), but American Urological Association (AUA) guidelines recommend weighing success against the increased anesthesia requirement and higher morbidity of urethroplasty.

The Optilume® Urethral Drug Coated Balloon is a 0.97 mm over-the-wire guidewire compatible catheter with a dual lumen design and a tapered, atraumatic tip.[13] The Optilume® Drug Coated Balloon is used to exert radial force to dilate narrow urethral strictures. Using a guidewire, the catheter is inserted into the area of the urethra that has a stricture, and the balloon is inflated to mechanically dilate the urethra and improve urine flow. During balloon inflation, paclitaxel is transferred from the balloon to the urethra to prevent stricture recurrence.

REGULATORY STATUS

In April 2019, the iTind System (Olympus; previously, Medi-Tate Ltd., Hadera, Israel) was granted a de novo 510(k) classification by the U.S. Food and Drug Administration (FDA) (DEN190020; product code: QKA).[14] The new classification applies to this device and substantially equivalent devices of this generic type (e.g., K210138). The iTind System is intended for the treatment of symptoms due to urinary outflow obstruction secondary to benign prostatic hyperplasia (BPH) in men age 50 years and older.

In September 2021, the Optilume® Urethral Drug Coated Balloon (Urotronic, Inc.) received premarket approval from the U.S. FDA (P210020, product code: QRH).[13] The Optilume® Urethral Drug Coated Balloon is indicated for the treatment of obstructive urinary symptoms associated with anterior urethral stricture in adult males with urethral stricture less than or equal to three cm in length.

In June 2023, the Optilume® BPH Catheter System (Urotronic, Inc.) received premarket approval by the U.S. FDA (P220029; product code: QXB).[11] The Optilume® BPH Catheter System is indicated for the treatment of obstructive urinary symptoms associated with BPH in males age 50 years and older.

EVIDENCE SUMMARY

TEMPORARILY IMPLANTED NITINOL DEVICE

Clinical Context and Therapy Purpose

The purpose of temporarily implanted nitinol devices in patients who have lower urinary tract symptoms due to BPH is to provide a treatment option that is an alternative to or an improvement on existing therapies such as medical management, transurethral resection of the prostate (TURP), or prostatic urethral lift (PUL).

Both short-term (up to 12 months) and long-term (12 months and longer) outcomes should be assessed. Treatment-related morbidity can also be assessed in the immediate post-procedure period.

Some validated patient-reported scales are summarized in Table 1.

Table 1. Patient-Reported Health Outcome Measures Relevant to Benign Prostatic Hyperplasia

Measure	Outcome Evaluated	Description	Clinically Meaningful Difference (If Known)
Male Sexual Health Questionnaire for Ejaculatory Dysfunction (MSHQ-EjD)[15]	Ejaculatory function and quality of life	Patient-administered, 4-item scale. Symptoms rated as absent (15) to severe (0). QOL assessed as no problem (0) to extremely bothered (5).	NR
Sexual Health Inventory for Men (SHIM)[16]	Erectile function	Patient-administered, 5-item scale. Erectile dysfunction rated as severe (1-7), moderate (8-11), mild to moderate (12-16), or mild (17-21). Fewest symptoms present for patients with scores 22-25.	5-point change[17]
American Urological Association Symptom Index (AUASI); International Prostate Symptom Score (IPSS)[1, 3, 18]	Severity of lower urinary tract symptoms	Patient-administered, 7-item scale. Symptoms rated as mild (0-7), moderate (8-19), or severe (20-35). IPSS asks an additional question, rating QOL as delighted (0) to terrible (6).	• Minimum of 3-point change[1, 18] • Minimum of 30% change[19]
Benign Prostatic Hyperplasia Impact Index (BII)[2]	Effect of urinary symptoms on health domains	Patient-administered, 4-item scale. Symptoms rated as absent (0) to severe (13).	Minimum of 0.4-point change[18]

QOL: quality of life; NR: not reported.

Study Selection Criteria

Methodologically credible studies were selected using the following principles:

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs;
- In the absence of such trials, comparative observational studies were sought, with a preference for prospective studies.
- To assess long-term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Consistent with a 'best available evidence approach,' within each category of study design, studies with larger sample sizes and longer durations were sought.
- Studies with duplicative or overlapping populations were excluded.
- Studies concerning older versions of the technology that are no longer commercially marketed were excluded, including Bertolo (2015)[20] and Porpiglia (2018).[21]

Review of Evidence

Systematic Reviews

In 2021, Franco published a Cochrane network meta-analysis assessing the comparative effectiveness of minimally invasive treatments for lower urinary tract symptoms in men with BPH.[22] Twenty-seven trials representing 3017 men were included through February 2021. Compared to TURP at short-term follow-up, temporary implantable nitinol devices (TIND) may result in worse urologic symptoms scores (mean difference [MD] of IPSS score, 7.5; 95% CI, 0.68 to 15.69; low-certainty evidence) and little to no difference in quality-of-life scores (MD, 0.87; 95% CI, -1.04 to 2.79; low-certainty evidence).

Randomized Controlled Trials

Chughtai (2021) published the results of a multicenter, single-blinded RCT of the iTind implant compared to sham for the treatment of lower urinary tract symptoms secondary to benign prostatic hyperplasia.[23] . Fifty-seven participants received sham treatment, and out of 128 participants randomized to receive iTind, 10 did not undergo the procedure. The primary endpoint was the response rate, defined as the percentage of patients achieving a reduction of at least three points on the IPSS scale at three months. Patients were unblinded to their treatment after the 3-month follow-up visit. Mean patient age was 61.1 years and baseline characteristics were similar between groups, except for a higher Charlson Comorbidity Index score among iTind recipients (2.52 vs. 1.26; p<0.001). While a significantly higher proportion of patients treated with iTind achieved the primary endpoint compared to sham at three months (78.6% vs. 60%; p=.029), changes in overall IPSS, IPSS QoL, Qmax, SHIM, and International Index of Erectile Function (IIEF) scores were not statistically different between groups. Patients treated with iTind were followed through 12 months. Of 78 iTind subjects in the per-protocol population, a mean reduction of 9.25 points on the IPSS was found at 12 months, suggesting durability of treatment. A total of 16 serious adverse events among 10 subjects was reported within 0-30 days in the iTind group compared to two events in two subjects in the sham group. In the iTind group, a total of five serious adverse events were classified as device- or

procedure-related, including urinary retention (n=2), urinary tract infection (n=2) and sepsis (n=1). Six individuals (4.7%) had an alternative BPH surgery during 12-month follow-up due to deterioration of symptoms. An additional six participants (4.7%) resumed medication for symptomatic BPH. An RCT comparing the iTind device to the UroLift prostatic urethral lift (PUL) procedure is ongoing (NCT04757116).

Using questionnaire data from the Chughtai (2021)[23] study, Elterman (2023)[24] reported the effect of iTind on sexual function. Patient-reported sexual health data from subjects who completed study visits at 3 and 12 months, and who were not taking medication to treat BPH were included. Using primarily SHIM scores, the study found no evidence of decrease in sexual function due to iTind at 12 months. Limitations of the study include that the total number of study subjects that provided data and the n-values of the subgroups (stratified by age, prostate volume, and questionnaire scores) were not specified. Another major limitation was that the 12-month comparison was between baseline and 12-month scores within the iTind treatment arm, with no comparison between the iTind treatment and the sham treatment at 12-months.

Single-Arm Studies

MT-02 Cohort

81 subjects with lower urinary tract symptoms due to BPH were implanted with the second-generation iTind device and followed for up to three years.[25-27] Mean (SD) patient age was 65 (8.9) years with mean prostate volume 40.5 (12.25) milliliter (mL), Qmax 7.3 (2.6) mL/s, and IPSS score 22.5 (5.6). Devices were retrieved at a mean of 5.9 (1.1) days after implantation and no intraoperative complications were reported. At the 6-month and 12-month visits, 85.2% and 88.9% of treated patients reported a 3-point or greater improvement in IPSS, respectively. Compared to baseline, none of the 61 sexually active participants who completed a 12-month, two-item questionnaire reported sexual or ejaculatory dysfunction. Statistically significant improvements in total IPSS, Qmax, IPSS QoL, and post-void residual (PVR) volume were observed through 36 months. Clavien-Dindo grade I, II, and IIIa treatment-related adverse events were reported in 33 (41%), 5 (6.2%), and 8 (9.9%) patients within the first month post-treatment, respectively. Most common adverse events were hematuria (12.3%), urinary urgency (11.1%), acute urinary retention (9.9%), and pain (9.9%). No further adverse events were reported during long-term follow-up. From baseline through 36 months, 12 (14.8%) patients were considered treatment failures, of which seven were later found to have obstructive median lobes (p<.0001). Subsequent drug therapy was required in five (6.2%) patients and eight (8.6%) underwent surgical retreatment via TURP or laser. Sexually active patients who completed a two-item questionnaire reported no sexual or ejaculatory dysfunction through three years.

MT-06 Cohort

De Nunzio (2021) reported six-month interim outcomes for 70 subjects with lower urinary tract symptoms due to BPH seeking to preserve ejaculatory function who were implanted with the second-generation iTind device.[28] Mean patient age was 62.3 years with mean prostate volume 37.68 mL, Qmax 7.3, and IPSS urinary symptoms score 21.2. At six months, statistically significant improvements were seen in IPSS urinary symptoms, IPSS QoL, Qmax, and MSHQ-EjD. No significant changes in PVR volume, SHIM total score, or ISI total score were reported. Clavien-Dindo grade I, IIIa, and IIIb treatment-related adverse events were reported in 53 (75.7%), 3 (4.3%), and 1 (1.4%) patient(s), respectively. The most common

adverse events were transient hematuria (18.6%), dysuria (17%), urinary urgency (12.8%), and pain (11.4%). Follow-up is planned for three years.

Section Summary: Temporarily Implanted Nitinol Device

The prospective, international, multicenter, single-arm MT-02 prospective study of the iTind device has reported statistically significant improvements in total IPSS score, IPSS QoL score, Qmax, and PVR volume through three years. The subsequent single-arm MT-06 study enrolling men desiring to preserve ejaculatory function reported no significant change in the SHIM total score and a statistically significant improvement on the MSHQ-EjD questionnaire at six months. One RCT comparing the iTind device to sham treatment reported an improvement of at least three points on the IPSS scale at three months in 78.6% versus 60% of participants, respectively (p=.029). However, changes in overall IPSS, IPSS QoL, Qmax, SHIM, and IIEF scores were not significantly different between groups. Major limitations of the RCT include high loss to follow-up (~30% in each treatment arm) and short duration of follow-up. A follow-up study reported no evidence of decrease in sexual function at 12 months due to iTind, but evidence was limited by lack of comparison between the treatment arms. One network meta-analysis compared the safety and efficacy of various minimally-invasive treatments for lower urinary tract symptoms associated with BPH, finding that iTind may result in worse urologic symptoms scores compared to TURP at short-term follow-up. No studies have directly compared iTind to established alternatives. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

OPTILUME® BPH CATHETER SYSTEM

Clinical Context and Therapy Purpose

Use of a drug-coated balloon catheter system in patients who have obstructive urinary symptoms associated with BPH is to provide a treatment alternative to, or an improvement on, existing therapies such as pharmacological therapies, prostate ablation (e.g., laser, vapor), PUL, prostatectomy, or TURP.

Both short-term (up to 12 months) and long-term (12 months and longer) outcomes should be assessed. Treatment-related morbidity can also be assessed in the immediate post-procedure period. Some validated patient-reported scales are summarized in Table 1.

Randomized Controlled Trials

Kaplan (2023) published results of the PINNACLE double-blind, sham-controlled, multi-center RCT that assessed the Optilume® BPH Catheter System. 148 male participants 50 years or older, with symptomatic BPH and a prostate size between 20 and 80 grams, were randomized to receive the active treatment (n=100) or sham treatment (n=48). Sham treatment consisted of rigid cystoscopy followed by insertion of a sheathed (21F) Optilume® BPH Predilation Catheter that was not inflated. The timing, analgesia, and anesthesia protocols were the same in active and sham treatment groups. Participants and evaluators were blinded through one-year follow-up. Average improvement in IPSS from baseline to one year was significantly greater with active treatment (11.5±7.8) than sham treatment at three months (8.0±8.3), with an estimated difference of 3.4 between groups (95% CI, 0.6 to 6.2; p=0.008). However, this result was not significant when a 25% super-superiority margin was used (p=0.18). IPSS improved on average by 49% from baseline to one year in the active treatment group (95% CI, 42.7% to 55.4%), which met the prespecified performance goal of 30% (p<0.001). Significantly

more participants experienced at least a 30% improvement in IPSS at one year when compared to the sham group at three months (76.6% [66 of 96] versus 52.1% [25 of 48], p=0.003). The change in Qmax from baseline also significantly favored Optilume® BPH at 12 months over sham at three months (+9.7±10.1 versus +5.5±7.4 mL/s, p=0.009). Five serious treatment-related events occurred. Four post-procedural hematuria events that required cystoscopic management or extended observation, which resolved without sequelae, occurred. One event of urethral false passage required extended catheterization. Common nonserious adverse events that occurred in the Optilume® BPH arm, regardless of relatedness, included hematuria (40% [39 of 98]), urinary tract infection (14% [14 of 98], dysuria (9.2% [9 of 98]), urge/mixed incontinence (8.2% [8 of 98]), mild stress incontinence (7.1% [7 of 98]), bladder spasms (6.1% [6 of 98]), elevated PSA (6.1% [6 of 98]), and urinary urgency (6.1% [6 of 98]). This study is limited by different follow-up times for the Optilume BPH and sham treatment groups and eligibility criteria were limited to men with prostates below 80 grams.

Single-Arm Studies

Kaplan (2021) published one-year outcomes of the EVEREST-I single-arm study that evaluated the safety and efficacy of the Optilume® BPH Catheter System. Participants were greater than 50 years old with moderate to severe LUTS secondary to BPH, peak urinary flow rate of 5 to 15 mL/s, prostatic urethra length 30 to 55 millimeters, and prostate volume 20 to 80 grams (n=80). After treatment, participants were followed up at time of Foley catheter removal, two weeks, 30 days, and 3, 6, and 12 months after treatment. The primary endpoint was the proportion of subjects with greater than or equal to 40% improvement in IPSS. 75 participants completed the one-year follow-up. At three months and one year, 81% of participants experienced greater than or equal to 40% improvement in IPSS from baseline (90% CI, 72.6 to 88.1). Mean IPSS was 22.3 at baseline and 7.9 at one year. Qmax improved from 10.9 to 18.4 mL/s, and IPSS-measured quality of life improved from 4.6 to 1.3 at one-year follow-up. 113 adverse events were reported. The most frequent treatment-related adverse events were post-procedural hematuria (15.0%), postoperative urinary retention (13.8%), urinary incontinence (13.8%), urinary tract infection (8.8%), ejaculation disorder (8.8%), and dysuria (7.5%). Most postoperative urinary retention events were caused by clots blocking the Foley catheter outlet, and greater than 90% (11 of 12) events resolved within one week. Interim data analysis revealed a worse safety profile with use of the large diameter balloon catheter, including higher rates of bleeding and incontinence. As a result, this device size option was removed for the last 31 participants treated in the study. This study is limited by lack of a control group, and longer-term follow-up is necessary to determine treatment durability.

Section Summary: Optilume® BPH Catheter System

Data from one RCT and one single-arm study suggest that the Optilume® BPH Catheter System may improve peak urinary flow rate and symptoms associated with benign prostatic hyperplasia, but symptom scores did not reach statistical significance in the RCT. There are multiple limitations of the data including lack of control group in one study, concerns about serious adverse events (hematuria was most common), and the treatment may not be generalizable for prostates above 80g. Long-term follow-up is also needed to determine durability of this treatment. No studies have directly compared the Optilume® BPH Catheter System to established treatments. There is also a lack of data on paclitaxel in tissues at long-term follow-up. There is not yet enough evidence that the technology results in an improvement in the net health outcome.

OPTILUME® DRUG COATED URETHRAL DILATION CATHETER

Clinical Context and Therapy Purpose

Use of a drug-coated urethral dilation catheter in male patients who have obstructive urinary symptoms associated with anterior urethral stricture is to provide a treatment alternative to, or an improvement on, existing therapies such as urethral dilation with an uncoated balloon catheter, endoscopic management or urethroplasty. Relevant outcomes include patient-reported measures such as the AUASI and IPSS to assess symptoms, uroflowmetry to determine severity of obstruction, and evaluation of stricture diameter with urethroscopy, retrograde urethrography, or ultrasound urethrography.

Randomized Controlled Trials

Elliot (2022) published one-year outcomes from the ROBUST III multi-center, single-blind trial that evaluated the safety and efficacy of the Optilume® DCB for treatment of recurrent anterior urethral strictures.[29] Participants were adult males with anterior urethral strictures less than or equal to 12Fr in diameter and less than or equal to three cm long, who had at least two prior endoscopic treatments, IPSS score greater than or equal to 11, and maximum urine flow rate less than 15 mL per second. The primary efficacy endpoint was anatomical success, defined as diameter greater than or equal to 14Fr determined by urethral cystoscopy or calibration at six months. 127 participants were randomized 2:1 to treatment and control groups and were blinded to treatment through six months. Endoscopic control treatments were the standard of care at each site and included treatment with an uncoated balloon catheter, direct visual internal urethrotomy (DVIU), serial diltion with urethral sounds, or a combination of these treatments. Post-procedure follow-up occurred at Foley catheter removal (two to five days in both groups), 30 days, three months, six months, and one year. At six months, anatomical success was 75.6% in the DCB group and 26.8% in the control group, with an estimated difference of 44.4% ($p<0.0001$). Freedom from repeat intervention through one year was significantly higher for the DCB group than the control group (83.2% versus 21.7%, $p<0.0001$). From baseline to 30 days, both groups experienced a significant increase in Qmax, IPSS, and IPSS quality of life scores. However, the control group experienced deterioration in all of these categories by one year while the significant improvements remained at one year in the DCB group. Adverse event types and rates were similar between groups, except that the DCB group had higher rates of post-procedure mild hematuria and dysuria (11.4% versus 2.1% for both event types). A limitation of this study is that Optilume DCB was compared to dilation and DVIU, so it is unknown how this treatment compares to urethroplasty, which is considered standard of care for urethral stricture. The authors also acknowledged that these early positive results could be impacted by surgeons dilating the urethra with Optilume, but in this study the immediate post-treatment diameter was similar between treatment groups.

Single-Arm Studies

DeLong (2022) published interim, one-year results from the ROBUST II study that investigated the safety and efficacy of a paclitaxel-coated balloon for treatment of recurrent urethral strictures. The study included 16 adult males with a single anterior urethral stricture less than or equal to three cm in length, and who had at least two prior stricture treatments.[30] The primary safety endpoint was the rate of treatment-related serious complications 90 days after treatment. Efficacy outcomes were symptomatic assessments (IPSS), erectile function (IIEF), Qmax, and anatomic success defined by the ability to pass a 16F flexible cystoscope through the treatment site. Anatomic success was achieved for 73% of participants at six months.

Average IPSS improved from 18.4 to 6.0 at one year (p<0.001). Qmax improved from 6.9 mL/s to 20.8 mL/s (p<0.001). There was no change in IIEF. Four participants received additional treatment for urethral stricture within one year. No treatment-related serious complications occurred. This study is limited by small sample size and lack of a comparison group.

Virasoro (2020) published interim, one-year results from the ROBUST I study that enrolled 53 males with bulbar urethral strictures less than or equal to two cm with one to four prior endoscopic treatments.[31] All participants were treated with mechanical balloon dilation or DVIU prior to drug-coated balloon treatment. 46 participants completed the 12 month follow up. The preliminary efficacy endpoint was anatomic success, defined by urethral lumen greater than or equal to 14Fr at 12 months. The primary safety endpoint was serious complications through 90 days. Anatomic success was achieved in 32 of 46 participants (70%; 95% CI 54 to 82%) at 12 months. The 14 failures included seven cystoscopic recurrences, five retreatments, and two patients who exited the study early due to symptom recurrence. There were no serious adverse events related to the treatment within 90 days and no serious adverse events related to the procedure at 12 months. Follow-up is planned through five years post-treatment for the ROBUST I study, and published two- and three-year outcomes are discussed below.

Mann (2021) published two-year outcomes of the ROBUST I study in which 46 participants completed the 24-month follow-up.[32] The primary efficacy endpoint was greater than or equal to 50% improvement in IPSS at 24 months, and the primary safety endpoint was serious urinary adverse events. 43% of participants had undergone at least one or more previous urethral dilation procedure. The primary endpoint was achieved in 32 of 46 participants (70%), and baseline IPSS improved from a mean of 25.2 to 6.9 at 24 months (p<0.0001). There were no treatment-related serious adverse events at 24 months. There were 71 mild-to-moderate adverse events, most frequently: urinary tract infection (17%), fever (8%), dysuria (7%), acute urinary retention (6%), and headache (6%).

Virasoro (2022) published three-year outcomes of ROBUST I which included results for 33 participants who completed the three-year follow-up visit and 10 patients who experienced clinical failures at previous visits (n=43).[33] The primary efficacy endpoint, greater than or equal to 50% reduction in IPSS, occurred in 29 of 43 participants (67%). Average IPSS improved from 25.2 at baseline to 5.5 at three years (p<0.0001). 33 of 43 participants (77%) did not require retreatment. Significant improvements were also observed in quality of life, urinary flow rate, and post-void residual urine volume. Similar to previous results at earlier follow-ups, device-related adverse events were mild or moderate and resolved quickly after onset. There were no serious treatment-related adverse events. The ROBUST I study is limited by lack of a comparator group and small sample size.

Section Summary: Optilume® Drug Coated Urethral Dilation Catheter

Data from one RCT and two single-arm studies reported that the Optilume® Urethral Drug Coated Balloon significantly reduced stricture recurrence, increased urinary flow rate, and improved urinary symptom scores. The RCT reported significantly greater improvement with the drug-coated balloon than with endoscopic management. Drug-coated balloon treatment was more durable than endoscopic treatment at one year follow-up. Limitations of the RCT are that most participants had bulbar urethral strictures, so it is unknown whether the treatment is generalizable to all types of urethral strictures; hematuria was more common with the drug-coated balloon; and this treatment has not been compared to urethroplasty which is most successful for treating recurrent strictures. In these studies, long-term follow-up beyond one-

year occurred only in small single-arm studies. Further, additional long-term data on paclitaxel in tissues is needed to assess device safety. There is not yet enough evidence that the technology results in an improvement in the net health outcome.

PRACTICE GUIDELINE SUMMARY

AMERICAN UROLOGICAL ASSOCIATION

In 2021, the American Urological Association (AUA) published guidelines on the surgical evaluation and treatment of lower urinary tract symptoms attributed to benign prostatic hyperplasia.[5] These guidelines do not address the use of temporarily implanted nitinol devices or drug-coated balloon catheters.

In 2023, the AUA published an amendment to the 2016 guidelines for the treatment of urethral stricture disease.[12] These guidelines state, “Surgeons may offer urethral dilation or direct visual internal urethrotomy, combined with drug-coated balloons, for recurrent bulbar urethral strictures less than three cm in length (Conditional Recommendation; Evidence Level: Grade B).”

SUMMARY

TEMPORARY IMPLANTED NITINOL DEVICES

There is not enough research to show that temporarily implanted nitinol devices (e.g., iTind) work better than established treatments to improve health outcomes for people with benign prostatic hyperplasia. No clinical guidelines based on research recommend temporarily implanted nitinol devices to treat benign prostatic hyperplasia. Therefore, temporarily placed nitinol devices (e.g., iTind) are considered investigational for all indications, including but not limited to treatment of symptoms due to benign prostatic hyperplasia.

OPTILUME® BENIGN PROSTATIC HYPERPLASIA CATHETER SYSTEM

There is not enough research to show that drug-coated balloon catheters (e.g., Optilume® BPH) work better than established treatments to improve health outcomes for people with benign prostatic hyperplasia. No clinical guidelines based on research recommend drug-coated balloon catheter systems to treat benign prostatic hyperplasia. Therefore, drug-coated balloon catheter systems (e.g., Optilume® BPH) are considered investigational for all indications, including but not limited to treatment of symptoms due to benign prostatic hyperplasia.

OPTILUME® URETHRAL DRUG COATED BALLOON

There is not enough research to show that drug-coated balloon catheters (e.g., Optilume® Urethral Drug Coated Balloon) work better than established treatments to improve health outcomes for people with urethral stricture or stenosis. The AUA recommends drug-coated balloons conditionally and only in combination with established endoscopic management of urethral strictures. Therefore, drug-coated balloon catheter systems (e.g., Optilume® Urethral Drug Coated Balloon) are considered investigational for all indications, including but not limited to treatment of symptoms due to urethral stricture or stenosis.

Radiofrequency Ablation and Injection of Sacroiliac Joint Nerves

Effective: January 1, 2024

Next Review: August 2024
Last Review: August 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Radiofrequency ablation (RFA), also known as radiofrequency neurotomy, involves heating a portion of a pain-transmitting nerve to functionally denervate a designated joint (e.g., sacroiliac) and prevent the transmission of pain signals to the brain. A nerve block is injected prior to the RFA procedure for diagnostic purposes.

MEDICAL POLICY CRITERIA

Radiofrequency ablation (neurotomy) or injection (e.g., anesthetic agent, steroid) of the nerves innervating the sacroiliac joint is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

3. Sacroiliac Joint Fusion, Surgery, Policy No. 193

BACKGROUND

The sacroiliac joint (SIJ) is a joint between the sacrum and ilium of the pelvis. The SIJ is a strong weight bearing joint with a self-locking mechanism that provides stability with movement on the left and right side of the sacrum. Similar to other structures in the spine, it is assumed that the SIJ may be a source of low back pain.

Treatments being investigated for SIJ pain include prolotherapy, corticosteroid injection, radiofrequency ablation, stabilization, and arthrodesis. Radiofrequency ablation (denervation, neurotomy) involves destruction of the nerves using heat generated by a radiofrequency current. A catheter or electrode is placed near or in the target nerve. The position of the electrode is confirmed by fluoroscopy. Once the electrode is in place, a radiofrequency current is applied to heat and destroy the surrounding tissues, including the target nerve. Before the RFA procedure, a nerve block is injected into one or two of the nerves innervating the SIJ to locate the target nerve for ablation.

REGULATORY STATUS

A number of radiofrequency generators and probes have been cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process. In 2005, the Sinergy® (Halyard; formerly Kimberly-Clark), a water-cooled single-use probe, was cleared by the FDA, listing the Baylis Pain Management Probe as a predicate device. The intended use is in conjunction with a radiofrequency generator to create radiofrequency lesions in nervous tissue.

FDA product codes: GXD, GXI.

EVIDENCE SUMMARY

The principal outcome for treatment of pain is symptom relief and improved functional level. Relief of pain can be subjective depending on the validity of the measurement tool used. Randomized controlled trials (RCTs) are desirable to control for the placebo effect and determine whether any treatment effect provides a significant advantage over the placebo. In addition, well-designed studies comparing radiofrequency ablation (RFA) treatment with conventional treatment are important to determine the overall effectiveness of this therapy for the treatment of sacroiliac joint (SIJ) pain. This evidence review includes both SIJ RFA and injections (e.g., anesthetic, steroid).

Systematic Reviews

Maccagnano (2022) published a systematic review (SR) comparing clinical outcomes of thermal (RFT) versus cooled radiofrequency ablation (RFC) in patients (n=276) with SIJ pain.[1] The analysis revealed a small and non-significant difference in pain reduction and an improvement in quality of life in RFT subgroup (pain measured in Visual Analogic Scale: RFT subgroups standardized mean difference (SMD) =-3.643 (95% confidence interval [CI] -4.478 to 2.807), RFC subgroup SMD = -3.285 (95% confidence interval [CI] -4.428 to -2.141), p=0.587; Quality of Life measured in Oswestry Disability Index: RFT subgroup SMD=-35.969 (95% CI -53.993 to -17.945), RFC subgroup SMD=-20.589% (95% CI -33.424 to -7.754), p=0.123). Publication bias was found in quality-of-life assessment due to the low number and high heterogeneity of studies. Two techniques showed no major complications.

Chou (2021) conducted a SR and meta-analysis on interventional treatments for acute and chronic pain for the Agency for Healthcare Research and Quality for use by the Centers for Medicare and Medicaid Services.[2] The systematic review identified two trials (n=79) on cooled RFA versus sham for SIJ pain with results at three months, and one trial (n=28) on cooled RFA versus sham with results at one month. Meta-analysis indicated that cooled RFA is probably more effective for pain and function compared to sham at one and three months with moderate to large benefits. The strength of evidence was rated moderate for pain and function at three months and low for function at one month. When comparing cooled RFA to conventional RFA, one trial (n=43) showed no differences at one or three-month follow-up and a small, nonstatistically significant reduction in pain at six months. The strength of evidence was rated as low.

Chappel (2020) performed a meta-analysis of RFA for chronic back pain.[3] The review included five RCTs comparing RFA to sham or medical treatment in patients with chronic SIJ pain with follow-up from one to three months, and one study that had a follow-up to 12 months. This meta-analysis did not include pulsed RFA. Low-quality evidence indicated that RFA led to a modest reduction in pain at one to three-month follow-up, but there was no significant reduction in pain in the single RCT (n=228) that had six- and 12-month follow-up. The RCT by Juch (2017) with 12-month follow-up is described in greater detail below. [4]

Chen (2019) published a meta-analysis of five RCTs comparing RFA to sham or medical treatment in patients with chronic SIJ pain.[5] Various RFA procedures were represented, including percutaneous, cooled, and palisade SIJ radiofrequency neurotomy. Pain outcomes from all RCTs were pooled for the meta-analysis. Disability outcomes were only available for two studies utilizing cooled RFA. While studies showed no significant heterogeneity for disability outcomes, heterogeneity was high for pain outcomes.

Randomized Controlled Trials

Cohen (2023) published the results from a multicenter, randomized comparative effectiveness study to assess cooled RFA with standard medical management for chronic SIJ pain.[6] Patients (n=210) with clinically suspected sacroiliac joint pain who obtained short-term benefit from diagnostic sacroiliac joint injections and prognostic lateral branch blocks were randomly assigned to receive cooled radiofrequency ablation (cRFA) of the L5 dorsal ramus and S1-S3 lateral branches or standard medical management (SMM) consisting of pharmacotherapy, injections and integrative therapies. The primary outcome measure was mean reduction in low back pain score on a 0-10 Numeric Rating Scale (NRS) at three months. Secondary outcomes included measures of quality of life (QOL) and function. The mean NRS pain score for the cRFA group was 3.8 ± 2.4 (mean reduction 2.5±2.5) compared with 5.9 ±1.7 (mean reduction 0.4±1.7) in the SMM group ($p<0.0001$). More than half (52.3%) of subjects in the cooled radiofrequency ablation group experienced > 2.0 points (30%) pain relief and were deemed responders versus 4.3% of standard medical management patients ($p<0.0001$). Comparable improvements favoring cooled radiofrequency ablation were noted in Oswestry Disability Index score (mean 29.7 ± 15.2 vs 41.5 ± 13.6; $p<0.0001$) and QOL (mean EuroQoL-5 score 0.68 ± 0.22 vs 0.47 ± 0.29; $p<0.0001$). Long term outcomes are lacking and there is potential bias as each of the authors are consultants for the RFA device company.

Mehta (2018) published results from a double-blind, randomized, sham-controlled trial assessing the efficacy of radiofrequency neurotomy with a strip-lesioning device in patients with chronic SIJ pain.[7] Seventeen of 30 enrolled patients were randomized to active (n=11) or

sham (n=6) treatment. Recruitment was terminated after an interim analysis indicated a statistically significant difference in the pain outcome between groups. After the three-month study endpoint, patients receiving sham treatment were allowed to crossover. While a statistically significant reduction in pain scores was reported at three months, there was no significant difference in functional outcome as measured by the Physical Component Score at three months. Due to the crossover design, it is difficult to gauge long-term outcomes and durability of the treatment.

Dutta (2018) published a randomized prospective study comparing RFA with depo-methylprednisolone (DMP) injection for SIJ pain.[8] Patients (n=30) were randomly assigned to RFA or DMP injection of the L4 medial branch and L5 dorsal rami and the lateral sacral branches. Both groups reported a reduction in pain as measured by the Numeric Rating Scale (NRS) at one month. At six months the NRS score began to rise for the DMP group while the RFA group remained the same (since the last visit). Both groups had improvement in the Oswestery Disability Index (ODI) score at three and six months with the RFA group having a lower score at both time points. This study is limited by a small sample size.

Juch (2017) reported a nonblinded multicenter RCT of radiofrequency denervation in 228 of 2498 patients with suspected sacroiliac pain who were asked to participate in the trial.[4] Patient selection criteria included body mass index (<35 kg/m^2), age (<70 years old), and pain reduction of at least 50% within 30 to 90 minutes of receiving a diagnostic sacroiliac block (n=228). An additional 202 patients had a negative diagnostic sacroiliac block; 1666 patients declined to participate in the trial. Patients meeting criteria were randomized to exercise plus radiofrequency denervation (n=116) or an exercise program alone (n=112) and were followed for a year. The RFA group had a modest improvement for the primary outcome at 3 months (-0.71; 95% CI: -1.35 to -0.06), but the control group improved over time and there were no statistically significant differences between the groups for pain intensity score (p=.09) or in the number of patients who had more than a 30% reduction in pain intensity (p=0.48) at 12 months. Limitations included the use of several techniques to achieve radiofrequency denervation, self-selection, lack of blinding, and a high dropout rate (31%) in the control group.

Van Tilburg (2016) reported a sham-controlled randomized trial of percutaneous RFA in 60 patients with SIJ pain.[9] Patients selected had clinically suspected SIJ pain and a decrease of two or more points on a 10-point pain scale with a diagnostic sacroiliac block. At three-month follow-up, there was no statistically significant difference in pain level over time between groups (group by period interaction, p=0.56). Both groups improved over time (≥ 2.0 points out of 10; p-value for time, p<.001). In their discussion, trialists mentioned the criteria and method used for diagnosing SIJ pain might have resulted in the selection of some patients without SIJ pain.

Canovas (2016) published a randomized, prospective study comparing blockade injection, bipolar thermal RFA (needle distance 1 cm) and a modified bipolar RFA (needle distance > 1.0 cm) in 60 patients.[10] One month after the treatment, pain reduction was >50% in the three groups p<0.001. Three and 12 months after the technique, the patients of the group A did not have a significant reduction in pain. At three months, almost 50% patients of the group B referred to improvement of the pain (p=0.03), and <25% at 12 months, and those results were statistically significant (p=0.01) compared to the baseline. Group C showed an improvement of 50% at three and 12 months (p<.001). All patients completed the study.

Zheng (2014) reported on an RCT of palisade sacroiliac RFA in 155 patients with ankylosing spondylitis.[11] Palisade RFA uses a row of radiofrequency cannulae perpendicular to the dorsal sacrum. Inclusion criteria were ages 18 to 75 years; diagnosis of ankylosing spondylitis; chronic low back pain for at least three months; axial pain below L5; no peripheral involvement; pain aggravation on manual pressing of the SIJ area; and at least 50% pain relief following fluoroscopically guided anesthetic injection into the joint. Patients who met the inclusion criteria were randomized to palisade RFA or celecoxib. Blinded evaluation to 24 weeks found that RFA (2.8) resulted in lower global VAS scores than celecoxib (5.0; p<.001) as well as improved scores for secondary outcome measures. This study lacked a sham control.

Patel (2012) reported a randomized, double-blind, placebo-controlled trial of lateral branch neurotomy with a cooled radiofrequency probe.[12] Twelve-month follow-up was reported in 2016.[13] Fifty-one patients who had a positive response to two lateral branch blocks were randomized 2:1 to lateral branch radiofrequency or to sham. At a three-month follow-up, significant improvements were observed in pain levels (-2.4 vs -0.8), physical function (14.0 vs 3.0), disability (-11.0 vs 2.0), and QOL (0.09 vs 0.02) for radiofrequency treatment compared with controls (all respectively). With treatment success defined as a 50% or greater reduction in numeric rating scale score, 47% of radiofrequency-treated patients and 12% of sham-treated patients achieved treatment success. The treatment response was durable to 12 months in the 25 of 34 patients who completed all follow-up visits.[13] Of the nine patients who terminated study participation, four of 34 (12%) were considered treatment failures.

Section Summary

There are no sham controlled RCTs that support injections of the nerves that innervate the sacroiliac joint to treat pain. Meta-analysis of available sham controlled RCTs suggests that there may be a small effect of RFA on SIJ pain at short-term (one- to three-months) follow-up. However, the randomized trials of RFA have methodologic limitations, and there is limited data on the duration of the treatment effect. The single RCT with six and 12-month follow-up showed no significant benefit of RFA compared to an exercise control group at these time points. In addition, heterogeneity of RFA treatment techniques precludes generalizing results across different studies.

PRACTICE GUIDELINE SUMMARY

AMERICAN SOCIETY OF PAIN AND NEUROSCIENCE

In 2021, the American Society of Pain and Neuroscience published practice a guideline on radiofrequency ablation (neurotomy).[14] All of the workgroup members utilized radiofrequency neurotomy in clinical practice. A consensus statement, based on Grade II-1 evidence (well-designed, controlled, nonrandomized clinical trial), was that "lateral branch radiofrequency ablation (neurotomy) may be used for the treatment of posterior sacral ligament and joint pain following positive response to appropriately placed diagnostic blocks."

AMERICAN SOCIETY OF ANESTHESIOLOGISTS & AMERICAN SOCIETY OF REGIONAL ANESTHESIA AND PAIN MEDICINE

The American Society of Anesthesiologists and the American Society of Regional Anesthesia and Pain Medicine have a 2010 guideline for chronic pain management.[15] The guideline recommends that “Diagnostic sacroiliac joint injections or lateral branch blocks may be considered for the evaluation of patients with suspected sacroiliac joint pain.” Based on the

opinions of consultants and society members, the guideline recommends that “Water-cooled radiofrequency ablation may be used for chronic sacroiliac joint pain.”

SUMMARY

There is not enough research to show that radiofrequency ablation (RFA) or injection (e.g., anesthetic agent, steroid) of the nerves innervating the sacroiliac joint (SIJ) improves net health outcomes in patients with sacroiliac joint pain. High quality data from randomized controlled trials are needed to compare RFA and injections to the nerves innervating the SIJ with the currently accepted treatments for SIJ pain. Therefore, the use of radiofrequency ablation (RFA) or injection (e.g., anesthetic agent, steroid) of the nerves innervating the sacroiliac joint for the treatment of sacroiliac joint pain is considered investigational.

Vertebral Body Tethering and Stapling

Effective: January 1, 2024

Next Review: November 2024
Last Review: November 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Vertebral body stapling and vertebral body tethering, both fusionless surgical procedures, have been evaluated to determine whether the procedures could be used as alternatives to traditional orthotic bracing.

MEDICAL POLICY CRITERIA

Vertebral body stapling and vertebral body tethering for the treatment of scoliosis are considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

None

BACKGROUND

SCOLIOSIS

Scoliosis is an abnormal lateral and rotational curvature of the vertebral column. Adolescent idiopathic scoliosis is the most common form of idiopathic scoliosis, defined by the U.S. Preventive Services Task Force as “a lateral curvature of the spine with onset at ≥10 years of age, no underlying etiology, and risk for progression during puberty.”[1] Progression of the curvature during periods of rapid growth can result in deformity, accompanied by cardiopulmonary complications. Diagnosis is made clinically and radiographically. The curve is measured by the Cobb angle, which is the angle formed between intersecting lines drawn perpendicular to the top of the vertebrae of the curve and the bottom vertebrae of the curve. Patients with adolescent idiopathic scoliosis are also assessed for skeletal maturity, using the Risser sign, which describes the level of ossification of the iliac apophysis.

The Risser sign measures remaining spinal growth by progressive anterolateral to posteromedial ossification. Risser sign ranges from 0 (no ossification) to 5 (full bony fusion of the apophysis). Immature patients will have 0% to 25% ossification (Risser grade 0 or 1), while 100% ossification (Risser grade 5) indicates maturity with no spinal growth remaining. Children may progress from a Risser grade 1 to grade 5 over a brief (eg, 2-year), period.

Males and females are equally affected by scoliosis, but curve progression is up to 10 times more common in females than males.[2] Patients who are overweight or obese have a greater risk of presenting with larger Cobb angles and more advanced skeletal maturity, possibly due to delayed detection.[3] A retrospective review of 341 patients with adolescent idiopathic scoliosis who underwent surgery at a single tertiary pediatric hospital between 2013 and 2018 found that the major curve magnitude at presentation was significantly higher in patients with public compared to private insurance (50.0° versus 45.1°; p=.0040 and in Black compared to White patients (51.8° versus 47.0°; p=.042). Additionally, the odds of having an initial major curve magnitude <40° within the range of nonoperative treatment were 67% lower among Black patients with public insurance compared to Black patients with private insurance (odds ratio [OR], 0.33; 95% CI, 0.13 to 0.83; p=.019).[4]

Treatment

Treatment of scoliosis currently depends on 3 factors: the cause of the condition (idiopathic, congenital, secondary), the severity of the condition (degrees of the curve), and the growth of the patient remaining at the time of presentation. Children who have vertebral curves measuring between 25° and 40° with at least 2 years of growth remaining are considered to be at high risk of curve progression. Genetic markers to evaluate the risk of progression are also being evaluated. Because severe deformity may lead to compromised respiratory function and is associated with back pain in adulthood, surgical intervention with spinal fusion is typically recommended for curves that progress to 45° or more.

Bracing

Bracing is used to reduce the need for spinal fusion by slowing or preventing further progression of the curve during rapid growth. Commonly used brace designs include the Milwaukee, Wilmington, Boston, Charleston, and Providence orthoses. The longest clinical experience is with the Milwaukee cervical-thoracic-lumbar-sacral orthosis. Thoracic-lumbar-sacral orthoses, such as the Wilmington and Boston braces, are intended to improve tolerability and compliance for extended (>18-hour) wear and are composed of lighter weight plastics with a low profile (underarm) design. The design of the nighttime Charleston and Providence braces is based on the theory that increased corrective forces will reduce the needed wear time (ie, daytime), thereby lessening social anxiety and improving compliance.

The smart brace consists of a standard rigid brace with a microcomputer system, a force transducer, and an air-bladder control system to control the interface pressure. Braces that are more flexible than thoracic-lumbar-sacral orthoses or nighttime braces, such as the SpineCor® Scoliosis System, are also being evaluated. The SpineCor is composed of a thermoplastic pelvic base with stabilizing and corrective bands across the upper body.

Surgery

Fusionless surgical procedures, such as vertebral body stapling and vertebral body tethering, are being evaluated as alternatives to bracing. Both procedures use orthopedic devices off-label. The goal of these procedures is to reduce the rate of spine growth unilaterally, thus allowing the other side of the spine to “catch up.” The mechanism of action is believed to be down-regulation of the growth plate on the convex (outer) side by compression and stimulation of growth on the endplate of the concave side by distraction. In the current stapling procedure, nickel-titanium alloy staples with shape memory are applied to the convex side of the curve. The shape memory allows the prongs to be straight when cooled and clamp down into the bone when the staple returns to body temperature. Anterolateral tethering uses polyethylene ligaments that are attached to the convex side of the vertebral bodies by pedicle screws or staples. The ligament can be tightened to provide greater tension than the staple. The optimum degree of tension is not known. The polyethylene ligaments are more flexible than staples and are predicted to allow more spinal mobility. The goal of a fusionless growth modulating procedure is to reduce the curve and prevent progression, maintain spine mobility following correction, and provide an effective treatment option for patients who are noncompliant or who have a large curve but substantial growth is remaining. Observational data suggest that overweight patients may be at higher risk for scoliosis progression after surgery.[5]

Regulatory Status

Staples, using a shape memory nickel-titanium alloy, have been cleared for marketing by the FDA through the 510(k) process for various bone fixation indications. For example, nitinol staples (Sofamor Danek) are indicated for fixation with spinal systems. Other memory shape staples cleared for marketing by the FDA through the 510(k) process for bone fixation include the OSStaple™ (BioMedical Enterprises) and the reVERTO™ Dynamic Compression Device. FDA product code: JDR. Vertebral body stapling in scoliosis is considered off-label use.

A vertebral body tethering device (The Tether™; Zimmer Biomet Spine) received an FDA Humanitarian Device Exemption (HDE) (H190005, product code QHP) in June 2019. The FDA HDE states that this device is indicated for "skeletally immature patients that require surgical treatment to obtain and maintain correction of progressive idiopathic scoliosis, with a major Cobb angle of 30 to 65 degrees whose osseous structure is dimensionally adequate to accommodate screw fixation, as determined by radiographic imaging. Patients should have failed bracing and/or be intolerant to brace wear."

EVIDENCE SUMMARY

VERTEBRAL BODY STAPLING

Review of Evidence

Nonrandomized Comparative Study

In a multicenter study, Cuddihy (2015) reported on a matched comparison of VBS and bracing for immature patients with moderate (25° to 44°) idiopathic scoliosis.[6] Forty-two consecutive patients in the VBS group (57 curves) met inclusion criteria, and 52 patients in the bracing group (66 curves) were matched by initial Cobb angle, age at the start of treatment, follow-up of at least 2 years, and sex. The average curve size was 31°, and the average follow-up was 40.8 months in the VBS group and 105 months in the bracing group (maturity). For smaller thoracic curves (25° to34°), there was a nonstatistically significant trend for stapling to be more effective (progression <10°, 81%) compared with bracing (61%; p=.16). For larger thoracic curves (>35°), VBS did not halt curve progression, with a success rate of 18% compared with 50% for bracing. For lumbar curves (25° to 34°), results were comparable for VBS and bracing. There were insufficient numbers of patients with lumbar curves of 35° or greater to compare results.

Observational Studies

Several case series and one case-control study evaluating VBS are described below and in Tables 1 and 2.

Cuddihy (2015) compared VBS to bracing in a matched cohort of skeletally immature patients with moderate idiopathic scoliosis.[6] A total of 52 patients (66 curves) were matched according to age at the start of treatment (10.6 years vs. 11.1 years, respectively) and gender. In smaller thoracic curves (25° to 34°) there was a nonsignificant trend toward better results with VBS versus bracing. For those with thoracic curves ≥35°, VBS was not found to be effective, and for lumbar curves 25° to 35°, results appear to be similar for both VBS and bracing.

Murray (2020) described VBS in 7 patients with a mean age of 9.3 years (range, 7.8 to11.1 years) and an average preoperative Cobb angle of 30° (standard deviation [SD], 6°); the mean follow-up was 83 months (range, 72 to 95 months).[7] At the first postoperative visit and most recent follow-up visit, the average Cobb angle was 20° (SD, 7°) and 37° (SD, 22°), respectively. One patient showed improvement of greater than 10° from preoperative to final postoperative Cobb angle, 4 patients showed no change in their curve, and 2 showed progression of their curves by greater than 10° compared with preoperative imaging.

Bumpass (2015) described VBS in 31 consecutive patients with a mean age of 10.5 years (range, 7.0 to 14.6 years) and scoliotic curves of 25° to 40°.[8] Not all patients could (or would) wear a brace. At a mean follow-up to maturity of 48 months (range, 25 to 79 months), curves less than 35° had a control rate (<10° progression) of 75% while curves with a Cobb angle of at least 35° had a control rate of 22% (p=.01). The overall control rate was 61%, with 11 (31%) patients requiring subsequent fusion and 2 (6%) overcorrections.

Theologis (2013) described VBS in 12 children younger than 10 years old (range, 6.3 to 9.7 years) who were considered extremely likely to require fusion (ie, curves of 30° to 39° in a young child).[9] At an average 3.4-year follow-up (range, 2.2 to 5.4 years), curves had decreased by a mean of 10° (range, -3° to 20°). All curves in this high-risk population were successfully treated, with either no change (within 10°) or improvement in the curve (>10°).

Laituri (2012) retrospectively reviewed 7 children ages 8 to 11 years old who had undergone VBS and had at least 2 years of follow-up.[10] All children either had curve progression, despite bracing, or were unable to wear a brace. Before stapling, the mean angle was 34.1°. The mean percentage correction was 36% (range, 16.2% to 56%). None of the children had curve progression or required postoperative bracing or spinal fusion.

O’Leary (2011) reported that VBS in young children with large Cobb angles was ineffective.[11] Patients with adolescent idiopathic scoliosis were not included in this report. Diagnoses included myelodysplasia, congenital scoliosis, juvenile and infantile idiopathic scoliosis, Marfan syndrome, paralytic scoliosis, and neuromuscular scoliosis. At an average 22-month follow-up, curves averaged 69°, and 8 of 11 patients had undergone or were scheduled to undergo further spinal surgery for curve progression. It is unknown whether the young age at surgery, the severe preoperative curve, or the nature of underlying scoliosis contributed to the high failure rate.

Betz (2010) reported on 29 patients with juvenile or adolescent idiopathic scoliosis (from a database of 93 patients) who met the study inclusion criteria.[12] Selected were patients with idiopathic scoliosis, a coronal curve magnitude of 20° to 45°, Risser grade 0 or 1, and staples with tines proportional to staple size (beginning in 2002). The average age at the time of stapling was 9.4 years (range, 4 to 13 years), with an average follow-up of 3.2 years (range, 2 to 5.3 years). For thoracic curves greater than 35° at baseline, 75% progressed to greater than 50° (the threshold for recommending spinal fusion). For thoracic curves less than 35° at baseline, 6% of patients progressed to greater than 50° (the threshold for surgery).

Section Summary: Vertebral Body Stapling

Evidence on the use of VBS for patients with idiopathic scoliosis consists of a nonrandomized comparative study, a case-control study, and several small case series. Results from the nonrandomized comparative study and case-control study have indicated that VBS might slow curve progression in children with thoracic curves less than 35° and is at least as effective as bracing, but VBS appears to be less effective than bracing in patients with Cobb angles of 35° or more. Results from these studies are considered preliminary because few patients have been followed to skeletal maturity. Studies from other centers are consistent with results from those of the inventor of the procedure. Complications can include broken staples, staple dislodgement, curve overcorrection, congenital diaphragmatic hernia rupture, contralateral pleural effusion, pneumothoraces, and superior mesenteric artery syndrome. Investigators have commented that their approach is almost always to recommend bracing first and offer stapling only if the child or adolescent has difficulty wearing the brace. Notably, for patients with thoracic curves of 35° or greater, Cuddihy (2015) now perform vertebral body tethering (see next section) instead of VBS.

VERTEBRAL BODY TETHERING

Review of Evidence

Systematic Reviews

Mariscal (2023) published a meta-analysis of 12 studies on the efficacy and safety of anterior vertebral body tethering (AVBT) in adolescent idiopathic scoliosis[13]. Significant corrections of the main thoracic, proximal thoracic, and thoracolumbar/lumbar curves were seen at 1-2 years post procedure, but no significant corrections were seen in the sagittal plane. Follow-up time was 24-60 months. The most common complications were overcorrection (8%) and tether breakage (5.9%) The reoperation rate was 10%. The studies included case series and cohort studies with no control groups, and there were no clinical trials. The authors note that while AVBT corrects curve deformities in the coronal plane, full assessment of AVBT is not possible with the available evidence.

Zhu (2022) published a systematic review and meta-analysis of 26 studies representing 1045 subjects (mean age range, 11.1 to 14.9 years) treated with vertebral body tethering (VBT) for scoliosis, finding that the Cobb angle of the major curve was significantly corrected from 40.0° to 59.0° at baseline to 15.9° to 38.0° immediately post-surgery and 10° to 38° at final follow-up.[14] The overall clinical success rate was 73.02% (95% CI, 68.31% to 78.05%). The pooled overall unplanned reoperation rate after VBT was 8.66% (95% CI, 5.53% to 13.31%; 23 studies). The top 3 reinterventions were conversion to posterior spinal fusion (3.51%; 95% CI, 2.45% to 5.01%), tether removal (2.3%; 95% CI, 1.47% to 3.58%), and tether replacement (1.09%; 95% CI, 0.57% to 2.08%). The overall complication incidence rate was 36.8% (95% CI, 23.9% to 49.7%; 24 studies). Most common complications included curve progression with tether breakage (16.79%; 95% CI, 7.43% to 26.15%), pulmonary complications (6%; 95% CI, 4.66% to 7.68%), and overcorrections (4.55%; 95% CI, 3.4% to 6.06%). A subgroup analysis of patients with more than 36 months follow-up time indicated that these patients had increased clinical success (73.88% vs. 65.93%), unplanned reoperation (15.8% vs. 4.55%), and complication rates (52.17% vs. 23.79%) compared to those with less than 36 months follow-up, respectively. Thus, based on the increased reoperation and complication rates observed with longer follow-up, the authors concluded that further improvements to the implant and refinement of patient selection criteria are warranted and should be assessed in the

context of high-quality randomized controlled trials. Study demographics and outcomes based on race, ethnicity, and sex were not reported, potentially limiting the generalizability of these findings.

Observational Studies

As noted in the Regulatory section above, in June 2019, the U.S. Food and Drug Administration (FDA) granted a Humanitarian Device Exemption to a new vertebral body tethering device called The Tether (Zimmer Biomet Spine, HDE #H190005, product code QHP). Available evidence for The Tether includes only one small retrospective cohort study of 57 pediatric patients that is yet unpublished and is only summarized in the FDA's Humanitarian Device Exemption Summary of Safety and Probable Benefit report.[15] In this study, pediatric patients who failed brace treatment (e.g., greater than 5° of progression and/or intolerance to brace wear) received vertebral body tethering with Dynesys vertebral body screws, which are similar to those of the marketed version of The Tether , but that have a slightly higher screw profile. Study participants were 86.4% female, with a mean age of 12.4 years. At baseline, mean Cobb angles were 30° to 44° in 75.4% of participants and 45° to 65° in 24.6% of participants. After 2 years, among the 44 subjects with 24-month data (out of the original 57), 43 met the probable benefit success criteria of achievement of a Cobb angle of 40°or less. Overall, the mean Cobb angles improved from 40.4° to 14.3° (+65%). Although assessment of quality of life at the last follow-up visits were described as "positive" based on the Pediatric Quality of Life Inventory, the clinical importance of this data is unclear as no baseline assessments were completed for comparison. A total of 8 participants had serious adverse events (14%), including overcorrection of the instrumented curve (8.8%), definite cord break (1.8%), development of a new curve (1.8%), and spondylolisthesis (1.8%). Other common adverse events were back pain (24.6%), overcorrection of the instrumented curve (21.1%), nausea/vomiting (21.1%), and extremity pain (21.1%). A total of 8 patients (6%) required surgical revision due to adverse events.

As noted in a 2015 review article, other devices used for vertebral body tethering are under development, and the optimum tension for vertebral body tethering is currently unknown.[16]

Other studies not included in the Zhu (2022) systematic review[14] are discussed below.

Samdani (2014, 2015) published 2 retrospective reviews on the off-label use of the Dynesys system for anterior vertebral body tethering for idiopathic scoliosis.[17, 18] They reported pursuing vertebral body tethering at their children’s hospital due to lack of success with VBS for thoracic curves greater than 35°. At the time of these reports, 32 patients had a minimum of 1-year follow-up,[18] and 11 consecutive patients had a 2-year follow-up.[17] The mean age at surgery was 12 years, and all patients were skeletally immature. Three patients also had VBS for their lumbar curves. For the 11 patients with 2-year follow-up, on average, 7.8 levels (range, 7 to 9 levels) were tethered. Thoracic Cobb angle averaged 44.3° preoperatively, was corrected to 20.3° after surgery, and improved to 13.5° at 2 years. The lumbar curve improved from 25.1° preoperatively to 7.2° at 2 years. Two patients required that tension be reduced after 2 years due to overcorrection.

Pehlivanoglu (2021) conducted a prospective cohort study of 13 skeletally immature patients (mean age, 11.8 years) who underwent vertebral body tethering with the Dynesys system for adolescent idiopathic scoliosis with double curves.[19] At baseline, the mean thoracic/thoracolumbar and lumbar curve magnitudes were 48.2° and 45.3°, respectively. An average of 11.8 levels of tethering were undertaken. Postoperatively, mean

thoracic/thoracolumbar curve magnitudes were 14.3° to 17.3°. At the last follow-up (mean, 36.4 months), the mean thoracic/thoracolumbar curve magnitudes were 8.2° to 9.7°. No major complications were reported.

Meyers (2022) performed a retrospective review of adolescent scoliosis patients (N=49; 74% female) treated with VBT via the Dynesys system after reaching peak height velocity (Risser stage 3-5).[20] Mean patient age was 15 ±- 1.9 years with mean follow-up duration 32.5 ± 9.1 months. In patients with thoracic major curvatures (n=24), the Cobb angle improved from 51.1 ± 6.9° to 27.2 ± 8.1° (47.7% correction; p<.01). In those with thoracolumbar major curves, curvature improved from 37.2 ± 10.7° to 18.8 ± 9.4° (49.5% correction; p<.01). Improvements in major curve inclinometer measurements and SRS-22 domains improved significantly (p≤.05), except for the SRS-22 activity domain. Overall, 37/49 (76%) of patients were deemed clinically successful with residual major curves ≤30°. At final follow-up, 2 major complications were reported. At 3.1 years after VBT, 1 patient required posterior fusion of the thoracic curve due to curve progression and revision of the thoracolumbar tether due to tether breakage. A second patient developed late onset superior mesenteric artery syndrome (SMAS) 1 year postoperatively which required Ladd's derotation surgery. Overall, 20 (41%) patients experienced tether breakage. However, only 4 of 19 (21%) patients with broken tethers failed to meet criteria for clinical success which was comparable to the 7 of 29 (24%) patients with intact tethers. Thus, treatment success in subjects with limited remaining skeletal growth was feasible. While treatment success was not impacted by age or Risser stage, patients with treatment failures reported slightly larger major Cobb angles at baseline.

Section Summary: Vertebral Body Tethering

There is limited published evidence on vertebral body tethering. The Tether is the only vertebral body tethering device that the FDA has approved for marketing based on a June 2019 Humanitarian Device Exemption. Available evidence for The Tether is limited to a small, single-center, uncontrolled, unpublished retrospective cohort study of 57 pediatric patients. Although reported Cobb angle corrections are promising, serious adverse events occurred, data are lacking on other important health outcomes, and there are important study design limitations, including lack of a control group. Additional early reports of a correction in Cobb angle from published reports on the Dynesys system are also promising, but little is known about longer-term outcomes with this procedure. A meta-analysis of vertebral body tethering studies with more than 36 months follow-up reported a 74% clinical success rate, a 52% complication rate, and a 16% unplanned reoperation rate. Most commonly reported complications were tether breakages, pulmonary complications, and overcorrections. Larger, controlled studies are needed to verify these preliminary findings.

PRACTICE GUIDELINE SUMMARY

SOCIETY ON SCOLIOSIS ORTHOPAEDIC AND REHABILITATION TREATMENT

The guidelines from the Society on Scoliosis Orthopaedic and Rehabilitation Treatment (2016) included recommendations on the following conservative treatments for idiopathic scoliosis[21]: assessment, bracing, physiotherapy, physiotherapeutic scoliosis-specific exercises and other conservative treatments for idiopathic scoliosis, exercises, special inpatient rehabilitation, and bracing (nighttime rigid bracing, soft bracing, part-time rigid bracing, full-time bracing). The guidelines did not address vertebral body stapling or vertebral body tethering.

SCOLIOSIS RESEARCH SOCIETY

The Scoliosis Research Society has indicated that the treatment of adolescent idiopathic scoliosis falls into 3 main categories (observation, bracing, surgery) and is based on the risk of curve progression.[22] Vertebral body stapling and tethering are not addressed by the Society.

AMERICAN ACADEMY OF ORTHOPAEDIC SURGEONS

Information updated on the American Academy of Orthopaedic Surgeons' OrthoInfo website indicates that the type of treatment required for idiopathic scoliosis in children and adolescents depends on the kind and degree of the curve, child's age, and the number of remaining growth years until the child reaches skeletal maturity.[2] Vertebral body tethering and VBS are not addressed.

NATIONAL INSTITUTE FOR HEALTH AND CARE EXCELLENCE

In 2022, the National Institute for Health and Care Excellence (NICE) published an interventional procedures guidance on vertebral body tethering for idiopathic scoliosis in children and young people.[23] Recommendations stated that "evidence on the safety of vertebral body tethering for idiopathic scoliosis in children and young people is limited but raises concerns of serious complications. Evidence on its efficacy is inadequate in quality and quantity. Therefore, this procedure should only be used in the context of research."

SUMMARY

There is not enough evidence to show that vertebral body tethering or stapling improves net health outcomes in patients with scoliosis. No clinical practice guidelines based on research recommend the use of vertebral body tethering or stapling for the treatment of scoliosis. Therefore, vertebral body tethering and/or stapling for the treatment of scoliosis is considered investigational.

Coronary Intravascular Lithotripsy

Effective: January 1, 2024

Next Review: December 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Coronary intravascular lithotripsy is used to prepare stenotic, calcified de novo coronary vessels for stent placement. Ultrasound waves are applied intravascularly to selectively break-up calcium deposits to aid with stent placement.

MEDICAL POLICY CRITERIA

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

1. New and Emerging Medical Technologies and Procedures, Medicine, Policy No. 149

BACKGROUND

Coronary artery calcification (CAC) can interfere with percutaneous coronary intervention (PCI)

due to inadequate stent expansion, difficulty transiting the catheter through a calcified lesion, coated drug separation from a stent, proclivity for in-stent restenosis and stent thrombosis, and a change to the underlying pharmacokinetics.

Shockwave intravascular lithotripsy (IVL) utilizes a percutaneous catheter device to produce acoustic pressure waves to break superficial and deep calcium deposits and aid with the subsequent deployment of a vascular stent. Guidance with an intravascular imaging device either with intravascular ultrasound or optical coherence tomography (OCT) is used to define calcium density and to aid in choosing the lesion modification strategy. There are several adjunctive therapies to aid in the modification of calcified plaques in order to facilitate stent delivery. These include rotational atherectomy (RA), scoring, cutting and super high-pressure balloons, orbital atherectomy (OR), laser atherectomy (LA) and IVL.[1]

REGULATORY STATUS

In 2021, The US Food and Drug administration (FDA) granted Premarket Approval (PMA) for the Shockwave Intravascular Lithotripsy (IVL) System with Shockwave C2 Coronary Intravascular Lithotripsy (IVL) Catheter (Product code QMG, PMA number P200039).[2]

The Shockwave Intravascular Lithotripsy (IVL) System with Shockwave C2 Coronary IVL Catheter is indicated for lithotripsy-enabled, low-pressure balloon dilatation of severely calcified, stenotic *de novo* coronary arteries prior to stenting.[3]

EVIDENCE SUMMARY

CORONARY INTRAVASCULAR LITHOTRIPSY (IVL)

The evidence summary includes systematic reviews and randomized clinical trials not included in the systematic reviews.

Systematic Reviews

Caminiti (2023) published a systematic review with meta-analysis to investigate the success rate of IVL for the treatment of stent underexpression (SU) because of coronary calcified plaque.[4] The meta-analysis included 13 studies with 354 patients, majority male (77%). The mean follow-up time was 2.6 months (95% CI 1 to 15.3). Strategy success was seen in 88.7% (95% CI 82.3 to 95.1) of patients. The mean minimal stent area was reported in 6 studies, the pre-IVL value was 3.4 mm2 (95% CI 3 to 3.8), and the post-IVL value was 6.9 mm2 (95% CI 6.5 to 7.4). The mean diameter stenosis (percentage) was reported in seven studies, the pre-IVL value was 69.4% (95% CI 60.7 to 78.2), and the post-IVL value was 14.6% (95% CI 11.1 to 18). The rate of intraprocedural complications was 1.6% (95% CI 0.3 to 2.9). The authors concluded that the “stent through” technique was safe to treat SU.

Mhanna (2022) published a systematic review evaluating the utility of adjunctive IVL.[5]The study included a total of eight single-arm observational studies, including 980 patients (1011 lesions), were included. 48.8% of the patients presented with acute coronary syndrome. Severe calcifications were present in 97% of lesions. Clinical success was achieved in 95.4% of patients (95%CI:92.9%-97.9%). Angiographic success was achieved in 97% of patients (95%CI:95%-99%). There was an overall increase in postprocedural lumen area as well as significant reduction of calcium angle and maximum calcium thickness.

Most of the evidence of safety and effectiveness of Coronary IVL extends from the four prospective, nonrandomized, single arm, manufacturer sponsored, multisite DISRUPT CAD studies: Disrupt CAD I (NCT02650128); Disrupt CAD II (NCT03328949); Disrupt CAD III; and Disrupt CAD IV (NCT04151628). The following publications (systematic review with meta-analysis, meta-analysis, and a pooled analysis) discuss the results of these, as well as retrospective registry studies.[6-8]

Satter (2022) published a meta-analysis for IVL outcomes in severely calcified coronary lesions.[6] The primary outcomes included clinical and angiographic success event ratios. The secondary outcomes included minimal lumen diameter (MLD), diameter stenosis (DS), lumen area, maximum calcium thickness, and calcium angle at minimal lumen area (MLA) and final minimal stent area (MSA). A total of seven studies (n = 760) were included. The DISRUPT CAD I – IV, a subgroup analysis of the DISRUPT CAD I study, and two registry (retrospective cohort analysis) studies. The primary outcomes: pooled clinical and angiographic success event ratio parentage of IVL was 94.4 % and 94.8 %, respectively. On a random effect model for standard inverse variance for secondary outcomes showed: minimal lumen diameter increase with IVL was 4.68 mm (p < 0.0001, 95 % CI: 1.69 to 5.32); diameter decrease in the stenotic area after IVL session was -5.23 mm (95 % CI: -22.6 to 12.8). At the MLA and final MSA sites, MLA gain was 1.42 mm2 (95 % CI: 1.06 to 1.63; p < 0.00001) and 1.34 mm2 (95 % CI: 0.71 to 1.43; p < 0.00001), respectively. IVL reduced calcium thickness at the MLA site (SMD -0.22; 95 % CI: -0.40 to 0.04; p = 0.02); calcium angle was not affected at the MLA site. The tertiary outcomes: most common complication was MACEs (n = 48/669), and least common complication was abrupt closure of the vessel (n = 1/669). The analysis was limited by inclusion of only single-arm observational studies. The definition of sever calcification was not uniform likely due to a lack of consistency of imaging type (ultrasound or optical coherence tomography). Only two studies reported diameter stenosis data. The post procedural outcomes did not include any form of adjunctive treatment (atherectomy or specialty cutting balloons). The authors suggest that more studies, including randomized, double-blind trials, are needed to study safety and efficacy in a head-to-head comparison with other debulking procedures.

Kereiakes (2021) published a pooled safety and effectiveness results from the four DISRUPT CAD I-IV studies.[7] Data was included from patients (n = 628) enrolled in 72 sites from 12 countries. The primary safety endpoint was a composite score of cardiac death, all myocardial infarction, or target vessel revascularization at 30 days. Procedural success was defined as stent delivery with a residual stenosis of >= 30% assessed by quantitative coronary angiography and without in-hospital major adverse CV events. The primary safety and effectiveness endpoints were achieved in 92.7% and 92.4% of patients, respectively. The rate of in-hospital major adverse cardiovascular events was 6.5% (4.7% to 8.8%), driven by non-Q-wave myocardial infarction (5.7%, 4.1% to 7.9%). The rate of 30-day major adverse cardiovascular events was 7.3% (5.4% to 9.7%), also driven by non-Q-wave myocardial infarction (5.9%, 4.2% to 8.1%). At 30 days, the rates of target lesion failure, cardiac death, and stent thrombosis were 7.2%, 0.5%, and 0.8%, and rates of postprocedure and final serious angiographic complications were 2.1% and 0.3%, respectively, with no procedure associated perforations, abrupt closure, or episodes of no reflow, suggesting procedural success in treating both eccentric and concentric calcified lesions. Results of multivariate logistic regression show that treatment of bifurcation lesion (p = 0.006), prior myocardial infarction (p = 0.04), and lesion length ≥ 25 mm (p = 0.049) were independent predictors of 30-day major adverse cardiovascular events. Prior myocardial infarction (p = .016) and treatment of

bifurcation lesion (P = .015) were predictors of lack of procedural success. Several of the authors of this analysis have professional affiliations with the device manufacture.

Sattar (2021) published a SR with meta-analysis examining the safety and efficacy of coronary IVL for left coronary calcified disease (LCAD).[8]They included four studies in their analysis (n = 282 patients) including results from the Disrupt CAD I and CAD II trials. In LCAD, ICL can yield lumen gain of up to 4.16 mm. The overall post-procedure lumen diameter was significantly higher than the pre-procedure diameter. The authors concluded that IVL offer a significant improvement in the vessel lumen to facilitate coronary stent delivery and deployments in severely calcified coronary arteries. They also indicated recommended that there is a need for randomized controlled trials and longer-term follow-up before recommending the routine use of Coronary Intravascular Lithotripsy.

Sheikh (2021) published a systematic review assessing the efficacy and feasibility of IVL in treating severe coronary calcification.[9] The review included a total of 62 studies with 1389 patients (1414 lesions; 74.7% male patients with a mean age of 72.03 years) with significant coronary calcification or under-expanded stents underwent IVL. Significant improvement was demonstrated in acute and sustained vessel patency with a procedural success rate of 78.2 – 100% in hospital. The authors conclude that recent studies have highlighted that the use of IVL with adjuvant intracoronary imaging has revolutionized the way of treating heavily calcified, non-dilatable coronary lesions and is likely to succeed the conventional ways of treating these complex lesions. And that further studies are needed to gauge the long-term efficacy and safety of IVL against techniques currently available for calcium modification including conventional balloons, cutting or scoring balloons, rotational atherectomy and laser atherectomy.

Randomized Controlled Trials

Two studies published in 2023 reported the results of the ROTA shock trial.[10, 11] The ROTA shock study is a randomized, prospective, non-blinded, double-arm, multicenter non-inferiority trial. Patients (n=70) were randomly (1:1) assigned to undergo either IVL or rotational atherectomy (RA) before percutaneous coronary intervention of severely calcified coronary lesions. The mean patient age was 73.3 ± 7.2 years, and the majority were male (75.4%). The primary endpoint minimal stent area (MSA) was lower but non-inferior after IVL (mean: 6.10 mm^2 , 95% confidence interval [95% CI]: 5.32-6.87 mm^2) versus RA (6.60 mm^2 , 95% CI: 5.66-7.54 mm^2 ; difference in MSA: -0.50 mm^2 , 95% CI: -1.52-0.52 mm^2 ; non-inferiority margin: -1.60 mm^2). Stent expansion was similar (RA: 0.83 ± 0.10 vs. IVL: 0.82 ± 0.11; p = 0.79). There were no significant differences regarding contrast media consumption (RA: 183.1 ± 68.8 vs. IVL: 163.3 ± 55.0 mL; p = 0.47), radiation dose (RA: 7269 ± 11288 vs. IVL: 5010 ± 4140 cGy cm^2; p = 0.68), and procedure time (RA: 79.5 ± 34.5 vs. IVL: 66.0 ± 19.4 min; p = 0.18). Two patients randomized to IVL were required to crossover to the RA group. In addition to small sample size and gender bias, limitations included a lower threshold for non-inferiority than originally predicted and the baseline vessel dimensions and reference vessel area in final OCT scans were larger in the RA than in the IVL group, leading to a bias for the comparison of MSA between these two groups.[10] An additional evaluation of the ROTA shock trial compared plaque modification of severely calcified lesions by coronary intravascular lithotripsy (IVL) with that of rotational atherectomy (RA) using optical coherence tomography (OCT). They concluded that RA leads to a greater acute lumen gain, IVL induces more and longer fractures of the calcified plaque.[11]

A 2023 prospective single center randomized study to investigate if pre-treatment with IVL in severely calcified lesions increases stent expansion, assessed by optical coherence tomography (OCT), when compared to predilatation with conventional and/or specialty balloon strategy.[12] A total of 40 patients were included. The minimal stent expansion in the IVL-group (n = 19) was 83.9 ± 10.3% and 82.2 ± 11.5% in the conventional group (n = 21) (p = 0.630). Minimal stent area was 6.6 ± 1.5 mm^2 and 6.2 ± 1.8 mm^2, respectively (p = 0.406). No peri-procedural, in-hospital and 30-day follow-up major adverse cardiac event (MACE) were reported. The authors concluded that in severely calcified coronary lesions there were no significant difference in stent expansion measured by OCT when comparing IVL, as plaque modification, with conventional and/or specialty angioplasty balloons.

Section Summary

Coronary intravascular lithotripsy (IVL) is a relatively new technology. The evidence reviewed includes six systematic reviews (SR) and two recent randomized clinical trials. All SRs are based on single armed studies and in mostly male subjects. Most of the evidence of safety and effectiveness of Coronary IVL extends from the four prospective, nonrandomized, single arm, manufacturer sponsored, multisite DISRUPT CAD studies: Disrupt CAD I (NCT02650128); Disrupt CAD II (NCT03328949); Disrupt CAD III; and Disrupt CAD IV (NCT04151628), which predisposes to publication bias. Two randomized trials were recently published including a prospective non-inferiority trial (n = 70) comparing outcomes of IVL or rotational atherectomy (RA) and a prospective study (n = 40) comparing pretreatment with IVL to predilatation with conventional and/or speciality balloon strategy. Both studies suggested IVL is not inferior to the comparator procedures. The RCTs have limitations such as small sample size, mostly male participants, heterogeneity of baseline lumen diameters. Adequately powered randomized controlled trails comparing IVL to currently used procedures are needed to assess the safety and efficacy of IVL.

PRACTICE GUIDELINE SUMMARY

None

SUMMARY

There is not enough research to support the use of coronary intravascular lithotripsy in any indication. No clinical guidelines based on research recommend coronary intravascular lithotripsy. Therefore, coronary intravascular lithotripsy is considered investigational for all indications.

Uniform Medical Plan

Gender Affirming Interventions for Gender Dysphoria: Clinical Criteria and Policy

Document Number: 54-0006
Issued: January 1, 2017
Effective: January 1, 2017
Revised: September 16, 2019

UMP members should refer to Regence medical policy 153 for information about UMP's coverage of transgender services, with the exception of information in the "Medical Policy Criteria" box in policy 153. Instead of the criteria listed in that box, the UMP-specific clinical criteria outlined below must be met to receive transgender surgical services.

I. Medical Treatments for Gender Dysphoria

A. Psychotherapy may be considered medically necessary as a treatment of gender dysphoria.
B. Continuous hormone therapy may be considered medically necessary as a treatment of gender dysphoria when all of the following criteria are met:
    1. Clinical records document that the patient has the capacity to make fully informed decisions and consent for treatment; and hormone therapy is part of a comprehensive, patient-centered treatment plan; and
    2. A licensed behavioral health practitioner or a licensed physician, advanced registered nurse practitioner (ARNP), physician's assistant (PA) or psychologist is treating the patient for primary care or transgender services and:
        a) Assesses the patient and makes or confirms the diagnosis of gender dysphoria as defined by the DSM-V criteria, and
        b) Determines or confirms that the gender dysphoria is not due to another mental or physical health condition.

II. Surgical Treatments of Gender Dysphoria

A. Gender reassignment surgery (see UMP clinical criteria policy and Regence medical policy 153 guidelines) may be considered medically necessary in the treatment of gender dysphoria when all of the following criteria are met:
    1. Age at least 18 years. For patients younger than 18 years of age, mastectomy may be considered a medically necessary surgical procedures. Other requirements outlined in this section must be met to proceed with mastectomy in those younger than 18 years of age.
    2. Clinical records document that the patient has the capacity to make fully informed decisions and consent for treatment as part of a comprehensive, patient-centered treatment plan; and that any other mental health condition, if present, is adequately controlled; and
    3. At least 2 licensed mental health professionals have diagnosed gender dysphoria, and recommend surgical treatment (*Only one mental health professional referral is required for mastectomy); and
        a) Assesses the patient and makes or confirms the diagnosis of gender dysphoria as defined by the DSM-V criteria, and
        b) Determines or confirms that the gender dysphoria is not due to another mental or physical health condition; and

4. Documentation of continuous hormonal therapy for at least 12 months, unless there is a documented medical contraindication to hormonal therapy. Hormonal therapy is not required prior to mastectomy; and
5. Twelve months of living in a gender role that is congruent with the patient's gender identity.

B. Prior authorization is required for all proposed surgical interventions. Section II.A of this policy lists the requirements and documentation that must be submitted for prior authorization review. Surgeries are not required to be completed at the same time and, instead, may be performed and receive prior authorization in progressive stages. UMP covers the following procedures with prior authorization that meet medical necessity criteria:
   1. Blepharoplasty, covered only if restorative function medical criteria are met (not specific to transgender surgery);
   2. Breast augmentation will require preauthorization with following criteria:
      a) Documentation of continuous hormonal therapy for at least 12 months, unless there is documented medical contraindication to hormonal therapy; and
      b) Have not reached a Tanner Stage 5.
   3. Bilateral mastectomy with or without chest reconstruction;
   4. Clitoroplasty;
   5. Colovaginoplasty;
   6. Colpectomy;
   7. Genital surgery;
   8. Genital electrolysis and laser hair removal as required as part of the genital surgery is covered with prior authorization and is limited to the genitals and, if applicable, the graft site, as required for genital surgery. Electrolysis and laser hair removal not meeting these guidelines and the guidelines for Surgical Treatments of Gender Dysphoria outlined in the Gender Affirming Interventions for Gender Dysphoria Criteria and Policy is not covered.
   9. Hysterectomy;
   10. Labiaplasty;
   11. Metoidioplasty;
   12. Orchiectomy;
   13. Penectomy;
   14. Phalloplasty;
   15. Placement of testicular prosthesis;
   16. Rhinoplasty, covered only if restorative function medical criteria are met (not specific to transgender surgery);
   17. Salpingo-oophorectomy;
   18. Scrotoplasty;
   19. Urethroplasty;
   20. Vaginectomy; and
   21. Vaginoplasty.

C. Other than gender reassignment surgeries listed in this policy, surgery and/or additional treatments to change specific appearance characteristics are considered not medically necessary as treatments of gender dysphoria, including, but not limited to the following:
   1. Brow lifts;
   2. Calf implants;
   3. Cheek/malar implants;
   4. Chin/nose implants;
   5. Chondrolaryngoplasty;
   6. Collagen injections;

7. Drugs for hair loss or growth;
8. Facial or trunk hair removal via laser or electrolysis;
9. Facial feminization;
10. Face lift;
11. Forehead lift;
12. Hair transplantation;
13. Jaw shortening;
14. Lip reduction;
15. Liposuction;
16. Mastopexy;
17. Neck tightening;
18. Pectoral implants;
19. Reduction thyroid chondroplasty;
20. Removal of redundant skin;
21. Suction-assisted lipoplasty of the waist;
22. Trachea shave;
23. Voice modification surgery; and
24. Voice therapy/lessons.

Medical Policy Manual Surgery, Policy No. 52

Ventricular Assist Devices and Total Artificial Hearts

Effective: January 1, 2022

Next Review: December 2021
Last Review: December 2021

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Ventricular assist devices and total artificial hearts provide mechanical circulation for patients with end-stage heart disease who are waiting for, or cannot survive, a heart transplant.

MEDICAL POLICY CRITERIA

Note: This policy does not address the use of percutaneous ventricular assist devices (pVADs) which may be considered medically necessary.

I. Implantable ventricular assist devices (i.e., LVADs, RVADs and BiVADs)

A. Implantable ventricular assist devices with FDA PMA, 510(k), or HDE clearance may be considered **medically necessary** for any of the following indications (1-3):

1. As a bridge to transplantation for patients who meet all of the following criteria:

a. Currently listed as a heart transplantation candidate or undergoing evaluation to determine candidacy for heart transplantation

b. Not expected to survive until a donor heart can be obtained

2. For use in the post-cardiotomy setting in patients who are unable to be weaned off cardiopulmonary bypass.
3. As destination therapy in patients meeting all of the following criteria:
    a. End-stage heart failure
    b. Documented ineligibility for human heart transplantation
    c. One of the following criteria is met:
        i. New York Heart Association (NYHA) class III or IV* for at least 28 days who have received at least 14 days support with an intraaortic balloon pump or are dependent on intravenous inotropic agents, with two failed weaning attempts. (NYHA Class III = marked limitation of physical activity; less than ordinary activity leads to symptoms. NYHA Class IV = inability to carry on any activity without symptoms; symptoms may be present at rest.)
        ii. NYHA class IV* heart failure for at least 60 days. (NYHA Class IV = inability to carry on any activity without symptoms; symptoms may be present at rest)

B. Ventricular assist devices and aortic counterpulsation devices are considered **investigational** in all other circumstances, including but not limited to the use of a non-FDA approved device.

II. Total Artificial Hearts

A. Total artificial hearts with FDA PMA, 510(k), or HDE clearance may be considered **medically necessary** as a bridge to heart transplantation in patients meeting all of the following criteria:
1. Have biventricular failure
2. Currently listed as heart transplantation candidate or undergoing evaluation to determine candidacy for heart transplantation
3. Not considered a candidate for a univentricular or biventricular support device
4. Have no other reasonable medical or surgical treatment options
5. Not expected to survive until a donor heart can be obtained

B. Total artificial hearts are considered **investigational** in all other circumstances, including but not limited to the following:
1. Use as destination therapy
2. Use of a total artificial heart that does not have FDA PMA, 510(k), or HDE clearance

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision

outcome.

- History and Physical/Chart Notes
- For Implantable Ventricular Assist Devices:
    - Documentation as to whether this is a bridge to heart transplant, being used post-cardiotomy for patient who is unable to be weaned of cardiopulmonary bypass, or as destination therapy
    - For destination therapy:
        - Documentation of end-stage heart failure, ineligibility for human heart transplant, and current NYHA classification, including duration of NYHA classification, symptoms, and treatments tried.
- For Total Artificial Heart:
    - Documentation that this is a bridge to heart transplant and patient has biventricular failure; is listed as heart transplant candidate or undergoing evaluation to determine candidacy for heart transplant; is not considered a candidate for univentricular or biventricular support device; has no other reasonable medical or surgical treatment options; and is not expected to survive until a donor heart can be obtained

BACKGROUND

VENTRICULAR ASSIST DEVICES (VADS)

Biventricular, Right Ventricular, and Left Ventricular Devices

There are three kinds of ventricular assist devices: biventricular (BiVADs), right ventricular (RVADs), and left ventricular (LVADs). Surgically implanted ventricular assist devices (VADs) are attached to the native heart and vessels to provide temporary mechanical circulatory support by augmenting cardiac output. LVADs to support the left ventricle are the most commonly used VADs, but right ventricular and biventricular devices may also be used. LVADs are most commonly used as a bridge to transplantation for those patients who are not expected to survive without mechanical support until a heart becomes available. LVADs may also be used as a bridge to recovery in patients with reversible conditions affecting cardiac output (e.g., post-cardiotomy cardiogenic shock). More recently, given the success of LVADs for prolonged periods of time, there has been interest in using LVADs as permanent "destination" therapy for patients with end-stage heart disease who are not candidates for human heart transplantation due to age or other comorbidities.

Aortic Counterpulsation Devices

Intra-aortic balloon pump (IABP) devices have been developed as a treatment for cardiogenic shock. IABPs consist of a helium-filled balloon placed in the aorta that deflates during cardiac systole to increase forward blood flow. The inflation and deflation of the balloon is computer-

controlled and can be regulated by either a pressure-sensing catheter or an electrocardiogram. These devices have not been FDA approved.

TOTAL ARTIFICIAL HEARTS

The total artificial heart (TAHs) replaces the native ventricles and is attached to the pulmonary artery and aorta; the native heart is typically removed. TAHs may be implanted temporarily as a bridge to heart transplantation or permanently as destination therapy in those who are not candidates for transplantation.

The CardioWest™ Total Artificial Heart is a temporary TAH, which is used in the inpatient hospital setting as a bridge to heart transplantation. The CardioWest TAH is implanted after the native ventricles have been excised. The AbioCor® Implantable Replacement Heart is a permanent TAH currently available as destination therapy for people who are not eligible for a heart transplant and who are unlikely to live more than a month without intervention. The device has an internal battery that allows the recipient to be free from all external connections for up to one hour. The system also includes two external batteries that allow free movement for up to two hours. During sleep and while batteries are being recharged, the system can be plugged into an electrical outlet. In order to receive the AbioCor® artificial heart, in addition to meeting other criteria, patients must undergo a screening process to determine if their chest volume is large enough to hold the two-pound device which is too large for about 90% of women and many men.

REGULATORY STATUS

Device Name	Device Type	Manufacturer	FDA Approval	Indication
HeartMate II®	LVAD	Thoratec Corp.	PMA	Bridge to transplant and destination therapy
HeartMate 3™	LVAD	Thoratec Corp.	PMA	Bridge to transplant and destination therapy
Thoratec® IVAD	BiVAD	Thoratec Corp.	PMA + Supplement	Bridge to transplant and post-cardiotomy
Levitronix Centrimag®	RVAD	Levitronix, LLC	HDE	Postcardiotomy (temporary circulatory support for up to 14 days)
Novacor®	LVAD	World Heart, Inc.	PMA	Bridge to transplant
DeBakey VAD® Child	LVAD	MicroMed Technology, Inc.	HDE	Bridge to transplant in children 5-16 years of age
EXCOR® Pediatric System	BiVAD	Berlin Heart, Inc.	HDE	Bridge to transplant, pediatric (newborns to teens)
Jarvik 2000	LVAD	Jarvik Heart, Inc.	*IDE-Investigational*†	
HeartWare® Ventricular Assist System (HVAD®)	VAD	Heartware Intl., Inc.	PMA	Bridge to transplant – for use in-hospital or out-of-hospital

Device Name	Device Type	Manufacturer	FDA Approval	Indication
AutoCat 2 WAVE® IABP System	IABP	Arrow Intl., Inc.	none	
Maquet CS300™ IABP	IABP	Maquet Cardiovascular, LLC	none	
SynCardia Temporary TAH (formerly called CardioWest™)	Temporary total artificial heart	SynCardia Systems, Inc.	510(k)	Bridge to transplant – for use inside the hospital
AbioCor® TAH	Implantable Replacement Heart System	AbioMed, Inc.	HDE	Destination therapy

†FDA Investigational Device Exemption (IDE) is not considered a full FDA approval. Devices with an IDE designation are considered investigational.

In August 2015, the U.S. Food and Drug Administration (FDA) published a safety communication about serious adverse events with implantable left ventricular assist devices.[1]

In August 2016, HeartWare® recalled its VAD Pumps due to a design flaw that was deemed by FDA as potentially causing serious injuries or death (class I recall). The devices affected were manufactured and distributed from March 2006 and May 2018. FDA product codes: 204 and 017.

A class I recall was issued for the HeartMate 3™ in April 2018 affecting all manufacturing dates. FDA product code: DSQ.

Although adverse events have been reported, the FDA recognizes “that LVADs are life-sustaining, life-saving devices for patients with advanced left ventricular heart failure. When used for the currently approved indications in appropriately selected patients, we believe the benefits of these LVADs continue to outweigh the risks”

EVIDENCE SUMMARY

The principal outcome associated with treatment of refractory heart failure (HF) is to prolong survival, either temporarily as a bridge to decision, recovery, or heart transplantation, or permanently as a replacement for the damaged heart in patients who are not candidates for heart transplantation.

VENTRICULAR ASSIST DEVICES

BRIDGE TO TRANSPLANTATION, LEFT VENTRICULAR ASSIST DEVICES

Systematic Reviews

A systematic review published in 2011 supported the conclusions reached in the 1996 BCBSA TEC assessment.[2, 3] The 2011 review included 31 observational studies that compared outcomes of transplant in patients who did and did not have pre-transplant left ventricular assist devices (LVADs). Survival at one year was more likely in patients who had

LVAD treatment, but this benefit was confined to patients who received an intra-corporeal device (relative risk [RR]: 1.8, 95% confidence interval [CI] 1.53 to 2.13). For patients treated with an extracorporeal device, the likelihood of survival was not different from patients who were not treated with an LVAD (RR: 1.08, 95% CI 0.95 to 1.22). There was no difference in the risk of rejection between patients who did and did not receive LVAD treatment.

Nonrandomized Studies

Adult patients

Additional reports not included in the 1996 TEC assessment or the 2011 systematic review are consistent with the above analysis.[4-6] It should be recognized that left ventricular assist devices cannot change the number of patients undergoing heart transplantation due to the fixed number of donor hearts. However, the LVAD will categorize its recipient as a high priority heart transplant candidate. Currently available LVADs consist of pulsatile devices that require both stiff power vent lines that perforate the skin and bulky implantable pump chambers. There is considerable research interest in developing non-pulsatile axial flow systems that have the potential for small size and low-noise levels.[7-12]

Aissaoui (2018) published an observational study comparing 224 patients in Germany and France with end-stage heart failure who received VAD as first option (group I, n=83) or either heart transplantation or medical therapy as first option (group II, n=141).[13] The estimated two-year survival was 44% for group I and 70% for group II (p<0.001). The study was limited by the lack of randomization and possible patient selection bias.

Grimm (2016) compared outcomes for patients based on the duration of LVAD use, using data from the United Network for Organ Sharing database.[14] Of the 1,332 included patients, 130 (9.8%) were classified as short duration (< 90 days), 729 (54.7%) were classified as intermediate duration (90 to 365 days), and 473 (35.5%) were classified as long duration (>365 days). A greater proportion of patients in the intermediate and long duration groups were considered functionally independent prior to transplantation compared with the short duration patients. There was no difference in 30-day survival, six-month survival, or one-year survival between the groups. Also, despite worse renal function in the intermediate and long-term groups, there was no difference between groups in new-onset post-transplant renal failure.

Another report by Grimm (2016),which used the United Network for Organ Sharing database, suggested that patients bridged to transplant with an LVAD have better outcomes than those bridged with TAH or biventricular assist devices.[15] Cheng (2016) compared BiVAD to TAH outcomes in this database, and found similar wait-list survival between the groups.[16]

Deo (2014) reported no significant differences in outcomes for 37 patients bridged to transplant with a ventricular assisted device (VAD) and 70 patients who underwent a heart transplant directly.[17] In 2013, Slaughter reported combined outcomes for patients included in the HeartWare® bridge-to-transplant study.[18] The study included 322 patients with heart failure, eligible for heart transplant, who received the HeartWare® (140 patients from the original study; 190 patients in the continue-access protocol) who were monitored to outcome or had completed 180 days of follow-up at the time of this analysis. Survival at 60, 180, and 360 days was 97%, 91%, and 84%, respectively. The most common adverse events were respiratory dysfunction, arrhythmias, sepsis, and driveline exit-site infections. Patients generally had improvements in quality of life measures.

Aaronson (2012) reported results of a multicenter, prospective study of a newer generation LVAD, the HeartWare®, which is a smaller, continuous flow centrifugal device that is implanted in the pericardial space.[19] The study enrolled 140 patients who were awaiting heart transplantation who underwent HeartWare® implantation. A control group of 499 subjects was comprised of patients drawn from the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, which collects data on patients who receive FDA-approved durable mechanical circulatory support devices. The study's primary outcome was defined as survival on the originally implanted device, transplantation, or explantation for ventricular recovery at 180 days. Secondary outcomes were comparisons of survival between groups and functional, quality of life, and adverse event outcomes in the HeartWare® group. Success occurred in 90.7% of the HeartWare® group and 90.1% of controls ($p<0.001$, noninferiority with a 15% margin). Serious adverse events in the HeartWare® group included, most commonly, bleeding, infections, and perioperative right heart failure.

Evidence suggests that the HeartMate II® axial achieves similar or better results than the earlier pulsatile HeartMate I model. In six reports with samples ranging from 32 to 279 patients, most participants received the new device as a bridge to transplantation.[20-25] Survival rates at six months and one year were 67% to 87%, and 50% to 80%, respectively. These rates are similar to those reported from INTERMACS.[26] An additional report from INTERMACS comparing the HeartMate II® to other LVAD devices for patients who received them with a bridge to transplantation indication reported that 80% and 91% of HeartMate II® and other LVAD patients reached transplant, cardiac recovery, or ongoing LVAD support by six months.[27] One report, however, compared HeartMate I and HeartMate II® recipients at a single center, finding the same one year survival and similar rates of subsequent development of right heart failure.[22] Serious adverse events occurring after HeartMate II® implantation included bleeding episodes requiring reoperation, stroke, infection, and device failure. A European study that included 67 bridge to transplant patients and 31 destination therapy patients found similar one-year survival rates in the two groups: 63% and 69%, respectively. A report on HeartMate II® recipients at a single institution found that out of 250 LVAD patients between November 2011 and June 2016, 6% (16) required a device pump exchange during the study period, and all but one patient survived until hospital discharge.[28]

Pediatric Patients

Publications on children using VADs as a bridge to transplantation have reported positive outcomes. For example, a retrospective study of all children listed for a heart transplant at a single center between 1993 and 2009 found that mortality dropped significantly after the availability of VADs.[29] Davies (2008) reported that pediatric patients requiring a pretransplantation VAD had similar long-term survival to those not receiving mechanical circulatory support.[30]

A retrospective registry study by Jeewa (2018) assessed long-term outcomes for pediatric VAD use as a bridge to transplantation in patients from the Berlin Heart investigational device exemption trial.[31] These patients (n=109) were compared with matched controls from the Pediatric Heart Transplant Study who did not require mechanical circulatory support (n=166). There was no significant difference between the groups for five-year survival (81% for VAD, 88% for non-VAD, $p=0.09$) or for rates of infection or rejection.

Bulic (2017) identified all U.S. children between 1 and 21 years of age at heart transplant between 2006 and 2015 for dilated cardiomyopathy who were supported with an LVAD or

vasoactive infusions alone at the time of heart transplant from the Organ Procurement and Transplant Network registry (n=701).[32] Children receiving LVAD were older, on a higher level of hemodynamic support, more likely to be on dialysis and waited long to receive a donor heart than children receiving vasoactive infusions. Functional status as measured by the median Karnofsky Performance Scale at heart transplant was higher for children receiving LVAD compared with vasoactive infusion (6 vs 5, p<0.001) and children receiving LVAD were more likely to be discharged from the hospital at the time of transplant. The percent of children having stroke at the time of transplant was higher in those receiving LVAD (3% vs 1%, p=0.04).

Almond (2013) reported results from a prospective, multicenter registry to evaluate outcomes in children who received the Berlin Heart EXCOR® device as a bridge to transplant.[33] All patients were followed up from the time of EXCOR® implantation until transplantation, death, or recovery. The study included 204 children, 67% of whom received the device under compassionate use. Survival at 12 months on EXCOR® support was 75%, including 64% who survived to transplantation, 6% who recovered (device explanted and patient survived 30 days), and 5% alive with the device in place. In a follow-up study which evaluated 204 children from the same registry, Jordan reported relatively high rates of neurologic events in pediatric patients treated with the EXCOR® device (29% of patients), typically early in the course of device use.[34] A 2016 report on this group included 358 bridge-to-transplant EXCOR® patients, and found that short- and mid-term post-transplant survival in these patients was similar to that of patients who did not receive pre-transplant mechanical circulatory support.[35]

Wehman (2016) reported on post-transplant survival outcomes for pediatric patients who received a VAD, extracorporeal membrane oxygenation (ECMO), or no mechanical circulatory support, in the pre-transplant period.[36] The study included 2,777 pediatric patients who underwent heart transplant from 2005 to 2012, who were identified through the United Network for Organ Sharing Database, of whom 428 were bridged with VADs and 189 were bridged with ECMO. In unadjusted analysis, the actuarial five-year survival was highest in the direct-to-transplant group (77%), followed by the VAD group (49%) and then the ECMO group (35%). In a proportional hazards model to predict time to death, restricted to the first four months post-transplant, ECMO bridging was significantly associated with higher risk of death (adjusted hazard ratio [HR] 2.77 vs direct-to-transplant, 95% CI 2.12 to 3.61, p<0.0001). However, a model to predict time to death excluding deaths in the first four months post-transplant, the bridging group was not significantly associated with risk of death.

Section Summary

In adults, the evidence on the efficacy of LVADs as bridge to transplant consists of numerous nonrandomized studies comparing different LVADs devices among patients who have no other treatment options. In children, the evidence consists of several nonrandomized studies. These studies report that substantial numbers of patients survive the transplant in situations in which survival would not be otherwise expected. Despite the lack of high-quality studies, this evidence is sufficient to determine that outcomes are improved in patients who have no other options for survival.

VENTRICULAR ASSIST DEVICES AS BRIDGE TO RECOVERY

VADs may have a role in bridging patients to recovery, particularly if there is reverse remodeling of the left ventricle. Several additional studies have investigated the role of VADs in bridging patients to decision.

Nonrandomized Studies

Support from VADs was originally indicated for the treatment of postcardiotomy cardiogenic shock in patients who could not be weaned from cardiopulmonary bypass. VAD use in this setting is temporary and brief, lasting between 1.4 and 5.7 days. The overall salvage rate for this indication is low, at approximately 25%; however, without VAD support, patients with refractory postcardiotomy cardiogenic shock would experience 100% mortality.[6, 37, 38]

Agrawal (2018) published a retrospective cohort study evaluating the 30-day readmissions of 2,510 patients undergoing LVAD implantation.[39] Of the patients who met the inclusion criteria, 788 (31%) were readmitted within 30 days after surviving initial index hospitalization. Cardiac causes accounted for 23.8% of readmissions, 13.4% due to heart failure, and 8.1% to arrhythmias. Infection (30.2%), bleeding (17.6%), and device-related causes (8.2%) comprised the 76.2% of non-cardiovascular causes for readmission. The study's limitations relate to the nature of nonclinical data collection and gaps in current subject knowledge.

A retrospective cohort study by Adesyiun (2017) assessed LVAD complications and overall effect on mortality to determine factors associated with development of early and long-term complications.[40] Utilizing logistic regression and Cox proportional hazards analyses at univariable and multivariable stages, the study found 24% of patients developed early complications and 18.5% developed both early and late complications. There was a significant association between death and early complications (p=0.017), while the additional presence of two or more complications produced a 2.7-fold increase in mortality odds (p=0.016). Mortality odds increased by 20% with each subsequent complication (p=0.004). The study was limited in that, during its long, 13-year team span, practice associated with LVAD maintained had changed but were not address by the study. Further limitations include the difficulty in determining the strictness to which a patient might have met the complication definitions, as well as the small sample size of the study.

Kawajiri (2017) evaluated the outcomes of patients with end-stage heart failure who had conventional surgery as opposed to transplant or mechanical support.[41] A total of 133 patients of this retrospective cohort study were identified with left ventricular ejection fraction (LVEF) less than 20% and VO2 max < 14 mL/min/m^2 and, after initial referral for advanced therapies, were instead offered a conventional procedure. Of the originally identified 133 patients, 68 were determined transplant eligible. Actuarial survival at 5 and 10 years was 72% and 39%, respectively, after 12% in-hospital mortality. Outcomes were acceptable for conventional cardiac surgery in highly selected patients with end-stage HF, and long-term survival was comparable with advanced surgical therapies. The study was limited by a small study population, its nonclinical nature, and the potential underestimation the VAD/transplant mortality by measuring survival dates starting from first surgery as opposed to date of decision.

Raju (2017) focused their retrospective cohort study on consecutive LVAD patients who received more than one year of total LVAD support time.[42] During the study period, 103 patients received LVADs, 37 received LVAD support for more than one year, and 18 received support for more than two years. Average support time was 786 days. Mortality and hospital readmissions were used to determine the efficacy of continuous-flow LVADs. During a median follow-up of two years, the one-year conditional survival was 74%. Readmission reasons were due to major infection (24%), major bleeding (19%), and device malfunction/thrombosis (13%), and totaled 112 completed readmission procedures, 60% of which were done in 13% (n=5) of patients. The study had the limitations of a descriptive retrospective analysis and small sample

size, and quality of life (QOL) self-assessments would have provided necessary patient perspective.

Takayama (2014) reported outcomes for a retrospectively-defined cohort of 143 patients who received a CentriMag® VAD as a “bridge to decision” for refractory cardiogenic shock due to a variety of causes.[43] Patients were managed with a bridge-to-decision algorithm. Causes of cardiogenic shock included failure of medical management (n=71), postcardiotomy shock (n=37), graft failure post-heart transplantation (n=2), and right ventricular failure post-implantable LVAD (n=13). The device configuration was biventricular in 67%, isolated right VAD in 26%, and isolated left VAD in 8%. After a mean duration of support of 14 days (interquartile range 8 to 26 days), 30% of patients had myocardial recovery, 15% had device exchange to an implantable VAD, and 18% had a heart transplantation.

Acharya (2016) reported on patients who underwent VAD placement in the setting of acute myocardial infarction (AMI) who were enrolled in the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) registry, a prospective national registry of FDA-approved durable mechanical circulatory support devices.[44] Patients who had an AMI as the admitting diagnosis or a major myocardial infarction (MI) as a hospital complication that resulted in VAD implantation (n=502) were compared with patients who underwent VAD implantation for non-AMI indications (n=9,727). Patients in the AMI group were generally sicker at baseline, with higher rates of smoking, severe diabetes, and peripheral vascular disease, but had fewer cardiac surgeries and recent cardiovascular hospitalizations. Most AMI patients (53.8%) were implanted with a “bridge-to-candidacy” strategy. At one-month post VAD, 91.8% of the AMI group were alive with the device in place. At one-year post-VAD, 52% of the AMI group were alive with the device in place, 25.7% had received a transplant, 1.6% had their VAD explanted for recovery, and 20.7% died with the device in place. Another retrospective study of 15,138 patients in the INTERMACS registry found that the incidence of recovery was significantly higher in bridge-to-recovery patients than in non-bridge-to-recovery patients (11.2% vs 1.2%, $p<0.0001$).[45]

Topkara (2016) reported a similar analysis of 13,454 INTERMACS adults with implants between June 2006 and June 2015 without TAH, pulsatile-flow LVAD, or heart transplant.[46] Device explant rates for cardiac recovery were 0.9% at one-year, 1.9% at two-year, and 3.1% at three-year follow-up. An additional 9% of patients demonstrated partial cardiac recovery.

In a smaller single-center retrospective cohort study, Mohamedali (2015) reported outcomes for 48 patients treated with biventricular support with the CentriMag® device as a “bridge to decision”, 18 of whom had biventricular support with venoarterial (VA) extracorporeal membrane oxygenation (ECMO), while the remainder received just biventricular VAD support.[47] Overall, 23 patients were explanted, nine to recovery, 14 to a durable LVAD, with three additional patients explanted for withdrawal of care. However, given that the study included patients who received VA ECMO, it is difficult to assess the relative impact of VAD support alone.

Six studies using the Centrimag® RVAD included between 12 and 32 patients, the majority of whom received biventricular devices.[38, 48-52] Indications and numbers of patients in these five studies were: support for post-cardiotomy cardiogenic shock (bridge to recovery), bridge to long-term device implantation (n=9), treatment of right heart failure in patients who previously received LVADs, bridge to later decision when neurologic status is clarified, and acute donor graft failure. The mean time on mechanical circulatory support ranged from 9.4 days to 46.9

days. The 30-day mortality rates were between 17% and 63%. The proportion of patients discharged from the hospital was between 30% and 83%. Major complications included bleeding requiring reoperation, sepsis, and stroke. No device failures were observed in these studies.

In a prospective multicenter study to assess myocardial recovery in patients with LVAD implantation as a bridge to transplant, Maybaum (2007) evaluated 67 patients with heart failure who had undergone LVAD implantation for severe heart failure.[53] After 30 days, patients demonstrated significant improvements compared with pre-LVAD state in LVEF (17.1% vs 34.12%, p<0.001), left ventricular end-diastolic diameter (7.1 cm vs 5.1 cm, p<0.001), and left ventricular mass (320 g vs 194 g, p<0.001). However, only 9% of patients demonstrated enough recovery to have their LVAD explanted.

In a 2006 study, a series of 15 patients with severe heart failure due to nonischemic cardiomyopathy underwent implantation of LVADs, along with medical management designed to enhance myocardial recovery.[54] Eleven of 15 patients had enough myocardial recovery to undergo LVAD explantation; two patients died after explantation. Among those who survived, the cumulate rate of freedom from recurring heart failure was 100% and 88.9%, respectively, at one- and four-years post explantation. The same group subsequently reported results of their LVAD explantation protocol among patients with severe heart failure due to nonischemic cardiopathy who had nonpulsatile LVADs implanted.[55] They included 20 patients who received a combination of angiotensin converting enzyme ACE inhibitors, beta blockers, and adosterol antagonists followed by the β2-agonist clenbuterol. One patient was lost to follow-up and died after 240 days of support. Of the remaining 19 patients, 12 (63.2%) were successfully explanted after a mean 286 days; estimated survival without heart failure recurrence was 83.3% at one and three years.

Section Summary

The studies previously outlined indicate that a subset of patients who receive a VAD as a bridge to transplant demonstrate improvements in their cardiac function, sometimes to the point that they no longer require the VAD. However, questions remain about defining and identifying the population most likely to experience cardiac recovery with VAD placement. One clearly defined population in which the potential for myocardial recovery exists is in the postcardiotomy setting. Finally, current evidence is insufficient to allow the identification of other heart failure patient populations who might benefit from the use of a VAD as a specific bridge-to-recovery treatment strategy. Ongoing research studies are addressing this question, along with protocols for transitioning patients off VAD use.

LEFT VENTRICULAR ASSIST DEVICES AS DESTINATION THERAPY

Technology Assessment

The policy statement regarding LVADs as destination therapy was initially based on a 2002 TEC assessment[56] that offered the following observations and conclusions:

- The available evidence comes from a single, well-designed and rigorously conducted randomized trial, known as the REMATCH study.[57] The study was a cooperative effort of Thoratec, Columbia University and the National Institutes of Health.

- The randomized trial found that patients with end-stage heart failure who are not candidates for cardiac transplantation have significantly better survival on an LVAD compared with treatment by optimal medical therapy. Median survival was improved by approximately 8.5 months. Serious adverse events were more common in the LVAD group, but these appear to be outweighed by this group's better outcomes on function. NYHA Class was significantly improved, as was quality of life among those living to 12 months.

- LVAD patients spend a greater relative proportion of time inside the hospital than medical management patients do, but the survival advantage would mean a longer absolute time outside the hospital.

Randomized Controlled Trials

Park published a further follow-up of patients in the REMATCH trial, mentioned in the above TEC assessment, which found that survival and quality of life benefits were still apparent with extended two-year follow-up.[58]

Nonrandomized Studies

Jorde (2014) published results from an FDA-required postapproval study of the HeartMate II® device for destination therapy.[59] The study included the first 247 HeartMate II® patients identified as eligible for the device as destination therapy, outcomes and adverse events did not differ significantly from those treated in the original trial, which compared patients who received the HeartMate II® to earlier generation devices (Slaughter [2009], described below).[60] Survival in the postapproval cohort was 82% and 69% at one and two years postoperatively, respectively.

A subsequent prospective observational study comparing LVAD support (n=97) with optimal medical therapy (n=103) for patients with heart failure not requiring inotropes also reported superior survival and health-related quality of life in LVAD-treated patients.[61] Twelve-month survival was 80% in the LVAD group, compared with 63% in the best medical therapy group (p=0.022).

In addition, other case series suggest continuing improvement in outcomes related to ongoing improvements in the device and in patient management.[62] However, the durability of the HeartMate device used in the REMATCH trial is a concern; for example, at one participating institution, all six long-term survivors required device change-outs. Next generation devices consisting of smaller continuous flow devices are eagerly anticipated.

Section Summary

The primary evidence on the efficacy of LVADs as destination therapy in patients who are not transplant candidates is from the REMATCH study. This study reported that the use of LVADs led to improvements in survival, quality of life, and functional status.

DEVICE COMPARISONS

The mechanism of operation of LVADs has changed since their introduction. The earliest devices were pulsatile positive displacement pumps. The pulsatile pumps have been largely replaced by axial continuous-flow pumps. More recently centrifugal continuous-flow pumps have also been introduced.

The evidence of the comparative efficacy of centrifugal continuous-flow vs axial continuous-flow devices consists of two RCTs of two different centrifugal continuous-flow devices.[63-65] The MOMENTUM3 trial compared HeartMate 3™ centrifugal continuous-flow device with the HeartMate II® axial continuous-flow device in patients indicated for circulatory support as a bridge to transplant or destination therapy. HeartMate 3™ received PMA approval in August 2017 but was recalled in April 2018. The ENDURANCE trial compared HeartWare® centrifugal continuous-flow device with the HeartMate II® axial continuous-flow device in patients indicated for circulatory support as destination therapy. HeartWare® is FDA-approved for bridge to transplantation. Both trials found the centrifugal device to be noninferior to the axial device for the primary, composite outcome including measures of survival, freedom from disabling stroke, and freedom from device failure. While there are fewer device failures with the centrifugal devices without significant increase in disabling stroke, the HeartWare® device was associated with increased risk of any stroke over a period of two years.

The evidence on the comparative efficacy of continuous-flow vs pulsatile-flow devices consists of an RCT and several nonrandomized comparative studies. The RCT reported fairly large differences in a composite outcome measure favoring the continuous-flow devices, with increases in revision and reoperation rates for the pulsatile device group being the largest factor driving the difference in outcomes.[60] Other nonrandomized comparative studies, including a database study with large numbers of patients, have not reported important differences in clinical outcomes between devices.

Slaughter (2009) published data from an unblinded randomized multicenter trial.[60] Subjects were randomized to continuous-flow or pulsatile-flow devices on a 2:1 block-randomization basis. The primary outcome measured was a composite endpoint of two-year survival, free of disabling stroke or need for device replacement. Continuous-flow patients (n=134) reached the primary outcome at a rate of 46% (95% CI 38 to 55) compared to pulsatile-flow patients (n=66) rate of 11% (95% CI 3 to 18), which was a significant difference ($p<0.001$). Analysis of constituent factors indicated that a lower rate of devices needing replacement in the continuous-flow group had the largest effect on the composite endpoint; two-year death rate also favored this device (58% vs. 24%, $p=0.008$). Stroke and death (within two years of implantation) were similar in the two groups (stroke rate 12% and death rate 36%). Quality of life scores were also similar in the two groups. Although unblinded, this randomized trial adds to the evidence favoring continuous-flow devices.

Nonrandomized Studies

Dell'Aquila (2014) compared outcomes for patients treated with a third-generation continuous flow device, the HeartWare® device, with those for patients treated with earlier generation devices in a single-center study.[66] Comparison-group patients received either an earlier generation continuous flow device or a pulsatile flow device. Of 287 patients who received VAD support from 1993 to 2012, 52 received a HeartWare® device, 76 an earlier generation continuous flow device, and 159 a pulsatile device. Survival was significantly better for patients who received a third-generation device, with 24 months survival of 70.4%, compared with 33.7% for patients who received an earlier generation continuous flow device and 33.8% for patients who received a pulsatile flow device ($p=0.013$). The difference in survival associated with third generation devices was more pronounced for higher scores on the INTERMACs scale.

Nativi (2011) published a nonrandomized comparison of pulsatile versus continuous flow devices using data from the registry of the International Society for Heart and Lung Transplantation on 8,557 patients undergoing transplant.[67] Comparisons were made among patients receiving a pulsatile LVAD, a continuous flow LVAD, and no LVAD. Two time periods were used for analysis, the first was pre-2004, when nearly all LVADs were pulsatile devices, and post-2004 when continuous use devices began to be used in clinical care. There was a significantly greater risk of mortality in the first time period compared to the second time period (RR 1.30, 95% CI 1.03 to 1.65, p=0.03). When analysis was confined to the second time period, there was no significant improvement in survival for the continuous group compared to the pulsatile group (RR 1.25, 95% CI 1.03 to 1.65, p=0.03).

Other nonrandomized studies that have compared outcomes from different types of LVADs have been smaller and/or focused on physiologic outcomes.[68-71] In some of these studies, the continuous flow devices exhibit greater improvement in physiologic measures, but none of these studies have reported significant differences between devices in clinical outcomes.

Section Summary

The evidence of the comparative efficacy of centrifugal continuous-flow vs axial continuous-flow devices consists of two RCTs of two different centrifugal continuous-flow devices. The MOMENTUM3 trial compared HeartMate 3™ centrifugal continuous-flow device with the HeartMate II® axial continuous-flow device in patients indicated for circulatory support as a bridge to transplantation or destination therapy. HeartMate 3™ has been recalled. The ENDURANCE trial compared HeartWare® centrifugal continuous-flow device with the HeartMate II® axial continuous-flow device in patients indicated for circulatory support as destination therapy. HeartWare® is FDA-approved for bridge to transplantation. Both trials found the centrifugal device to be noninferior to the axial device for the primary, composite outcome including measures of survival, freedom from disabling stroke and freedom from device failure. While there are fewer device failures with the centrifugal devices without significant increase in disabling stroke, the HeartWare® device was associated with increased risk of any stroke over a period of two years.

The evidence on the comparative efficacy of continuous-flow vs pulsatile-flow devices consists of one RCT and several nonrandomized comparative studies. The RCT reported fairly large differences in a composite outcome measure favoring the continuous flow devices, with increases in revision and reoperation rates for the pulsatile device group being the largest factor driving the difference in outcomes. Other nonrandomized comparative studies, including one database study with large numbers of patients, have not reported differences between devices on clinical outcomes.

AORTIC COUNTERPULSATION DEVICES

Intra-aortic balloon pump (IABP) devices have been developed as a treatment for cardiogenic shock. IABPs consist of a helium-filled balloon placed in the aorta that deflates during cardiac systole to increase forward blood flow. The inflation and deflation of the balloon is computer-controlled and can be regulated by either a pressure-sensing catheter or an electrocardiogram. These devices have not been FDA approved, and therefore the evidence for these devices is not reviewed in detail.

TOTAL ARTIFICIAL HEARTS

BRIDGE TO TRANSPLANTATION

Nonrandomized Studies

In 2004, the CardioWest Total Artificial Heart (now called the SynCardia Total Artificial Heart) received FDA approval for use as a bridge to transplant. The approval was based on the results of a nonrandomized, prospective study of 81 patients.[72] Patients had failed inotropic therapy and had biventricular failure and thus were not considered appropriate candidates for an LVAD. The rate of survival to transplant was 79%, which was considered comparable to the experience with LVAD in patients with left ventricular failure. The mean time from entry into the study until transplantation or death was 79.1 days.

Other case series have been reported on outcomes of the TAH as a bridge to transplant. For example, Copeland reported on 101 patients treated with the SynCardia artificial heart as a bridge to transplant.[73] All patients either met established criteria for mechanically assisted circulatory support or were failing medical therapy on multiple inotropic drugs. The mean support time was 87 days, with a range of 1 to 441 days. Survival to transplant was 68.3% (69/101). Of the 32 deaths prior to transplant, 13 were due to multiple organ failure, 6 were due to pulmonary failure, and four were due to neurologic injury. Survival after transplant at 1, 5, and 10 years, respectively, was 76.8%, 60.5%, and 41.2%.

DESTINATION THERAPY

In currently available studies, the AbioCor® Implantable Replacement Heart has only been used as destination therapy for end-stage patients with congestive heart failure.

Nonrandomized Studies

Torregrossa (2014) reported on 47 patients who received a TAH at 10 worldwide centers and had the device implanted for more than one year.[74] Patients were implanted for dilated cardiomyopathy (n=23), ischemic cardiomyopathy (n=15), and “other” reasons (n=9). Over a median support time of 554 days (range, 365-1373 days), 34 patients (72%) were successfully transplanted, 12 patients (24%) died while on device support, and one patient (2%) was still supported. Device failure occurred in five patients (10%). Major complications were common, including systemic infection in 25 patients (53%), driveline infections in 13 patients (27%), thromboembolic events in nine patients (19%) and hemorrhagic events in seven patients (14%). Two of the deaths occurred secondary to device failure

Dowling (2004) reported on the first seven patients in the AbioCor® clinical trial.[75] The 30-day survival rate was 71% compared with the predicted survival rate of 13% with only medical therapy. At 60 days, 43% were still alive and as of July 2006 two patients were still alive 234 and 181 days postoperatively and remain hospitalized. Deaths were due to intraoperative bleeding at the time of implantation, cerebrovascular accidents, pulmonary embolism, and multiorgan failure. No reports of serious device malfunction have been reported for the seven patients. Frazier (2004) reported information on four additional patients receiving the AbioCor®.[76] Using the same inclusion criteria as in the above RCT the device supported three patients for greater than 100 days, whereas a fourth patient expired at 53 days. There were no device related problems reported.

SECTION SUMMARY

There is little evidence on the use of TAH as a bridge to transplantation, or as destination therapy, compared with the use of LVADs. The type of evidence on bridge to transplant is similar to that for LVADs (i.e., case series reporting substantial survival rates in patients without other alternatives). Therefore, this evidence is sufficient to conclude that TAH improves outcomes for these patients similar to LVADs and is a reasonable alternative for patients who require bridge to transplantation but who are ineligible for other types of support devices. Although TAHs show promise for use as destination therapy in patients who have no other treatment options, the available data on their use is extremely limited. There is insufficient evidence on the use of TAH as destination therapy to support conclusions about the efficacy of TAH in this setting.

PRACTICE GUIDELINE SUMMARY

SOCIETY FOR CARDIOVASCULAR ANGIOGRAPHY AND INTERVENTIONS

In 2015, the Society for Cardiovascular Angiography and Interventions (SCAI), the Heart Failure Society of America (HFSA), the Society of Thoracic Surgeons (STS), the American Heart Association (AHA), and the American College of Cardiology (ACC) published a clinical expert consensus statement on the use of percutaneous mechanical circulatory support (MCS) devices in cardiovascular care.[77] This statement addressed intra-aortic balloon pumps (IABPs), left atrial (LA)-to-aorta assist device (eg, TandemHeart), left ventricle (LV)-to-aorta assist devices (eg, Impella), extracorporeal membrane oxygenation (ECMO), and methods of right-sided support. Specific recommendations are not made, but the statement reviews the use of MCS in patients undergoing high-risk percutaneous intervention (PCI), those with cardiogenic shock, and those with acute decompensated heart failure.

AMERICAN ASSOCIATION FOR THORACIC SURGERY/INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION[78]

In 2020, the American Association for Thoracic Surgery/International Society for Heart and Lung Transplantation published guidelines on selected topics in mechanical circulatory support. The guidelines noted that “Compared with IABP, contemporary percutaneous circulatory support devices provide a significant increase in cardiac index and mean arterial pressure; however, reported 30-day outcomes are similar.” The level of evidence was graded at B and class of evidence was graded IIA.

AMERICAN COLLEGE OF CARDIOLOGY FOUNDATION / AMERICAN HEART ASSOCIATION / HEART FAILURE SOCIETY OF AMERICA (ACCF/AHA/HFSA)[79]

The 2013 ACCF/AHA practice guidelines for the management of heart failure included the recommendations below related to MCS which includes LVADs. All of these recommendations were rated II.a., level of evidence B, defined as a recommendation in favor of the treatment being useful, with some conflicting evidence from a single RCT or nonrandomized studies.

- MCS is considered beneficial in carefully selected patients with stage D heart failure with reduced ejection fraction (HFrEF) as a bridge to transplantation or recovery.
- Nondurable mechanical cardiac support including percutaneous and extracorporeal VADs are considered “reasonable” as a bridge to recovery or a bridge to decision for carefully selected patients with HFrEF with acute, profound hemodynamic compromise.

- Durable (permanent) MCS is considered reasonable to prolong survival for carefully selected patients with stage D HFrEF.

The guidelines note that, although optimal patient selection for MCS is an area of investigation, general indications for referral for MCS therapy include patient with LVEF<25% and NYHA class III-IV functional status despite guideline-directed medical therapy (GDMT) including cardiac resynchronization therapy (CRT), when indicated, with either high predicted one- to two-year mortality or dependence on continuous parenteral inotropic support.

In 2017, the ACCF/AHA/HFSA published a focused update of the 2013 recommendations released by the ACCF and AHA.[80] LVAD was one of several treatment options recommended for patients with refractory NYHA class III or IV heart failure (stage D). If symptoms were not improved after guideline-directed management and therapy, which included pharmacologic therapy, surgical management and/or other devices, then LVAD was presented as an additional treatment option. The 2017 update focused on changes in sections regarding biomarkers, comorbidities, and prevention of heart failure, while many of the previous recommendations remained unchanged.

THE HEART FAILURE SOCIETY OF AMERICA (HFSA)

The HFSA published guidelines in 2010 on surgical approaches to the treatment of heart failure. The guidelines are based on evidence and expert opinion.[72] The following recommendations were made regarding ventricular assist devices:

- Bridge to transplantation: Patients awaiting heart transplantation who have become refractory to all means of medical circulatory support should be considered for a mechanical support device as a bridge to transplant. (Strength of Evidence B - cohort and case-control studies)
- Bridge to recovery: Patients with refractory HF and hemodynamic instability, and/or compromised end-organ function, with relative contraindications to cardiac transplantation or permanent mechanical circulatory assistance expected to improve with time or restoration of an improved hemodynamic profile should be considered for urgent mechanical circulatory support as a "bridge to decision." These patients should be referred to a center with expertise in the management of patients with advanced HF. (Strength of Evidence C - expert opinion)
- Destination Therapy: Permanent mechanical assistance using an implantable assist device may be considered in highly selected patients with severe HF refractory to conventional therapy who are not candidates for heart transplantation, particularly those who cannot be weaned from intravenous inotropic support at an experienced HF center. (Strength of Evidence B - cohort and case-control studies)

SUMMARY

VENTRICULAR ASSIST DEVICES

There is enough research to show that implantable ventricular assist devices (VADs) as a bridge to transplantation or recovery, or as destination therapy, improve health outcomes in some patients with heart failure who might not otherwise survive. Therefore, implantable VADs may be considered medically necessary when the policy criteria are met.

There is not enough research to show that ventricular assist devices or aortic counterpulsation devices improve health outcomes for people with heart failure or other heart conditions when policy criteria are not met. Therefore, the use of ventricular assist devices or aortic counterpulsation devices when policy criteria are not met is considered investigational.

TOTAL ARTIFICIAL HEARTS

There is enough research to show that the use of a total artificial heart (TAH) as a bridge to heart transplantation improves survival and quality of life for patients in some specific situations. Therefore, total artificial hearts may be considered medically necessary as a bridge to heart transplantation when policy criteria are met.

There is not enough research to show that total artificial hearts (TAHs) as destination therapy improves health outcomes for patients. Therefore, the use of TAHs as destination therapy is considered investigational.

CODES

Note: There is no specific code for reporting prolonged extracorporeal percutaneous transseptal ventricular assist device; the appropriate code for reporting this procedure is 33999.

Codes	Number	Description
CPT	33927	Implantation of a total replacement heart system (artificial heart) with recipient cardiectomy
	33928	Removal and replacement of total replacement heart system (artificial heart)
	33929	Removal of a total replacement heart system (artificial heart) for heart transplantation (list separately in addition to code for primary procedure)
	33975	Insertion of ventricular assist device; extracorporeal, single ventricle
	33976	Insertion of ventricular assist device; extracorporeal, biventricular
	33977	Removal of ventricular assist device; extracorporeal, single ventricle
	33978	Removal of ventricular assist device; extracorporeal, biventricular
	33979	Insertion of ventricular assist device, implantable intracorporeal, single ventricle
	33980	Removal of ventricular assist device, implantable intracorporeal, single ventricular
	33981	Replacement of extracorporeal ventricular assist device, single or biventricular, pump(s), single or each pump

Codes	Number	Description
	33982	Replacement of ventricular assist device pump(s); implantable intracorporeal, single ventricle, without cardiopulmonary bypass
	33983	Replacement of ventricular assist device pump(s); implantable intracorporeal, single ventricle, with cardiopulmonary bypass
	33990	Insertion of ventricular assist device, percutaneous, including radiological supervision and interpretation; left heart, arterial access only
	33991	Insertion of ventricular assist device, percutaneous, including radiological supervision and interpretation; left heart, both arterial and venous access, with transseptal puncture
	33992	Removal of percutaneous left heart ventricular assist device, arterial or arterial and venous cannula(s), at separate and distinct session from insertion
	33993	Repositioning of percutaneous right or left heart ventricular assist device with imaging guidance at separate and distinct session from insertion
	33995	Insertion of ventricular assist device, percutaneous, including radiological supervision and interpretation; right heart, venous access only
	33997	Removal of percutaneous right heart ventricular assist device, venous cannula, at separate and distinct session from insertion
	33999	Unlisted procedure, cardiac surgery
	~~0451T~~	~~Insertion or replacement of a permanently implantable aortic counterpulsation ventricular assist system, endovascular approach, and programming of sensing and therapeutic parameters; complete system (counterpulsation device, vascular graft, implantable vascular hemostatic seal, mechano-electrical skin interface and subcutaneous electrodes)~~ (Deleted 01/01/2022)
	~~0452T~~	~~;aortic counterpulsation device and vascular hemostatic seal~~ (Deleted 01/01/2022)
	~~0453T~~	~~;mechano-electrical skin interface~~ (Deleted 01/01/2022)
	~~0454T~~	~~;subcutaneous electrode~~ (Deleted 01/01/2022)
	~~0455T~~	~~Removal of permanently implantable aortic counterpulsation ventricular assist system; complete system (aortic counterpulsation device, vascular hemostatic seal, mechano-electrical skin interface and electrodes)~~ (Deleted 01/01/2022)
	~~0456T~~	~~;aortic counterpulsation device and vascular hemostatic seal~~ (Deleted 01/01/2022)
	~~0457T~~	~~;mechano-electrical skin interface~~ (Deleted 01/01/2022)
	~~0458T~~	~~;subcutaneous electrode~~ (Deleted 01/01/2022)
	~~0459T~~	~~Relocation of skin pocket with replacement of implanted aortic counterpulsation ventricular assist device, mechano- electrical skin interface and electrodes~~ (Deleted 01/01/2022)
	~~0460T~~	~~Repositioning of previously implanted aortic counterpulsation ventricular assist device, subcutaneous electrode~~ (Deleted 01/01/2022)
	~~0461T~~	~~;aortic counterpulsation device~~ (Deleted 01/01/2022)
	~~0462T~~	~~Programming device evaluation (in person) with iterative adjustment of the implantable mechano-electrical skin interface and/or external driver to test the function of the device and select optimal permanent programmed values with analysis, including review and report, implantable aortic counterpulsation ventricular assist system, per day~~ (Deleted 01/01/2022)
	~~0463T~~	~~Interrogation device evaluation (in person) with analysis, review and report, includes connection, recording and disconnection per patient encounter, implantable aortic counterpulsation ventricular assist system, per day~~ (Deleted 01/01/2022)
HCPCS	L8698	Miscellaneous component, supply or accessory for use with total artificial heart system

Codes	Number	Description
	Q0477 – Q0509	Ventricular assist device accessories, code range

Medical Policy Manual Transplant, Policy No. 02

Heart Transplant

Effective: December 1, 2023

Next Review: March 2024
Last Review: October 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

A heart transplant consists of replacing a diseased heart with a healthy donor heart. Transplantation is used for patients with refractory end-stage cardiac disease.

MEDICAL POLICY CRITERIA

I. Human heart transplantation may be considered **medically necessary** for adults (18 years or older) with end-stage heart failure (see Policy Guidelines) when one or more of the following Criteria is met:

   A. Hemodynamic compromise due to heart failure demonstrated by any one of the following (1. – 5.) accepted indications[1]:

      1. Maximal VO2 (oxygen consumption) <10 mL/kg/min with achievement of anaerobic metabolism; or
      2. Refractory cardiogenic shock; or
      3. Documented dependence on intravenous inotropic support to maintain adequate organ perfusion; or
      4. Severe ischemia consistently limiting routine activity not amenable to bypass surgery or angioplasty, or

5. Recurrent symptomatic ventricular arrhythmias refractory to ALL accepted therapeutic modalities; or

B. Hemodynamic compromise due to heart failure demonstrated by one of the following (1. or 2.):

1. Any one of the following (i. – iii.) probable indications of hemodynamic compromise[1]:

i. Maximal VO2 <14 mL/kg/min and major limitation of the patient's activities, or

ii. Recurrent unstable ischemia not amenable to bypass surgery or angioplasty, or

iii. Instability of fluid balance/renal function not due to patient noncompliance with regimen of weight monitoring, flexible use of diuretic drugs, and salt restriction.

2. Patient is on a ventricular assist device (VAD) or artificial heart as a bridge to transplant.

II. Human heart transplantation may be considered **medically necessary** in pediatric patients (see Policy Guidelines) when one of the following Criteria is met:

A. There is a diagnosis of heart failure with persistent symptoms at rest and any one or more of the following Criteria are met:

1. Continuous infusion of intravenous inotropic agents; or
2. Mechanical ventilatory support; or
3. Mechanical circulatory support; or

B. There is a diagnosis of pediatric heart disease with symptoms of heart failure in patients who do not meet Criteria II.A but any one of the following Criteria (1 – 7) is met:

1. Severe limitation of exercise and activity (if measurable, such patients would have a peak maximum oxygen consumption <50% predicted for age and sex); or
2. Cardiomyopathies or previously repaired or palliated congenital heart disease, and significant growth failure attributable to the heart disease; or
3. Near sudden death and/or life-threatening arrhythmias untreatable with medications or an implantable defibrillator; or
4. Restrictive cardiomyopathy with reactive pulmonary hypertension; or
5. Reactive pulmonary hypertension and potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance that could preclude orthotopic heart transplantation in the future; or
6. Anatomical and physiological conditions likely to worsen the natural history of congenital heart disease in infants with a functional single ventricle; or
7. Anatomical and physiological conditions that may lead to consideration for heart transplantation without systemic ventricular dysfunction.

III. Human heart retransplantation after a failed primary heart transplant may be considered **medically necessary** in patients who meet criteria for heart transplantation.

IV. Human heart transplantation or retransplantation is considered **not medically necessary** when Criterion I., II., or III. is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Adults with histories of congenital heart disease may be considered under applicable criteria for either Adult Patients (Criteria I) or Pediatric Patients (Criteria II).

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

BACKGROUND

SOLID ORGAN TRANSPLANTATION

Solid organ transplantation offers a treatment option for patients with different types of end-stage organ failure that can be lifesaving or provide significant improvements to a patient's quality of life.[2] Many advances have been made in the last several decades to reduce perioperative complications. Available data supports improvement in long-term survival as well as improved quality of life, particularly for liver, kidney, pancreas, heart, and lung transplants. Allograft rejection remains a key early and late complication risk for any organ transplantation. Transplant recipients require life-long immunosuppression to prevent rejection. Patients are prioritized for transplant by mortality risk and severity of illness criteria developed by Organ Procurement and Transplantation Network (OPTN) and United Network for Organ Sharing (UNOS).

HEART TRANSPLANT

In 2022, 42,887 transplants were performed in the United States procured from almost 36,421deceased donors and 6,467 living donors. Heart transplants were the third most common procedure with 4,111 transplants performed from both deceased donors in 2022. As of March 2023, there were 3,404 patients on the waiting list for a heart transplant.[3]

The majority of heart transplant recipients are now hospitalized Status 1 patients at the time of transplant. This shift has occurred due to the increasing demand on the scarce resource of donor organs resulting in an increased waiting time for donor organs. Patients initially listed as a Status 2 candidates may deteriorate to a Status 1 candidate before a donor organ becomes available. At the same time, as medical and device therapy for advanced heart failure has improved, some patients on the transplant list will recover enough function to become delisted.

Bakhtiyar (2020) published the results of a retrospective cross-sectional analysis of outcomes in 98,323 candidates wait-listed for heart transplantation between January 1, 1987, and December 29, 2017 in the UNOS database.[4] Overall, the one-year survival on the waiting list increased from 34.1% in 1987-1990 to 67.8% in 2011-2017 (difference in proportions, 0.34%; 95% CI, 0.32%-0.36%; p<0.001). The one-year waiting list survival for candidates with ventricular assist devices (VADs) increased from 10.2% in 1996-2000 to 70.0% in 2011-2017 (difference in proportions, 0.60%; 95% CI, 0.58%-0.62%; p< 0.001) and from 53.9% in 1996-2000 to 66.5% in 2011-2017 (difference in proportions, 0.13%; 95% CI, 0.12%-0.14%; p<0.001) for patients without VADs. Improvement in the latter was attributed to changing mechanical circulatory support indications. In sum, temporally associated increases in heart transplant waiting list survival were found for all patient groups (with or without VADs, UNOS status 1 and status 2 candidates, and candidates with poor functional status).

Magnetta (2019) reported outcomes for children on the heart transplant waiting list, comparing the periods of December 16, 2011 to March 21, 2016 (era 1), and March 22, 2016 to June 30, 2018 (era 2).[5] There was a significant decrease from era 1 to era 2 in the proportion of patients listed as status 1 (70% vs 56%; p<0.001), while the proportion of patients with congenital heart disease (CHD) significantly increased across eras (49% to 54%; p=0.018). The median time on the waitlist increased from 68 days to 78 days (p=0.005). There were no significant differences across eras in the cumulative incidence of death on the waitlist among all candidates (subdistribution hazard ratio, 0.96; 95% CI, 0.80 to 1.14; p=0.63) and among those listed status 1A (subdistribution hazard ratio, 1.16; 95% CI, 0.95 to 1.41; p= 0.14). Graft survival at 90 days was also similar across eras in the overall population and in those with CHD (p>0.53 for both).

Alshawabkeh (2018) reported on the one-year probability of the combined outcome of death or delisting due to clinical worsening for patients on the heart transplant waiting list, comparing the periods of April 1, 1986 to January 19, 1999, (early era) and January 20, 1999 to June 2, 2014 (current era).[6] For adults without CHD, the probability of the combined outcome was lower in the current era compared with the early era, regardless of whether the patient was listed in status I (14.5% vs 22.7%; p<0.0001) or 2 (9.0% vs 12.8%, p<0.0001). When comparing the current and early eras in adults with CHD, a reduction in the probability of the combined outcome was demonstrated in those listed in status I (17.6% vs 43.3%, respectively; p<0.0001), whereas the outcome remained unchanged for those listed in status 2 (10.6% vs 10.4%, respectively; p=0.94).

In adults with CHD, factors associated with waitlist death or delisting due to clinical worsening within one year were also examined by Alshawabkeh (2016).[7] A multivariate analysis identified that an estimated glomerular filtration rate less than 60 ml/min/1.73 m2 (hazard ratio [HR], 1.4; 95% confidence interval [CI], 1.0 to 1.9; p=0.043), albumin less than 3.2 g/dl (HR, 2.0; 95% CI, 1.3 to 2.9; p<0.001), and hospitalization at the time of listing in the intensive care unit (HR, 2.3; 95% CI, 1.6 to 3.5; p<0.001) or a non-intensive care hospital unit (HR, 1.9; 95%

CI, 1.2 to 3.0; p=0.006) were associated with waitlist death or delisting due to clinical worsening within one year.

Johnson (2010) reported on waiting list trends in the U.S. between 1999 and 2008.[8] An increasing trend of adult patients with congenital heart disease and retransplantation was noted. The proportion of patients listed as Status 1 continued to increase, even as waiting list and post-transplant mortality for this group decreased. Meanwhile, Status 2 patients have decreased as a proportion of all candidates. Completed transplants have trended toward the extremes of age, with more infants and patients older than age 65 years having transplants in recent years. This is an update to what Lietz and Miller published in 2007, where they reported on patient survival on the heart transplant waiting list, comparing the era between 1990 and 1994 to the era of 2000 to 2005.[9] One year survival for UNOS Status 1 candidates improved from 49.5% to 69.0%. Status 2 candidates fared even better, with 89.4% surviving 1 year compared to 81.8% in the earlier time period.

As a consequence of improved survival in those on transplant waiting lists, aggressive treatment of heart failure has been emphasized in recent guidelines. Prognostic criteria have been investigated to identify patients who have truly exhausted medical therapy and thus are likely to derive the maximum benefit for heart transplantation. Maximal oxygen consumption (VO2), which is measured during maximal exercise, is one measure that has been suggested as a critical objective criterion of the functional reserve of the heart. The American College of Cardiology (ACC) has adopted maximal VO2 as one criterion for patient selection.[1] Studies have suggested that transplantation can be safely deferred in those patients with a maximal VO2 of greater than 14 mL/kg/min. The importance of maximal VO2 has also been emphasized by an American Heart Association Scientific Statement addressing heart transplant candidacy.[10] In past years, a left ventricular ejection fraction (LVEF) of less than 20% or a New York Heart Association (NYHA) Class III or IV status may have been used to determine transplant candidacy. However, as indicated by the ACC criteria, these measurements are no longer considered adequate to identify transplant candidates. These measurements may be used to identify patients for further cardiovascular workup but should not be the sole criteria for transplant.

Methods other than maximal VO2 have been proposed as predictive models in adults.[11-14] The Heart Failure Survival Scale (HFSS) and Seattle Heart Failure Model (SHFM) are two examples. In particular, the SHFM provides an estimate of 1-, 2-, and 3-year survival with the use of routinely obtained clinical and laboratory data. Information regarding pharmacologic and device usage is incorporated into the model, permitting some estimation of effects of current, more aggressive heart failure treatment strategies. In 2006, Levy and colleagues[15] introduced the model using multivariate analysis of data from the PRAISE1 heart failure trial (n=1,125). Applied to the data of five other heart failure trials, the SHFM correlated well with actual survival (r: 0.98, standard error of the estimate=$\pm$3). The SHFM has been validated in both ambulatory and hospitalized heart failure populations[16-18] but with a noted underestimation of mortality risk, particularly in Black adults and device recipients.[19, 20] None of these models have been universally adopted by transplant centers.

INITIAL HEART TRANSPLANT

In the U.S., over 6 million people 20 years of age and older have heart failure and 1 in 8 deaths have heart failure mentioned on the death certificate.[21, 22] The reduction of cardiac

output is considered to be severe when systemic circulation cannot meet requirements under minimal exertion.

Heart failure may be due to a number of etiologies, including ischemic heart disease, cardiomyopathy, or congenital heart disease (CHD). The leading indication for a heart transplant has shifted over time from ischemic to nonischemic cardiomyopathy. From 2009 to 2014, nonischemic cardiomyopathy was the dominant underlying primary diagnosis among patients 18 to 39 years (64%) and 40 to 59 years (51%) undergoing transplant operations.[23] Ischemic cardiomyopathy was the dominant underlying primary diagnosis among heart transplant recipients 60 to 69 years (50%) and 70 years and older (55%). Overall, ischemic cardiomyopathy is the underlying heart failure diagnosis in approximately 40% of men and 20% of women who receive a transplant. Approximately 3% of heart transplants during this time period were in adults with CHD.

HEART RETRANSPLANTATION

From 2008 to 2015, approximately 4% of heart transplants were repeated transplantations.[3] As of June 2020, there were 106 patients on the waitlist for a repeat heart transplant. Heart retransplantation raises ethical issues due to the lack of sufficient donor hearts for initial transplants. The United Network for Organ Sharing does not have separate organ allocation criteria for repeat heart transplant recipients.

REGULATORY STATUS

Solid organ transplants are a surgical procedure and, as such, are not subject to regulation by the U.S. Food and Drug Administration.

The U.S. Food and Drug Administration regulates human cells and tissues intended for implantation, transplantation, or infusion through the Center for Biologics Evaluation and Research, under Code of Federal Regulation Title 21, parts 1270 and 1271. Solid organs used for transplantation are subject to these regulations.

EVIDENCE SUMMARY

Evidence reviews assess the clinical evidence to determine whether the use of technology improves the net health outcome. Broadly defined, health outcomes are the length of life, quality of life, and ability to function-including benefits and harms. Every clinical condition has specific outcomes that are important to patients and managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of technology, two domains are examined: the relevance, and quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse

events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice. Due to the nature of the population discussed herein, there are no RCTs comparing heart transplantation with alternatives, including left ventricular assist devices (LVADs). Systematic reviews are based on case series and registry data. RCTs published on related topics (e.g., comparing surgical technique, infection prophylaxis regimens, or immunosuppressive therapy) are not relevant to this evidence review.

INITIAL HEART TRANSPLANT

Survival after heart transplant

According to the Organ Procurement and Transplantation Network (OPTN), Kaplan-Meier survival rates for heart transplants performed during 2008-2015 based on available U.S. data as of June 11, 2021, the one-year survival after heart transplant was 90.3% (95% confidence interval [CI], 89. 6% to 90.9%) and 90.7% (95% CI, 89.6% to 91.7% for men and women, respectively.[3] Three-year survival rates were 84.7% (95% CI, 83.8% to 85.5%) and 84.1% (95% CI, 82.7% to 85.4%)for men and women, respectively, and five-year survival rates were 77.8% (95% CI, 76.8% to 78.8%) and 75.9% (95% CI, 74.2% to 77.6%), respectively.

A systematic review by Almarsi (2019) was conducted to identify new variables associated with transplant outcomes that are not currently collected by the Organ Procurement and Transplantation Network (OPTN).[24] Eighty-one unique studies including 1,193, 410 transplant patients with median follow-up of 36 months posttransplant were included. Among the 108 unique risk factors identified, 104 were recipient-related and 4 were donor-related. The strongest relative association measure for a heart transplant outcome with a risk factor was 8.6 (recipient with the previous Fontan operation).

A retrospective case-control study by Suarez-Pierre (2021) was published that compared survival after heart transplantation with that of the general population.[25] Data from 31,883 adults in the OPTN who had undergone heart transplantation between 1990 and 2007 were matched (5:1) to control subjects (n=159,415) based on age, sex, race, and state of permanent residency. The ten-year survival of heart transplant recipients was 53%. The population expected mortality rate was 15.9 deaths per 100 person-years with an observed rate of 45.1 deaths per 100 person-years (standardized mortality rate [SMR] 2.84; 95% confidence interval, 2.82 to 2.87). Over time, the standardized mortality ratios declined (1990 to 1995, 3.09; 1996 to 2000, 2.90; 2001 to 2007, 2.58) and the largest discrepancies between observed and expected survival were in female (SMR 3.63), black (SMR 3.67), and Hispanic (SMR 4.12) transplant recipients.

A systematic review by Almarsi (2019) was conducted to identify new variables associated with transplant outcomes that are not currently collected by the Organ Procurement and Transplantation Network (OPTN).[24] Eighty-one unique studies including 1,193, 410 transplant patients with median follow-up of 36 months posttransplant were included. Among the 108 unique risk factors identified, 104 were recipient-related and four were donor-related. The strongest relative association measure for a heart transplant outcome with a risk factor was 8.6 (recipient with the previous Fontan operation).

Nguyen (2017) investigated the benefit of heart transplantation compared with waiting list while accounting for the estimated risk of a given donor-recipient match among 28,548 heart transplant candidates in the OPTN between July 2006 and December 2015.[26] Net benefit

from heart transplantation was evident across all estimates of donor-recipient status 1A and 1B candidates: status 1A (lowest-risk quartile hazard ratio [HR], 0.37; 95% CI, 0.31 to 0.43; highest-risk quartile HR=0.52; 95% CI, 0.44 to 0.61) and status 1B candidates (lowest-risk quartile HR=0.41; 95% CI, 0.36 to 0.47; highest-risk quartile HR=0.66; 95% CI, 0.58 to 0.74). Status 2 candidates showed a benefit from heart transplantation; however, survival benefit was delayed. For the highest-risk donor-recipient matches, a net benefit of transplantation occurred immediately for status 1A candidates, after 12 months for status 1B candidates, and after 3 years for status 2 candidates.

Lund (2016) examined the risk factors associated with 10-year posttransplant mortality among patients undergoing heart transplantation during 2000-2005 using the International Society for Heart and Lung Transplantation (ISHLT) Registry.[23] Markers of pretransplant severity of illness, such as pretransplant ventilator use (HR=1.35; 95% CI, 1.17 to 1.56; n=338), dialysis use (HR=1.51; 95% CI, 1.28 to 1.78; n=332), underlying diagnoses of ischemic (HR=1.16; 95% CI: 1.10 to 1.23; n=7822), congenital (HR=1.21; 95% CI, 1.04 to 1.42; n=456) or restrictive (HR=1.33; 95% CI, 1.13 to 1.58; n=315) heart disease (vs non-ischemic cardiomyopathy), and retransplant (HR=1.18; 95% CI, 1.02 to 1.35; n=489) were associated with post-transplant mortality risk at 10 years.

Ting (2016) published a report that retrospectively evaluated outcomes of 134 patients one month to 78 years old (average 28) who received mechanical circulatory support for acute myocarditis with cardiogenic shock, between 1994 and 2014.[27] Patients recovering without a transplant were compared to those who received a transplant under mechanical circulatory support. 54% of patients survived on mechanical circulatory support, without transplant. Only 5% of the patients underwent transplant. The authors concluded transplant survival under mechanical circulatory support had favorable mid- and long-term outcomes.

Starling (2016) and Svobodova (2016) published studies evaluating transplant outcomes based on biomarkers and/or antibodies. Sterling published a one year observational, multicenter, cohort study in which 200 heart transplant patients were evaluated for biomarkers that could predict heart transplant outcomes.[28] Laboratory tests included anti-AHL antibody analysis, ELISPOT Panel of reactive T cell (PRT) assays, plasma angiogenesis-related proteins, peripheral blood and tissue gene expression profiling. Svobodova published a single-center retrospective study that evaluated antibody-mediated rejection (AMR).[29] Data was analyzed for pre- and post-transplant antibodies and antigens in transplant recipients and/or donors. Median follow-up was 39 months. Starling concluded it is still difficult to find reliable biomarkers that can determine heart transplant outcomes. Svobodova stated monitoring pre- and post-transplant antigens and antibodies may predict rejection.

Rana (2015) conducted a retrospective analysis of solid organ transplant recipients registered in the UNOS database from 1987 to 2012, including 54,746 patients who underwent a heart transplant.[30] Transplant recipients were compared with patients listed for transplant, but who did not receive a transplant after propensity score matching based on a variety of clinical characteristics. After matching, the median survival was 9.5 years in transplant recipients compared with 2.1 years in waiting list patients.

A 2013 study examined characteristics of patients who survived longer than 20 years after heart transplantation at a single center.[31] Thirty-nine heart transplant recipients who survived over 20 years post-transplant were compared to 98 patients who died between one and 20-years post-transplant. Independent factors associated with long-term survival were younger

recipient age i.e., <45 years versus 45 years and older (OR: 3.9, 95% CI: 1.6-9.7) and idiopathic cardiomyopathy i.e. versus other etiologies (OR: 3.3, 95% CI: 1.4-7.8).

Bhama (2013) published results from study that reported on survival outcomes for heart transplantation in a cohort of adults with congenital heart disease (CHD) and identified risk factors for mortality that would help guide recipient and donor selection.[32] A retrospective analysis identified 19 patients that had transplantation for CHD and compared to 428 transplant patients that underwent transplantation for conditions other than CHD. There was no significant difference in survival (CHD vs control) at 30 days (89% vs 92%, p = 0.5567), one year (84% vs 86%, p = 0.6976), or five years (70% vs 72%, p = 0.8478). The only significant predictor of death in the CHD group was donor organ ischemic time >four hours (HR 13.26, 95% CI 1.3 to 132.2, p = 0.028). Authors suggested that adults with CHD have excellent early and mid-term survival after heart transplantation.

A 2012 study by Kalic analyzed prospectively collected data from the United Network for Organ Sharing (UNOS) registry.[33] The analysis included 9,404 individuals who had survived 10 years after heart transplant and 10,373 individuals who had died before 10 years. Among individuals who had died, mean survival was 3.7 years post-transplant. In multivariate analysis, statistically significant predictors of surviving at least 10 years after heart transplant included:

- Age younger than 55 years (odds ratio [OR]: 1.24, 95% confidence interval [CI]: 1.10 to 1.38),
- Younger donor age (OR: 1.01, 95% CI: 1.01 to 1.02),
- Shorter ischemic time (OR: 1.11, 95% CI: 1.05 to 1.18),
- White race (OR: 1.35, 95% CI: 1.17 to 1.56), and
- Annual center volume of nine or more heart transplants (OR: 1.31, 95% CI: 1.17 to 1.47).

Factors that significantly decreased the likelihood of 10-year survival in multivariate analysis included:

- Mechanical ventilation (OR: 0.53, 95% CI: 0.36 to 0.78), and
- Diabetes (OR: 0.67, 95% CI: 0.57 to 0.78).

Jalowiec (2011) compared clinical outcomes in sex-matched and sex-mismatched heart transplant recipients.[34] They retrospectively reviewed data from 347 heart transplant recipients; 237 (78.7%) received a heart from a same-sex donor, 40 (11.5%) cases involved a female donor and male recipient, and 34 (9.8%) cases involved a male donor and female recipient. There was not a statistically significant difference in the mortality rate during the first month post-transplant between the sex-matched and either sex-mismatched group. In adjusted analyses, two of the other nine study outcomes differed significantly among the three groups. The male donor-female recipient group had significantly more treated rejection episodes during the first year post-transplant and significantly more days of rehospitalization after the initial discharge than either of the other two groups. The incidence of steroid-induced diabetes, cardiac allograft vasculopathy, non-skin cancers, number of intravenous (IV)-treated infections post-transplant, and initial hospital length of stay were not significantly different among groups.

Pediatric considerations

The highest one- and three- year survival rate among pediatric patients undergoing heart transplant in the US, during 2008-2015, were 11-17 year old patients according to the Organ Procurement and Transplantation Network (OPTN).[3] Patients younger than one-year-old had the lowest one-, three-, and five-year survival among pediatric patients.

Khan (2021) published the results of a retrospective analysis of heart transplant survival in children with congenital heart disease with or without heterotaxy syndrome.[35] Waitlist outcomes and survival post-listing and transplant were analyzed from 4814 children of whom 196 (4%) had heterotaxy. No differences in waitlist outcomes of transplant, death, or removal were found between patients with or without heterotaxy. Post-transplant survival was worse for children with heterotaxy: one-year survival 77.2% vs. 85.1%, with and without heterotaxy, respectively. In addition, heterotaxy was an independent predictor for early mortality in the earliest era (1993-2004), HR 2.09, CI 1.16-3.75, p = 0.014, however, this improved over time. Lower freedom from infection and from severe rejection was found in patients with heterotaxy, but no difference in vasculopathy or malignancy was identified.

Rossano (2016) examined survival among pediatric heart transplant recipients using the ISHLT Registry. Among 12,091 pediatric patients undergoing heart transplantation during 1982-2014, the overall median survival was 20.7 years for infants, 18.2 years for children ages 1 to 5 years, 14.0 years for those ages 6 to 10 years, and 12.7 years for those ages 11 to 17 years. As the first year posttransplant represents the greatest risk for mortality, survival conditional on survival to one year was longer.[36]

Kulkami (2016) published an evaluation of a multicenter prospective single ventricle reconstruction trial to determine outcomes of infant patients with a single ventricle who were listed for transplant after the Norwood procedure.[37] A public database was used to compare infants while on the waiting list and after transplant. Risk factors were also evaluated for those patients put on the waiting list for a transplant and for those who survived without a transplant. Of 555 patients 33 were listed and underwent transplant. One-year survival after being put on the waiting list, including those that died after transplant was 48%. Diagnosis for being put on the transplant list after the Norwood procedure, included worsening right ventricular function, non-hypoplastic left heart syndrome, and a complex intensive care unit stay. The authors determined patients having heart transplant as a rescue procedure within a year of the Norwood procedure had a higher risk of complications and mortality.

Garbern (2016) published a study that evaluated transplant outcomes for pediatric patients with myocarditis versus dilated cardiomyopathy (DCM).[38] During the study 137 children with myocarditis and 1,249 children with DCM underwent heart transplant. Data was taken from the Organ Procurement and Transplant Network (OPTN) database. The data for children with myocarditis was evaluated for a higher risk of mortality pre-transplant. The authors noted several study limitations including that they could not confirm data accuracy, but stated after the adjustment for severity of illness, children with myocarditis were not at a higher risk of mortality pre- and post-transplant than patients with DCM.

According to OPTN data, in 2015, 423 heart transplants were performed in children younger than 18 years of age.[3] Five-year survival rates by age group were: less than one year: 68.6% (95% CI, 62.0% to 75.1%); one to five years: 69.4% (95% CI, 64.1% to 74.7%); six to ten years: 73.1% (95% CI, 66.7% to 79.5%); and 11-17 years: 75.1% (95% CI, 72.6% to 77.5%).

A retrospective analysis of OPTN data focusing on the adolescent population was published by Savia in 2014.[39] From 1987 to 2011, 99 adolescents (age, 13-18) heart transplants were

performed with myocarditis and 456 adolescents with coronary heart disease (CHD). Among adolescent transplant recipients with myocarditis, median graft survival was 6.9 years (95% CI, 5.6 to 9.6 years), which was significantly less than other age groups (i.e., 11.8 years and 12.0 years in younger and older adults, respectively). However, adolescents with CHD had a graft survival rate of 7.4 years (95% CI, 6.8 to 8.6 years), similar to that of other age groups.

According to the International Society for Heart and Lung Transplantation, 532 heart transplants in children younger than 18 years-old were reported worldwide in 2010.[40] This number compares to 543 reported in 2009. Among the pediatric transplants, about 25% were in infants younger than age one year, 37% were in children between the ages of one and 10 years, and 38% were in adolescents between the ages of 11 to 17 years. In infants, the most common indications for heart transplant were congenital heart disease (56%) and cardiomyopathy (40%). For children older than 10 years of age, the most common indication was cardiomyopathy (63%). Median survival has varied with age of the transplant recipient. Median survival was 19.2 years for infants, 15.6 years for one to 10 year-olds, and 11.9 years for 11-17 year-olds.

In 2011, a retrospective review of pediatric cardiac transplantation patients was published by Auerbach.[41] A total of 191 patients who underwent primary heart transplantation at a single center in the United States were included; their mean age was 9.7 years (range, 0 to 23.6 years). Overall graft survival was 82% at one year and 68% at five years; the most common causes of graft loss were acute rejection and graft vasculopathy. Overall patient survival was 82% at one year and 72% at five years. In multivariate analysis, the authors found that congenital heart disease (HR: 1.6, 95% CI: 1.02-2.64) and requiring mechanical ventilation at the time of transplantation (HR: 1.6, 95% CI: 1.13-3.10) were both significantly independently associated with an increased risk of graft loss. Renal dysfunction was a significant risk factor in univariate analysis but was not included in the multivariate model due to the small study group. Limitations of the study include that it was retrospective and conducted in only one center.

Patel (2010) presented a retrospective review of echocardiography and serum markers as a predictor of death or need for transplantation in newborns, children, and young adults with heart failure.[42] A total of 99 children with 139 admissions were evaluated on LVEF and tricuspid regurgitation, as well as on various serum markers for their predictive ability of death or need for transplantation in a stepwise multivariate Cox regression model. While brain natriuretic peptide (BNP) and tricuspid regurgitation were not predictive of need for transplantation, ejection fraction and lymphocytosis were predictive (ejection fraction odds ratio [OR]: 0.94, 95% CI: 0.90-0.98; for lymphocytosis, OR 5.40, 95% CI: 1.67–17.4). Serum levels of creatinine and sodium were also predictive. Clinical prediction rules based on these findings have not been compared to current strategies and await clinical validation.

Noting that children listed for heart transplantation have the highest waiting list mortality of all solid organ transplant patients, Almond analyzed data from the U.S. Scientific Registry of Transplant Recipients to determine if the pediatric heart allocation system, as revised in 1999, prioritizes patients optimally and to identify high-risk populations that may benefit from pediatric cardiac assist devices.[43] Of 3,098 children (younger than 18 years of age) listed between 1999 and 2006, a total of 1,874 (60%) were listed as Status 1A. Of those, 30% were placed on ventilation and 18% were receiving extracorporeal membrane oxygenation. Overall, 533 (17%) died, 1,943 (63%) received transplants, 252 (8%) recovered, and 370 (12%) remained listed. The authors found that Status 1A patients are a heterogeneous population

with large variation in mortality based on patient-specific factors. Predictors of waiting list mortality included extracorporeal membrane oxygenation support (hazard ratio [HR]: 3.1), ventilator support (HR: 1.9), listing status 1A (HR: 2.2), congenital heart disease (HR: 2.2), dialysis support (HR: 1.9), and non-white race/ethnicity (HR: 1.7). The authors concluded that the pediatric heart allocation system captures medical urgency poorly, specific high-risk subgroups can be identified, and further research is needed to better define the optimal organ allocation system for pediatric heart transplantation.

HEART RETRANSPLANTATION

Chen (2022) evaluated outcomes after heart re-transplantation in recipients > 60 years. A total of 1026 adult patients undergoing isolated heart re-transplantation were identified (> 60 years, n=177; ≤ 60 years, n=849).[44] Older recipients were more likely to be male and have diabetes or previous malignancies with higher baseline creatinine. They more frequently required pre-transplant ECMO (11.9% vs. 6.8%, p=0.02) and received re-transplantation due to primary graft failure (13.6% vs. 8.5%, p=0.03). After transplant, older recipients had a higher incidence of stroke (6.8% vs. 2.6%, p=0.01) and dialysis requirements (20.3% vs. 13.2%) before discharge (both p<0.05), and more frequently died from malignancy-related causes (16.3% vs. 3.9%, p<0.001). After adjustment, recipient age >60 was associated with an increased risk of both 5-year (HR 1.42, 95% CI 1.02-2.01, p=0.04) and 10-year mortality (HR 1.72, 95% CI 1.20-2.45, p=0.003).

Zhu (2022) evaluated outcomes after heart retransplantation for 123 patients (112 adult and 11 pediatric patients) as compared to those who received a primary heart transplant at a single-center over a 50-year period (January 6, 1968 to June 2019).[45] The indications for retransplantation included cardiac allograft vasculopathy (80%), primary graft dysfunction (15%), and refractory acute rejection (5%). The mean time interval between the primary and retransplant was 6.4 years. Patients who underwent a retransplantation were significantly more likely to have hypertension (73.3% vs. 53.3%; p=.0022), hyperlipidemia (66.7% vs. 30.7%; p<.0001), and require dialysis (11.7% vs. 2.9%; p=.0025) as compared to those undergoing a primary heart transplant. After matching, postoperative outcomes and complications including hospital stay (mean 22.9 vs. 25.8 days; p=.49), intensive care unit stay (mean 12.2 vs. 9.9 days; p=.48), respiratory failure (41.7% vs. 20.6%; p=.083), dialysis (21.2% vs. 24.2%; p=.82), pneumonia (12.9% vs. 9.6%; p=.48), septicemia (1.6% vs. 9.4%; p=.10), and rejection within the first year after transplantation requiring hospitalization (21.5% vs. 26.2%; p=.82) were similar between the retransplant and primary transplant groups, respectively. Matched median survival after retransplantation was 4.6 years versus 6.5 years after primary heart transplantation (p=.36).

In a study analyzing UNOS data from January 1996 to November 2017, Miller (2019) reported that 349 (0.6%) early/acute retransplants (occurring ≤ one year after the previous transplant) and 2,202 (3.5%) late retransplants (occurring > one year after the previous transplant) were performed from a sample of 62,112 heart transplants.[46] Compared with a matched group of patients undergoing initial transplantation, patients undergoing late retransplantation were not at an increased risk of death (HR, 1.08; p=0.084) or the combined outcome of death or retransplantation (HR, 1.07; p=0.114). Additionally, patients undergoing late retransplant had comparable rates of one-year all-cause mortality when compared to patients undergoing initial transplant (13.8% vs 14.5%, respectively; p=0.517). Conversely, patients undergoing early/acute transplant had higher rates of one-year all-cause mortality when compared to patients undergoing initial transplant (35% vs 21.6%; p<0.001). Furthermore, early/acute

retransplantation was associated with an increased risk of all-cause mortality (HR, 1.79; p<0.001) and the combined outcome of death or retransplantation (HR, 1.72; p<0.001).

An analysis of OPTN data from 1995 to 2012 by Belli (2014) reported that 987 retransplants were performed (of 28,464 heart transplants, 3.5% of all transplants).[47] Median survival among retransplant recipients was 8 years. The estimated survival at 1, 5, 10, and 15 years following retransplant was 80%, 64%, 47% and 30%, respectively. Compared with primary transplant recipients, retransplant patients had a somewhat higher risk of death (risk ratio [RR]=1.27, 95% CI, 1.13 to 1.42).

A number of studies have reviewed clinical experience with heart retransplantation in adults. In 2013, Saito published a retrospective review of data on 593 heart transplants performed at their institution; 22 of these (4%) were repeat transplantations.[48] The mean interval between initial and repeat transplant was 5.1 years. The indications for a repeat transplant were acute rejection in seven patients (32%), graft vascular disease in 10 patients (45%), and primary graft failure in five patients (23%). Thirty-day mortality after cardiac retransplantation was 32% (7 of 22 patients). Among patients who survived the first 30 days (n=15), 1-, 5- and 10-year survival rates were 93.3%, 79% and 59%, respectively. Comparable survival rates for patients undergoing primary cardiac transplants at the same institution (n=448) were 93%, 82% and 63%, respectively. An interval of one year or less between the primary and repeat transplantation significantly increased the risk of mortality. Three of nine patients (33.3%) with less than a year between the primary and retransplantation survived to 30 days. In comparison 12 of 13 patents (92%) with at least one year between primary and retransplantation were alive at 30 days after surgery.

Tjang (2008) published a systematic review of this literature that identified 22 studies reporting clinical outcomes of heart retransplantation in patients over 18 years old.[49] The most common indications for retransplantation were cardiac allograft vasculopathy (55%), acute rejection (19%) and primary graft failure (17%). The early mortality rate in individual studies was 16% (range: 5% to 38%). Some of the factors associated with poorer outcome after retransplantation were shorter transplant interval, refractory acute rejection, primary graft failure and an initial diagnosis of ischemic cardiomyopathy.

Topkara (2005) reviewed data on 766 adult patients who underwent heart transplantation between 1992 and 2002.[50] Forty-one (5%) of patients underwent repeat transplants; the indication for retransplantation was transplant-related coronary artery disease in 37 of 41 (90%) of these patients. Due to early experience with retransplantation, criteria at this institution were changed in 1993 so that patients with intractable acute rejection within 6 months of the initial transplant were ineligible for repeat transplants. One and five-year survival rates were 85.1% and 72.9%, respectively after primary transplantation and 72.2% and 47.5%, respectively after retransplantation. Survival rates were significantly lower in the retransplantation group, p<0.001. The authors did not report survival rates stratified by the length of time between initial and repeat transplantations.

Pediatric Considerations

Vazquez (2022) published an evaluation of retransplantation patients from the Pediatric Heart Transplant Society (PHTS) database analysis of retransplantation patients <18 years of age over three decades (Era 1: 1993-2001, Era 2: 2002-2010, Era 3: 2011-2018).[51] Survival was lower (p < .0001) for retransplant (n = 222) compared to primary transplant (n = 6548) (median 9.3 vs 20.2 years). Median survival increased from Era 1 to 2 (4.8 vs 9.3 years; p < .0001) with

no incremental change in Era 3. Era 2 and 3 retransplants had a longer inter-transplant interval (p < .0001), were less frequently for early graft failure (p = .0004) or acute rejection (p = .007), more frequently from a ventricular assist device (p = .0014), and less frequently from extracorporeal membrane oxygenation (p = .0024). Predictors of graft loss included Era 1 (HR 10.55, p = .001), congenital heart disease (HR 4.42, p = .01), inter-transplant interval <1 year (HR 5.34, p = .002), and mechanical support (ventricular assist device HR 7.47, p = .0042; extracorporeal membrane oxygenation HR 10.09, p < .0001). For each 1-year increase in inter transplant interval, graft loss risk decreased by 1.15 (p = .0002). Retransplantation was associated with more rejection, infection, and allograft vasculopathy. The authors conclude that graft survival has improved in pediatric retransplant and that retransplantation should be avoided in the setting of early graft failure especially requiring mechanical support.

Azeka (2020) published a retrospective cohort study reporting on patients who underwent primary heart transplant (PTx) <18 years old and subsequent retransplant (RTx) due to coronary allograft vasculopathy (CAV). [52] The maintenance immunosuppression protocol was double immunosuppression. Between 1992 and 2018, 200 children underwent heart transplantation. Ten re-transplantations were performed, for which 7 (70%) were for CAV. Ages at RTx ranged from 11.5 to 29.3 years (19.1 ± 5.68 years; median 18.2 years). The mean time between PTx and RTx was 12.9 ± 3.4 years (median 13.4 years). The Kaplan-Meier survival rate at 1 month, 3 years, and 5 years was 85.7%, 71.5%, and 47.6%, respectively. The authors conclude that cardiac RTx can be a management option for CAV in patients who have undergone PTx in childhood with double immunosuppression therapy.

As with initial heart transplants, children waiting for heart retransplantation have high waitlist mortality. Alsoufi (2015) published results from a retrospective analysis (1988 to 2013) that examined their experience with heart transplantations in pediatric patients with underlying congenital heart disease.[53] The study included sixteen patients who underwent primary heart transplantation. Participants were predominately male, and had a median age of 3.8 years. Competing risks analysis showed that at 10 years after heart transplantation, 13% of patients had undergone retransplantation, 43% of patients had died without retransplantation, and 44% of patients were alive without retransplantation. After retransplantation, 52% of patients were alive and 18% of patients had undergone a second retransplantation. Overall 15-year survival after initial heart transplantation was 41%. It is important to note this study has methodological considerations, which include but are not limited to, a small sample size; therefore, generalizability of results is limited.

Bock (2014) evaluated data on 632 pediatric patients who were listed for a heart retransplant at least one year (median, 7.3 years) after the primary transplant.[54] Patients' median age was four years at the time of the primary transplant and 14 years when they were relisted. Median waiting time was 75.3 days and mortality was 25.2% (159 of 632). However, waitlist mortality decreased significantly after 2006 (31% before 2006 and 17% after 2006, p<0.01).

Copeland (2014) published results from a retrospective chart review (n=183) and evaluated late survival among pediatric heart transplant patients, living for more than 15 years after transplant.[55] A total of 32 deaths were reported due to the following conditions: cardiac allograft vasculopathy (CAV); 11 (34.3%); posttransplant lymphoproliferative disease, 18.8%; acute rejection, 12.5%; sepsis, 6.3%; multiorgan failure, 3.1%; and unknown reasons, 25%. A total of 30 patients required cardiac retransplantation due to CAV. The authors concluded that heart transplantation in pediatric patients results in acceptable long-term survival. In patients

who develop CAV and renal dysfunction, heart retransplantation is an acceptable form of palliative treatment.

Friedland-Little (2014) published results from a retrospective analysis (1985-2011) of pediatric and young adult survivors who had undergone repeat heart transplantations.[56] Patients were included in the review who had a primary heart transplant before the age of 21, and had undergone a third transplant. Patients were matched 1:3 with a control group of second heart transplant patients by age, era and re-transplant indication. The authors found no difference between third heart transplant patients (n=27) and the control second heart transplantation patients (n=79) with respect to survival (76% vs 80% at one year, 62% vs 58% at five years and 53% vs 34% at 10 years, p = 0.75). However, generalizability of the study's results may be limited due to methodological limitations, such as small sample size.

Mahle (2005) reviewed data from the United Network for Organ Sharing (UNOS) on heart retransplantation in patients less than 18 years old.[57] A total of 219 retransplantations occurring 1987 to 2004 were identified. The median age at initial transplant was 3 years old and the median age at retransplantation was nine years old. The median interval between initial procedure and retransplantation was 4.7 years. The most common indications for retransplantation were coronary allograft vasculopathy (n=111, 51%), non-specific graft failure (n=34, 18%) and acute rejection (n=19, 9%). Retransplantation was associated with worse overall survival than initial transplantation. One,five, and ten year survival rates were 83%, 70% and 58%, respectively after primary transplantation and 79%, 53% and 44%, respectively after retransplantation. The most common causes of death after retransplantation were acute rejection (14%), coronary allograft vasculopathy (14%) and infections (13%).

In both the adult and pediatric studies, poorer survival after retransplantation than initial transplantation is not surprising given that patients undergoing retransplantation experienced additional clinical disease or adverse events. The increased mortality from retransplantation appears to be mainly from increased short-term mortality. Longer-term survival rates after retransplantation seem reasonable, especially when patients with a higher risk of poor outcomes (e.g., those with a shorter interval between primary and repeat transplantation) are excluded. Also, patients with failed initial transplant have no other options besides a retransplantation.

POTENTIAL CONTRAINDICATIONS

Individual transplant centers may differ in their guidelines, and individual patient characteristics may vary within a specific condition. In general, heart transplantation is contraindicated in patients who are not expected to survive the procedure or in whom patient-oriented outcomes, such as morbidity or mortality, are not expected to change due to comorbid conditions unaffected by transplantation (e.g., imminently terminal cancer or other disease). Further, consideration is given to conditions in which the necessary immunosuppression would lead to hastened demise, such as active untreated infection. However, stable chronic infections have not always been shown to reduce life expectancy in heart transplant patients.

Pretransplant malignancy is considered a relative contraindication for heart transplantation considering this has the potential to reduce life expectancy and could prohibit immune suppression after transplantation. However, with improved cancer survival over the years and use of cardiotoxic chemotherapy and radiotherapy, the need for heart transplantation has increased in this population,

Mistiaen (2015) conducted a systematic review to study the posttransplant outcome of pretransplant malignancy patients.[58] Most selected studies were small case series. Mean patient age varied from 6 years to 52 years. Hematologic malignancy and breast cancer were the most common type of pretransplant malignancies. Dilated, congestive, or idiopathic cardiomyopathy was mostly the common reason for transplantation in 4 case series, chemotherapy related cardiomyopathy was the most important reason for transplantation in the other series. Hospital mortality varied between 0% and 33%, with small sample size potentially explaining the observed variation, One large series reported similar short-term and long-term posttransplant survival of chemotherapy related (N=232) and other nonischemic cardiomyopathy (N=8890) patients. The 1-, 3-, and 5-year survival rates of were 86%, 79%, and 71% for patients with chemotherapy-related cardiomyopathy compared with 87%, 81%, and 74% for other transplant patients. Similar findings were observed for 1-year survival in smaller series. Two-, 5-, and 10-year survival rates among pretransplant malignancy patients were also comparable with other transplant patients. In addition to the nonmalignancy related factors such as cardiac, pulmonary, and renal dysfunction, two malignancy related factors were identified as independent predictors of 5-year survival. Malignancy-free interval (the interval between treatment of cancer and heart transplantation) of less than 1 year was associated with lower 5-year survival compared with a longer interval (<60% vs >75%). Patients with prior hematologic malignancies had an increased posttransplant mortality in three small series. Recurrence of malignancy was more frequent among patients with a shorter disease-free interval, 63%, 26%, and 6% among patients with less than 1 year, 1 to 5 years, and more than 5 years of disease-free interval, respectively.

Yoosabai (2015) conducted a retrospective review among 23,171 heart transplant recipient in the OPTN/UNOS database to identify whether pretransplant malignancy increases the risk of posttransplant malignancy.[59] Posttransplant malignancy was diagnosed in 2673 (11.5%) recipients during the study period. A history of any pretransplant malignancy was associated with increased risk of overall posttransplant malignancy (subhazard ratio [SHR], 1.51; p<0.01), skin (SHR=1.55, p<0.01), and solid organ malignancies (SHR=1.54, p<0.01) on multivariate analysis.

ISHLT guidelines have recommended to stratify each patient with pretransplant malignancy as to their risk of tumor recurrence and that cardiac transplantation should be considered when tumor recurrence is low based on tumor type, response to therapy and negative metastatic work-up. The guideline also recommended that the specific amount of time to wait to transplant after neoplasm remission will depend on these factors and no arbitrary time period for observation should be used.

OLDER AGE

Jamil (2017) conducted a retrospective study of age as it relates to primary graft dysfunction after heart transplantation.[60] Of the 255 heart transplants studied, 70 (27%) recipients were 65 years and older and 185 were younger; there were no significant differences in post-transplant morbidity (all p>0.12) or one-year survival between groups (p=0.88). The incidence of moderate or severe primary graft dysfunction was lower among the older patients (6%) than in the younger (16%; p=0.037). Study limitations included the single-center design, lack of data on long-term survival, and the potential for selection bias in retrospective studies.

Cooper (2016) published a retrospective cohort study evaluating transplant outcomes in elderly patients, by using data from the United Network for Organ Sharing database. Data on

three groups of patients 18-59, 60-69 and greater than or equal to 70 years of age were compared for five-year survival rates. The authors noted that patients greater than or equal to 70 had more ischemia and renal dysfunction than the 60-69 age group and received transplants from older donors who were more ill or had a history of drug abuse. Five-year survival rates were 26.9% for the 18-59 age group, 29.3% for the 60-69 age group, and 30.8% for the greater than or equal to 70 age group. The authors also noted limitations with this retrospective review including but not limited to potential risk of bias with patient transplant selection and quality of the data. The authors concluded the greater than or equal to 70 age group showed no significant difference in outcomes from the 60-69 age group and should not be excluded from receiving a transplant.

Awad (2016) reported on a single-center retrospective review of 704 adults who underwent heart transplantation from 1988 to 2012 to investigate the mortality and morbidity rates of heart transplantations among recipients 70 years of age and older (n=45) compared with recipients younger than 70 years (n=659).[61] The older and younger groups had similar 1-year (93.0 vs 92.1; p=0.79), 5-year (84.2 vs 73.4; p=0.18), and10-year (51.2 vs 50.2; p=0.43) survival rates, respectively.

Kilic (2012) analyzed data from the UNOS on 5,330 patients age 60 and older (mean age 63.7 years) who underwent heart transplantation between 1995 and 2004.[62] A total of 3,492 individuals (65.5%) survived to five years. In multivariate analysis, statistically significant predictors of five-year survival included younger age (OR: 0.97, 95% CI: 0.95 to 1.00), younger donor age (OR: 0.99, 95% CI: 0.99-1.00), white race (OR: 1.23, 95% CI: 1.02 to 1.49), shorter ischemic time (OR: 0.93, 95% CI: 0.87-0.99), and lower serum creatinine (OR: 0.92, 95% CI: 0.87 to 0.98). In addition, hypertension, diabetes, and mechanical ventilation each significantly decreased the odds of surviving to five years. Patients with two or more of these factors had a 12% lower rate of five years survival than those with none of them.

Daneshvar (2011) examined data on 519 patients who underwent heart transplantation between 1988 and 2009 at a single institution, with a particular focus on survival differences by age group.[63] There were 37 patients who were at least 70 years-old (group 1), 206 patients between 60 and 69 years (group 2), and 276 patients younger than 60 years (group 3). Median survival was 10.9 years in group one, 9.1 years in group two, and 12.2 years in group three (non-significant difference among groups). The five-year survival rate was 83.2% in group one, 73.8% in group two, and 74.7% in group three.

PULMONARY HYPERTENSION

Findings of several studies published in 2012 and 2013 suggested that patients with pulmonary hypertension who successfully undergo treatment can subsequently have good outcomes after heart transplant.[64-67] For example, De Santo (2012) reported on 31 consecutive patients who had been diagnosed with unresponsive pulmonary hypertension at baseline right heart catheterization.[64] After 12 weeks of treatment with oral sildenafil, right heart catheterization showed reversibility of pulmonary hypertension, allowing listing for heart transplant. Oral sildenafil treatment resumed following transplant. One patient died in the hospital. A right heart catheterization at three months post-transplant showed normalization of the pulmonary hemodynamic profile, thereby allowing weaning from sildenafil in the 30 patients who survived hospitalization. The reversal of pulmonary hypertension was confirmed at one year in the 29 surviving patients. Similarly, in a study by Perez-Villa (2013) , 22 patients considered high-risk for heart transplant due to severe pulmonary hypertension were treated

with bosentan. After four months of treatment, mean pulmonary vascular resistance (PVR) decreased from 5.6 to 3.4 Wood units. In a similar group of nine patients who refused participation in the study and served as controls, mean PVR during this time increased from 4.6 to 5.5 Wood units. After bosentan therapy, 14 patients underwent heart transplantation and the one-year survival rate was 93%.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF CARDIOLOGY, AND AMERICAN HEART ASSOCIATION

Guidelines from the American College of Cardiology Foundation and American Heart Association were updated in 2017.[68] Evaluation for heart transplantation was recommended for patients in whom heart failure is assessed as refractory based on New York Heart Association functional class III or IV (stage D) for heart failure after previous guideline-directed medical therapy, use of devices such as an implantable cardioverter defibrillator or a cardiac resynchronization therapy device, or surgical management.

INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION

In 2016, The International Society for Heart and Lung Transplantation (ISHLT) updated their heart transplantation criteria in and made the following updates to their recommendations:[69]

- 1.2 Use of heart failure prognosis scores. Heart failure prognosis scores should be performed along with cardiopulmonary exercise test to determine prognosis and guide listing for transplantation for ambulatory patients. An estimated one year survival as calculated by the Seattle Heart Failure Model (SHFM) of <80% or a Heart Failure Survival Score (HFSS) in the high/medium risk range should be considered as reasonable cut points for listing (Level of Evidence: C; primarily expert consensus opinion).
- 1.4.1 Age, obesity, and cancer as comorbidities and their implications for heart transplantation list.
    - Carefully selected patients >80 years of age may be considered for cardiac transplantation (Level of Evidence: C).
    - Pre-transplantation body mass index (BMI) >35kg/m^2 is associated with a worse outcome after cardiac transplantation. For such obese patients, it is reasonable to recommend weight loss to achieve a BMI of ≤ 35kg/m^2 before listing for cardiac transplantation (Level of Evidence: C).
- 1.4.2 Diabetes, Renal dysfunction, and peripheral vascular disease.
    - Diabetes with end-stage damage or persistent poor glycemic control (glycosylated hemoglobin >7.5% or 58 mmol/mol) despite optimal effort is a relative contraindication for transplant (Level of Evidence: C).
    - Renal function should be assessed using estimated glomerular filtration rate (eFGR) or creatinine clearance under optimal medical therapy. It is reasonable to consider the presence of irreversible renal dysfunction (eGRF <30 ml/min1.73m2) as a relative contraindication for heart transplantation alone (Level of Evidence: C).
    - Clinically server symptomatic cerebrovascular disease may be considered a contraindication to transplantation when it's presences limits rehabilitation and revascularization is not a viable option (Level of Evidence: C).
- 1.5.3 Psychosocial evaluation. Any patient for whom social supports are deemed insufficient to achieve compliant care in the outpatient setting may be regarded as

having a relative contraindication to transplant. The benefit of heart transplantation in patients with severe cognitive-behavioral disabilities or dementia has not been established, has the potential for harm, and therefore, heart transplantation cannot be recommended for this sub-group of patients (Level of Evidence: C).

- 1.8 Retransplantation. Retransplantation is indicated for those patients who develop significant CAV with refractory cardiac allograft dysfunction, without evidence of ongoing rejection (Level of Evidence: C).

THE AMERICAN HEART ASSOCIATION

The American Heart Association (AHA) Council on Cardiovascular Disease in the Young; the Councils on Clinical Cardiology, Cardiovascular Nursing, and Cardiovascular Surgery and Anesthesia; and the Quality of Care and Outcomes Research Interdisciplinary Working Group stated in 2007 that, based on level B (non-randomized studies) or level C (consensus opinion of experts), heart transplantation is indicated for pediatric patients as therapy for the following indications:[70]

- Stage D heart failure (interpreted as abnormal cardiac structure and/or function, continuous infusion of intravenous inotropes, or prostaglandin E1 to maintain patency of a ductus arteriosus, mechanical ventilatory and/or mechanical circulatory support) associated with systemic ventricular dysfunction in patients with cardiomyopathies or previous repaired or palliated congenital heart disease,
- Stage C heart failure (interpreted as abnormal cardiac structure and/or function and past or present symptoms of heart failure) associated with pediatric heart disease and severe limitation of exercise and activity, in patients with cardiomyopathies or previously repaired or palliated congenital heart disease and heart failure associated with significant growth failure attributed to heart disease, pediatric heart disease with associated near sudden death and/or life-threatening arrhythmias untreatable with medications or an implantable defibrillator, or in pediatric restrictive cardiomyopathy disease associated with reactive pulmonary hypertension,
- The guideline states that heart transplantation is feasible in the presence of other indications for heart transplantation, in patients with pediatric heart disease and an elevated pulmonary vascular resistance index >6 Woods units/m2 and/or a transpulmonary pressure gradient >15 mm Hg if administration of inotropic support or pulmonary vasodilators can decrease pulmonary vascular resistance to <6 Woods units/m2 or the transpulmonary gradient to <15 mm Hg.

SUMMARY

There is enough research to show that heart transplantation can improve survival for certain pediatric and adult patients. Guidelines based on research recommend heart transplant for people with certain indications. Therefore, heart transplant may be considered medically necessary in patients who meet the policy criteria.

There is enough research to show that heart retransplantation can improve survival for certain pediatric and adult patients who have had a prior transplant. Guidelines based on research recommend heart retransplantation for people with certain indications. Therefore, heart retransplantation may be considered medically necessary in patients who meet the policy criteria.

There is not enough research to show that heart transplantation or retransplantation improves health outcomes for all other indications. Therefore, heart transplantation or retransplantation is considered not medically necessary for indications when the policy criteria are not met.

Medical Policy Manual Transplant, Policy No. 03

Heart-Lung Transplant

Effective: May 1, 2024

Next Review: March 2025
Last Review: March 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

The heart/lung transplantation involves a coordinated triple operative procedure consisting of procurement of a donor heart-lung block, excision of the heart and lungs of the recipient, and implantation of the heart and lungs into the recipient. A heart/lung transplantation refers to the transplantation of one or both lungs and heart from a single cadaver donor.

MEDICAL POLICY CRITERIA

I. Heart/lung *transplantation* may be considered **medically necessary** for carefully selected patients with end-stage cardiac and pulmonary disease including, but not limited to, one of the following diagnoses:

   A. Irreversible primary pulmonary hypertension with heart failure
   B. Nonspecific severe pulmonary fibrosis, with severe heart failure
   C. Eisenmenger complex with irreversible pulmonary hypertension and heart failure
   D. Cystic fibrosis with severe heart failure
   E. Chronic obstructive pulmonary disease with heart failure
   F. Emphysema with severe heart failure
   G. Pulmonary fibrosis with uncontrollable pulmonary hypertension or heart failure

II. Heart/lung transplantation is considered **not medically necessary** in patients without end-stage cardiac and pulmonary disease.

III. Heart/lung *retransplantation* after a failed primary heart/lung transplant may be considered **medically necessary** in patients with end-stage cardiac and pulmonary disease as described in Criterion I above.

IV. Heart/lung retransplantation is considered **not medically necessary** in patients without end-stage cardiac and pulmonary disease.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

BACKGROUND

Solid organ transplantation offers a treatment option for patients with different types of endstage organ failure that can be lifesaving or provide significant improvements to a patient's quality of life.[1] Many advances have been made in the last several decades to reduce perioperative complications. Available data supports improvement in long-term survival as well as improved quality of life particularly for liver, kidney, pancreas, heart, and lung transplants. Allograft rejection remains a key early and late complication risk for any organ transplantation. Transplant recipients require life-long immunosuppression to prevent rejection. Patients are prioritized for transplant by mortality risk and severity of illness criteria developed by Organ Procurement and Transplantation Network (OPTN) and United Network of Organ Sharing (UNOS).

HEART/LUNG TRANSPLANT

The majority of recipients have Eisenmenger syndrome (37%), followed by idiopathic pulmonary artery hypertension (28%) and cystic fibrosis (14%). Eisenmenger syndrome is a form of congenital heart disease in which systemic-to-pulmonary shunting leads to pulmonary vascular resistance. Eventually, pulmonary hypertension may lead to a reversal of the intracardiac shunting and inadequate peripheral oxygenation, or cyanosis.[2]

However, the total number of patients with Eisenmenger syndrome has been declining in recent years, as a result of corrective surgical techniques and improved medical management of pulmonary hypertension. Heart/lung transplants have not increased appreciably for other indications either, as it has become more common to transplant a single or double lung and

maximize medical therapy for heart failure, rather than perform a combined transplant. In these, patient survival rates are similar to lung transplant rates. Bronchiolitis obliterans syndrome is a major complication; one, five, and 10-year patient survival rates are 68%, 50%, and 40%, respectively.[2]

In 2021, 45 individuals received heart/lung transplants in the United States. As of March 2022, there were 40 patients on the waiting list for heart/lung transplants.[3]

REGULATORY STATUS

Solid organ transplants are a surgical procedure and, as such, are not subject to regulation by the U.S. Food and Drug Administration. The U.S. Food and Drug Administration regulates human cells and tissues intended for implantation, transplantation, or infusion through the Center for Biologics Evaluation and Research, under Code of Federal Regulation Title 21, parts 1270 and 1271. Solid organs used for transplantation are subject to these regulations.

EVIDENCE SUMMARY

Due to the nature of the patient population requiring heart/lung transplantation, there were no randomized controlled trials (RCTs) comparing heart/lung transplant to alternatives. Systematic reviews are based on case series and registry data. The extant RCTs compare surgical technique, infection prophylaxis, and immunosuppressive therapy and are not germane to this policy. The following is a summary of evidence based on registry data, case series, and expert opinion.

PATIENT SELECTION

Patients who are eligible for heart/lung transplantation can be listed under both the heart and lung allocation systems in the United States. In 2005, United Network for Organ Sharing (UNOS) changed the method by which lungs were allocated, from one based on length of time on the waiting list, to a system that incorporates the severity of the patient's underlying disease, as well as likelihood of survival.[4] However, it has been noted that the individual systems underestimate the severity of illness in patients with both end-stage heart and lung failure, and modification of the lung allocation score can be appealed for patients with pulmonary hypertension who meet the following criteria:

- Deterioration on optimal therapy
- Right arterial pressure greater than 15 mm Hg
- Cardiac index less than 1.8 L/min/m^2.

INITIAL COMBINED HEART/LUNG TRANSPLANT

Sertic (2020) compared outcomes of bilateral lung transplantation with cardiac defect repair to combined heart/lung transplantation in adult patients with Eisenmenger's syndrome using the United Network for Organ Sharing (UNOS) database of heart/lung transplantations performed from 1987 to 2018.[5] Among 442 patients who underwent thoracic transplantation, 316 patients underwent heart/lung transplantation and 126 patients underwent double-lung transplantation with concomitant cardiac defect repair. Overall survival was similar between patients who underwent double-lung transplantation and those who underwent heart/lung transplantation at one year (63.1% vs 68.0%, respectively), five years (38.5% vs 47.3%), and 10 years (30.2% vs 30.5%) posttransplant (p=0.6). Overall survival did not differ among

patients who received transplantation between 1987 to 1999 and those who received transplantation between 2000 to 2018 (p=0.7).

PEDIATRIC CONSIDERATIONS

Riggs (2020) assessed outcomes for pediatric heart/lung transplantation among children with congenital heart disease (CHD) with Eisenmenger syndrome, CHD without Eisenmenger syndrome, primary pulmonary hypertension, and "other" categories using the UNOS database of heart/lung transplantations performed from 1987 to 2018.[6] Among 209 heart/lung transplantations performed during the specified time frame, 37 (17.7%) had CHD with Eisenmenger syndrome, 40 (19.1%) had CHD without Eisenmenger syndrome, 70 (33.5%) had primary pulmonary hypertension, 6 (2.9%) were retransplants, and 56 (26.8%) had another diagnosis. One-year, five-year, and 10-year survival rates post-transplant, respectively, were 75%, 44%, and 32% for pediatric patients with CHD with Eisenmenger syndrome, 56%, 21%, and 16% for patients with CHD without Eisenmenger syndrome, 77%, 41%, and 33% for patients with primary pulmonary hypertension, 40%, 0%, and 0% for retransplanted patients, and 70%, 44%, and 20% for patients with other diagnoses. Compared to the reference group of pediatric patients with primary pulmonary hypertension, patients with CHD without Eisenmenger syndrome (p=0.03) and patients who were retransplanted (p=0.008) had significantly lower survival rates. Other survival comparisons were not significant. Survival rates were not different when comparing patients who received transplants between 1987 to 1999 and 2000 to 2018. Infants (HR, 2.2; 95% CI, 1.04 to 4.55; p=0.04), one to 11 year old patients (HR, 1.78; 95% CI, 1.12 to 2.8; p=0.015), and patients on ECMO (HR, 4.1; 95% CI, 1.3 to 12.8; p=0.016) had the highest risk of mortality post-transplant.

A 2014 analysis of data from the Organ Procurement and Transplantation Network (OPTN) reported on indications for pediatric heart/lung transplantation.[7] The number of pediatric heart/lung transplants has decreased in recent years (i.e., 56 cases in 1993-1997; 21 cases in 2008-2013). The three most common indications for pediatric heart/lung transplant were primary pulmonary hypertension (n=55), congenital heart disease (n=37), and Eisenmenger syndrome (n=30). However, while 30 children received a heart/lung transplant for Eisenmenger syndrome through 2002, none were performed for this indication since then to the date of the analysis. Pediatric heart/lung transplants have also been performed for other indications including alpha1 antitrypsin deficiency, pulmonary vascular disease, cystic fibrosis, and dilated cardiomyopathy.

In 2012, the Registry of the International Society for Heart and Lung Transplantation (ISHLT) reported on pediatric heart/lung transplant data collected through June 2011.[8] In recent years, the number of heart/lung transplant procedures in children has decreased, and the number of lung transplants has increased. There were no heart/lung transplants in infants between 2007 and the date of the study. Overall, survival rates after heart/lung transplants are comparable in children and adults (median half-life of 4.7 and 5.3 years, respectively). For pediatric heart/lung transplants that occurred between January 1990 and June 2010, the five-year survival rate was 49%. The two leading causes of death in the first year after transplantation were non-cytomegalovirus infection and graft failure. Beyond three years post-transplant, the major cause of death was bronchiolitis obliterans syndrome. An updated report on pediatric lung and heart-lung transplant from the same registry in 2014 did not include updated data on pediatric heart-lung transplants due to the small number of patients available.[9]

RETRANSPLANTATION

Repeat heart-lung transplant procedures have been performed; only three published studies were identified that reported on outcomes after repeat heart-lung transplants. In 2014, the ISHLT described outcomes after retransplantation as compared with primary transplantation, including identifying risk factors leading to retransplantation and both transplant-related morbidities and mortality after retransplantation.[10] The authors reviewed 9,248 primary transplants and 602 retransplants. After retransplantation, early time-related risk of mortality was similar to that after primary transplantation (HR 1.07; 95% CI, 0.92 to 1.25; p=0.40), but both late-phase time-related risk of mortality (HR 1.67; 95% CI, 1.40 to 1.99; p<0.001) and requirement of an additional graft (HR 1.69; 95% CI, 1.18 to 2.43; p=0.004) were higher. Long-term morbidities were significantly more common after retransplantation than with primary transplantation. The authors concluded that retransplantation after primary transplant in the pediatric age group, although feasible with similar early survival, is associated with decreased long-term survival and an increase in transplant-related morbidities.

Yusen (2014) reported outcomes for adult heart-lung transplants, with a focus on retransplantation, using data from the ISHLT Registry.[11] Thirty-three participating centers reported 75 adult heart-lung transplants in 2012, a decline from the peak year for heart-lung transplants (1989) during which 226 heart-lung transplants were performed. From 1982-2012, 90 adults had a first heart–lung retransplant after a previous heart–lung transplant. These 90 patients had a median survival of 0.3 year, with an unadjusted survival rate of 52%, 43%, 36%, and 27% at three months, one year, three years, and five years, respectively. Those who survived to one year had a conditional mean survival of 7.9 years.

Shuhaiber (2008) published results from a review of data from the UNOS registry.[12] The authors identified 799 primary heart-lung and 19 repeat heart-lung transplants. According to Kaplan-Meier survival analysis, the observed median survival times were 2.08 years after primary transplant and 0.34 years after repeat transplants. In addition, the authors analyzed survival data in matched pairs of primary and repeat transplant patients, who were matched on a number of potentially confounding demographic and clinical characteristics. Matches were not available for four repeat transplant patients. For the 15 repeat transplant patients with primary transplant matches, survival time did not differ significantly in the two groups. Being on a ventilator was statistically significantly associated with decreased survival time. The main limitation of this analysis is the small number of repeat transplant procedures performed.

POTENTIAL CONTRAINDICATIONS

Individual transplant centers may differ in their guidelines, and individual patient characteristics may vary within a specific condition. In general, heart transplantation is contraindicated in patients who are not expected to survive the procedure, or in whom patient-oriented outcomes, such as morbidity or mortality, are not expected to change due to comorbid conditions unaffected by transplantation (e.g., imminently terminal cancer or other disease). Further, consideration is given to conditions in which the necessary immunosuppression would lead to hastened demise, such as active untreated infection. However, stable chronic infections have not always been shown to reduce life expectancy in heart transplant patients.

Malignancy

Concerns regarding a potential recipients history of cancer were based on the observation of significantly increased incidence of cancer in kidney transplant patients.[13] In fact, carcinogenesis is two to four times more common, primarily skin cancers, in both heart transplant and lung transplant patients, likely due to the higher doses of immunosuppression necessary for the prevention of allograft rejection.[2, 14] The incidence of *de novo* cancer in heart transplant patients approaches 26% at eight years post-transplant, the rate for lung transplant is 28% at ten years. For renal transplant patients who had a malignancy treated prior to transplant, the incidence of recurrence ranged from zero to more than 25%, depending on the tumor type.[15, 16]

In a 2013 retrospective cohort study, *de novo* cancer-related deaths in Australian liver and cardiothoracic transplant recipients were analyzed during a median five year follow-up.[17] *De novo* cancer-related mortality risk in liver and cardiothoracic recipients was significantly elevated compared to the matched general population (n = 171; SMR = 2.83; 95% confidence interval [95%CI], 2.43-3.27). Excess risk was observed regardless of transplanted organ, recipient age group or sex. Risk of death from *de novo* cancer was high in pediatric recipients (n = 5; SMR = 41.3; 95%CI, 13.4-96.5), four of the five deaths were non-Hodgkin lymphoma. Authors suggest that *de novo* cancer was a leading cause of late death, particularly in heart and liver transplantation.

However, it should be noted that the availability of alternate treatment strategies informs recommendations for a waiting period following high-risk malignancies: in renal transplant, a delay in transplantation is possible due to dialysis; end-stage cardiopulmonary failure patients may not have an option. A small study (n=33) of survivors of lymphoproliferative cancers who subsequently received cardiac transplant had one, five, and ten-year survival rates of 77%, 64%, and 50%, respectively.[18] By comparison, overall one, five, and ten-year survival rates are expected to be 88%, 74%, and 55%, respectively for the general transplant candidate. The evaluation of a candidate who has a history of cancer must consider the prognosis and risk of recurrence from available information including tumor type and stage, response to therapy, and time since therapy was completed. Although evidence is limited, patients in whom cancer is thought to be cured should not be excluded from consideration for transplant. UNOS has not addressed malignancy in current policies.

Human Immunodeficiency Virus

Solid organ transplant for patients who are HIV-positive (HIV+) was historically controversial, due to the long-term prognosis for human immunodeficiency virus (HIV) positivity and the impact of immunosuppression on HIV disease. The availability of highly active antiretroviral therapy (HAART), has markedly changed the natural history of the disease. A 2009 retrospective case series reported favorable outcomes for seven patients with HIV who received a heart transplant.[19] However, there is little data directly comparing outcomes for patients with and without HIV or for combined heart-lung transplants.

Current Organ Procurement and Transplantation Network (OPTN) policy permits HIV-positive transplant candidates.[20]

OTHER

Considerations for heart transplantation and lung transplantation alone may also pertain to combined heart-lung transplantation. For example, cystic fibrosis accounts for the majority of pediatric candidates for heart-lung transplantation, and infection with *Burkholderia* species is

associated with higher mortality in these patients. Also, experience with kidney transplantation in patients infected with HIV in the era of HAART has opened discussion of transplantation of other solid organs in these patients. These topics are addressed more fully in the separate policies on heart transplantation and lung transplantation.

PRACTICE GUIDELINE SUMMARY

THE INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION

In 2021, the International Society for Heart and Lung Transplantation updated their consensus-based guidelines.[21] The guideline states:

"Lung transplantation should be considered for adults with chronic, end-stage lung disease who meet all the following general criteria:

- High (>50%) risk of death from lung disease within 2 years if lung transplantation is not performed
- High (>80%) likelihood of 5-year post-transplant survival from a general medical perspective provided that there is adequate graft function."

For combined heart/lung transplant, the guidelines state:

> "Candidates should meet the criteria for lung transplant listing and have significant dysfunction of one or more additional organs, or meet the listing criteria for a non-pulmonary organ transplant and have significant pulmonary dysfunction." The guideline goes on to state: "The primary indication for heart-lung transplant is pulmonary hypertension, either secondary to idiopathic pulmonary arterial hypertension or congenital heart disease (CHD)."

SUMMARY

There is enough research to show that heart/lung transplantation can improve survival for certain patients. Therefore, heart/lung transplant may be considered medically necessary in patients who meet criteria. Similarly, heart/lung retransplantation may improve survival for certain patients who have had a prior transplant. Therefore, heart/lung retransplantation may be considered medically necessary in patients with a failed prior transplant who meet the clinical criteria for heart-lung transplantation.

Medical Policy Manual Transplant, Policy No. 03

Heart-Lung Transplant

Effective: June 1, 2023

Next Review: March 2024
Last Review: April 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

The heart/lung transplantation involves a coordinated triple operative procedure consisting of procurement of a donor heart-lung block, excision of the heart and lungs of the recipient, and implantation of the heart and lungs into the recipient. A heart/lung transplantation refers to the transplantation of one or both lungs and heart from a single cadaver donor.

MEDICAL POLICY CRITERIA

I. Heart/lung *transplantation* may be considered **medically necessary** for carefully selected patients with end-stage cardiac and pulmonary disease including, but not limited to, one of the following diagnoses:

   A. Irreversible primary pulmonary hypertension with heart failure
   B. Nonspecific severe pulmonary fibrosis, with severe heart failure
   C. Eisenmenger complex with irreversible pulmonary hypertension and heart failure
   D. Cystic fibrosis with severe heart failure
   E. Chronic obstructive pulmonary disease with heart failure
   F. Emphysema with severe heart failure
   G. Pulmonary fibrosis with uncontrollable pulmonary hypertension or heart failure

II. Heart/lung transplantation is considered **not medically necessary** in patients without end-stage cardiac and pulmonary disease.

III. Heart/lung *retransplantation* after a failed primary heart/lung transplant may be considered **medically necessary** in patients with end-stage cardiac and pulmonary disease as described in Criterion I above.

IV. Heart/lung retransplantation is considered **not medically necessary** in patients without end-stage cardiac and pulmonary disease.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

BACKGROUND

Solid organ transplantation offers a treatment option for patients with different types of endstage organ failure that can be lifesaving or provide significant improvements to a patient's quality of life.[1] Many advances have been made in the last several decades to reduce perioperative complications. Available data supports improvement in long-term survival as well as improved quality of life particularly for liver, kidney, pancreas, heart, and lung transplants. Allograft rejection remains a key early and late complication risk for any organ transplantation. Transplant recipients require life-long immunosuppression to prevent rejection. Patients are prioritized for transplant by mortality risk and severity of illness criteria developed by Organ Procurement and Transplantation Network (OPTN) and United Network of Organ Sharing (UNOS).

HEART/LUNG TRANSPLANT

The majority of recipients have Eisenmenger syndrome (37%), followed by idiopathic pulmonary artery hypertension (28%) and cystic fibrosis (14%). Eisenmenger syndrome is a form of congenital heart disease in which systemic-to-pulmonary shunting leads to pulmonary vascular resistance. Eventually, pulmonary hypertension may lead to a reversal of the intracardiac shunting and inadequate peripheral oxygenation, or cyanosis.[2]

However, the total number of patients with Eisenmenger syndrome has been declining in recent years, as a result of corrective surgical techniques and improved medical management of pulmonary hypertension. Heart/lung transplants have not increased appreciably for other indications either, as it has become more common to transplant a single or double lung and

maximize medical therapy for heart failure, rather than perform a combined transplant. In these, patient survival rates are similar to lung transplant rates. Bronchiolitis obliterans syndrome is a major complication; one, five, and 10-year patient survival rates are 68%, 50%, and 40%, respectively.[2]

In 2021, 45 individuals received heart/lung transplants in the United States. As of March 2022, there were 40 patients on the waiting list for heart/lung transplants.[3]

REGULATORY STATUS

Solid organ transplants are a surgical procedure and, as such, are not subject to regulation by the U.S. Food and Drug Administration. The U.S. Food and Drug Administration regulates human cells and tissues intended for implantation, transplantation, or infusion through the Center for Biologics Evaluation and Research, under Code of Federal Regulation Title 21, parts 1270 and 1271. Solid organs used for transplantation are subject to these regulations.

EVIDENCE SUMMARY

Due to the nature of the patient population requiring heart/lung transplantation, there were no randomized controlled trials (RCTs) comparing heart/lung transplant to alternatives. Systematic reviews are based on case series and registry data. The extant RCTs compare surgical technique, infection prophylaxis, and immunosuppressive therapy and are not germane to this policy. The following is a summary of evidence based on registry data, case series, and expert opinion.

PATIENT SELECTION

Patients who are eligible for heart/lung transplantation can be listed under both the heart and lung allocation systems in the United States. In 2005, United Network for Organ Sharing (UNOS) changed the method by which lungs were allocated, from one based on length of time on the waiting list, to a system that incorporates the severity of the patient's underlying disease, as well as likelihood of survival.[4] However, it has been noted that the individual systems underestimate the severity of illness in patients with both end-stage heart and lung failure, and modification of the lung allocation score can be appealed for patients with pulmonary hypertension who meet the following criteria:

- Deterioration on optimal therapy
- Right arterial pressure greater than 15 mm Hg
- Cardiac index less than 1.8 L/min/m^2.

INITIAL COMBINED HEART/LUNG TRANSPLANT

Sertic (2020) compared outcomes of bilateral lung transplantation with cardiac defect repair to combined heart/lung transplantation in adult patients with Eisenmenger's syndrome using the United Network for Organ Sharing (UNOS) database of heart/lung transplantations performed from 1987 to 2018.[5] Among 442 patients who underwent thoracic transplantation, 316 patients underwent heart/lung transplantation and 126 patients underwent double-lung transplantation with concomitant cardiac defect repair. Overall survival was similar between patients who underwent double-lung transplantation and those who underwent heart/lung transplantation at one year (63.1% vs 68.0%, respectively), 5 years (38.5% vs 47.3%), and 10 years (30.2% vs 30.5%) posttransplant (p=0.6). Overall survival did not differ among patients

who received transplantation between 1987 to 1999 and those who received transplantation between 2000 to 2018 (p=0.7).

PEDIATRIC CONSIDERATIONS

Riggs (2020) assessed outcomes for pediatric heart/lung transplantation among children with congenital heart disease (CHD) with Eisenmenger syndrome, CHD without Eisenmenger syndrome, primary pulmonary hypertension, and "other" categories using the UNOS database of heart/lung transplantations performed from 1987 to 2018.[6] Among 209 heart/lung transplantations performed during the specified time frame, 37 (17.7%) had CHD with Eisenmenger syndrome, 40 (19.1%) had CHD without Eisenmenger syndrome, 70 (33.5%) had primary pulmonary hypertension, 6 (2.9%) were retransplants, and 56 (26.8%) had another diagnosis. One-year, five-year, and 10-year survival rates post-transplant, respectively, were 75%, 44%, and 32% for pediatric patients with CHD with Eisenmenger syndrome, 56%, 21%, and 16% for patients with CHD without Eisenmenger syndrome, 77%, 41%, and 33% for patients with primary pulmonary hypertension, 40%, 0%, and 0% for retransplanted patients, and 70%, 44%, and 20% for patients with other diagnoses. Compared to the reference group of pediatric patients with primary pulmonary hypertension, patients with CHD without Eisenmenger syndrome (p=0.03) and patients who were retransplanted (p=0.008) had significantly lower survival rates. Other survival comparisons were not significant. Survival rates were not different when comparing patients who received transplants between 1987 to 1999 and 2000 to 2018. Infants (HR, 2.2; 95% CI, 1.04 to 4.55; p=0.04), one to 11 year old patients (HR, 1.78; 95% CI, 1.12 to 2.8; p=0.015), and patients on ECMO (HR, 4.1; 95% CI, 1.3 to 12.8; p=0.016) had the highest risk of mortality post-transplant.

A 2014 analysis of data from the Organ Procurement and Transplantation Network (OPTN) reported on indications for pediatric heart/lung transplantation.[7] The number of pediatric heart/lung transplants has decreased in recent years (i.e., 56 cases in 1993-1997; 21 cases in 2008-2013). The three most common indications for pediatric heart/lung transplant were primary pulmonary hypertension (n=55), congenital heart disease (n=37), and Eisenmenger syndrome (n=30). However, while 30 children received a heart/lung transplant for Eisenmenger syndrome through 2002, none were performed for this indication since then to the date of the analysis. Pediatric heart/lung transplants have also been performed for other indications including alpha1 antitrypsin deficiency, pulmonary vascular disease, cystic fibrosis, and dilated cardiomyopathy.

In 2012, the Registry of the International Society for Heart and Lung Transplantation (ISHLT) reported on pediatric heart/lung transplant data collected through June 2011.[8] In recent years, the number of heart/lung transplant procedures in children has decreased, and the number of lung transplants has increased. There were no heart/lung transplants in infants between 2007 and the date of the study. Overall, survival rates after heart/lung transplants are comparable in children and adults (median half-life of 4.7 and 5.3 years, respectively). For pediatric heart/lung transplants that occurred between January 1990 and June 2010, the five-year survival rate was 49%. The two leading causes of death in the first year after transplantation were non-cytomegalovirus infection and graft failure. Beyond three years post-transplant, the major cause of death was bronchiolitis obliterans syndrome. An updated report on pediatric lung and heart-lung transplant from the same registry in 2014 did not include updated data on pediatric heart-lung transplants due to the small number of patients available.[9]

RETRANSPLANTATION

Repeat heart-lung transplant procedures have been performed; only three published studies were identified that reported on outcomes after repeat heart-lung transplants. In 2014, the ISHLT described outcomes after retransplantation as compared with primary transplantation, including identifying risk factors leading to retransplantation and both transplant-related morbidities and mortality after retransplantation.[10] The authors reviewed 9,248 primary transplants and 602 retransplants. After retransplantation, early time-related risk of mortality was similar to that after primary transplantation (HR 1.07; 95% CI, 0.92 to 1.25; p=0.40), but both late-phase time-related risk of mortality (HR 1.67; 95% CI, 1.40 to 1.99; p<0.001) and requirement of an additional graft (HR 1.69; 95% CI, 1.18 to 2.43; p=0.004) were higher. Long-term morbidities were significantly more common after retransplantation than with primary transplantation. The authors concluded that retransplantation after primary transplant in the pediatric age group, although feasible with similar early survival, is associated with decreased long-term survival and an increase in transplant-related morbidities.

Yusen (2014) reported outcomes for adult heart-lung transplants, with a focus on retransplantation, using data from the ISHLT Registry.[11] Thirty-three participating centers reported 75 adult heart-lung transplants in 2012, a decline from the peak year for heart-lung transplants (1989) during which 226 heart-lung transplants were performed. From 1982-2012, 90 adults had a first heart–lung retransplant after a previous heart–lung transplant. These 90 patients had a median survival of 0.3 year, with an unadjusted survival rate of 52%, 43%, 36%, and 27% at three months, one year, three years, and five years, respectively. Those who survived to one year had a conditional mean survival of 7.9 years.

Shuhaiber (2008) published results from a review of data from the UNOS registry.[12] The authors identified 799 primary heart-lung and 19 repeat heart-lung transplants. According to Kaplan-Meier survival analysis, the observed median survival times were 2.08 years after primary transplant and 0.34 years after repeat transplants. In addition, the authors analyzed survival data in matched pairs of primary and repeat transplant patients, who were matched on a number of potentially confounding demographic and clinical characteristics. Matches were not available for four repeat transplant patients. For the 15 repeat transplant patients with primary transplant matches, survival time did not differ significantly in the two groups. Being on a ventilator was statistically significantly associated with decreased survival time. The main limitation of this analysis is the small number of repeat transplant procedures performed.

POTENTIAL CONTRAINDICATIONS

Individual transplant centers may differ in their guidelines, and individual patient characteristics may vary within a specific condition. In general, heart transplantation is contraindicated in patients who are not expected to survive the procedure, or in whom patient-oriented outcomes, such as morbidity or mortality, are not expected to change due to comorbid conditions unaffected by transplantation (e.g., imminently terminal cancer or other disease). Further, consideration is given to conditions in which the necessary immunosuppression would lead to hastened demise, such as active untreated infection. However, stable chronic infections have not always been shown to reduce life expectancy in heart transplant patients.

Malignancy

Concerns regarding a potential recipients history of cancer were based on the observation of significantly increased incidence of cancer in kidney transplant patients.[13] In fact, carcinogenesis is two to four times more common, primarily skin cancers, in both heart transplant and lung transplant patients, likely due to the higher doses of immunosuppression necessary for the prevention of allograft rejection.[2, 14] The incidence of *de novo* cancer in heart transplant patients approaches 26% at eight years post-transplant, the rate for lung transplant is 28% at ten years. For renal transplant patients who had a malignancy treated prior to transplant, the incidence of recurrence ranged from zero to more than 25%, depending on the tumor type.[15, 16]

In a 2013 retrospective cohort study, *de novo* cancer-related deaths in Australian liver and cardiothoracic transplant recipients were analyzed during a median five year follow-up.[17] *De novo* cancer-related mortality risk in liver and cardiothoracic recipients was significantly elevated compared to the matched general population (n = 171; SMR = 2.83; 95% confidence interval [95%CI], 2.43-3.27). Excess risk was observed regardless of transplanted organ, recipient age group or sex. Risk of death from *de novo* cancer was high in pediatric recipients (n = 5; SMR = 41.3; 95%CI, 13.4-96.5), four of the five deaths were non-Hodgkin lymphoma. Authors suggest that *de novo* cancer was a leading cause of late death, particularly in heart and liver transplantation.

However, it should be noted that the availability of alternate treatment strategies informs recommendations for a waiting period following high-risk malignancies: in renal transplant, a delay in transplantation is possible due to dialysis; end-stage cardiopulmonary failure patients may not have an option. A small study (n=33) of survivors of lymphoproliferative cancers who subsequently received cardiac transplant had one, five, and ten-year survival rates of 77%, 64%, and 50%, respectively.[18] By comparison, overall one, five, and ten-year survival rates are expected to be 88%, 74%, and 55%, respectively for the general transplant candidate. The evaluation of a candidate who has a history of cancer must consider the prognosis and risk of recurrence from available information including tumor type and stage, response to therapy, and time since therapy was completed. Although evidence is limited, patients in whom cancer is thought to be cured should not be excluded from consideration for transplant. UNOS has not addressed malignancy in current policies.

Human Immunodeficiency Virus

Solid organ transplant for patients who are HIV-positive (HIV+) was historically controversial, due to the long-term prognosis for human immunodeficiency virus (HIV) positivity and the impact of immunosuppression on HIV disease. The availability of highly active antiretroviral therapy (HAART), has markedly changed the natural history of the disease. A 2009 retrospective case series reported favorable outcomes for seven patients with HIV who received a heart transplant.[19] However, there is little data directly comparing outcomes for patients with and without HIV or for combined heart-lung transplants

Current Organ Procurement and Transplantation Network (OPTN) policy permits HIV-positive transplant candidates.[20]

OTHER

Considerations for heart transplantation and lung transplantation alone may also pertain to combined heart-lung transplantation. For example, cystic fibrosis accounts for the majority of pediatric candidates for heart-lung transplantation, and infection with *Burkholderia* species is

associated with higher mortality in these patients. Also, experience with kidney transplantation in patients infected with HIV in the era of HAART has opened discussion of transplantation of other solid organs in these patients. These topics are addressed more fully in the separate policies on heart transplantation and lung transplantation.

PRACTICE GUIDELINE SUMMARY

THE INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION

In 2015, the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation updated their 2006 their consensus-based guidelines [21, 22] The guideline states:

> "Patients with advanced cardiac and lung diseases not amenable to either isolated heart or lung transplant may be candidates for combined heart-lung transplantation. Most commonly, patients with irreversible myocardial dysfunction or congenital defects with irreparable defects of the valves or chambers in conjunction with intrinsic lung disease or severe PAH [pulmonary arterial hypertension] are considered for heart-lung transplantation."

The guidelines include criteria for absolute and relative contraindications, as well as special surgical and disease specific considerations for all types of organ transplants.

SUMMARY

There is enough research to show that heart/lung transplantation can improve survival for certain patients. Therefore, heart/lung transplant may be considered medically necessary in patients who meet criteria. Similarly, heart/lung retransplantation may improve survival for certain patients who have had a prior transplant. Therefore, heart/lung retransplantation may be considered medically necessary in patients with a failed prior transplant who meet the clinical criteria for heart-lung transplantation.

Medical Policy Manual Transplant, Policy No. 05

Liver Transplant

Effective: July 1, 2023

Next Review: March 2024
Last Review: May 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Liver transplantation is now routinely performed as a treatment of last resort for patients with end-stage liver disease. Liver transplantation may be performed with liver donation after brain, circulatory or cardiac death, or with a liver segment donation from a living donor. Patients are prioritized for transplant according to length of time on the waiting list, mortality risk and severity of illness criteria developed by the Organ Procurement and Transplantation Network (OPTN) and the United Network of Organ Sharing (UNOS).

MEDICAL POLICY CRITERIA

I. A liver transplant, using a cadaver or living donor, may be **medically necessary** for patients with irreversible, end-stage liver failure due to conditions that include, but are not limited to, the following:

   A. Cholestatic Liver Diseases

      1. Biliary atresia; or
      2. Familial cholestatic syndromes; or
      3. Primary biliary cirrhosis; or
      4. Secondary biliary cirrhosis; or

5. Primary sclerosing cholangitis; or
6. Secondary sclerosing cholangitis when the primary etiology is resolved; or
7. Alagille syndrome; or
8. Nonsyndromic paucity of the intrahepatic bile ducts; or
9. Cystic fibrosis; or

B. Hepatocellular Diseases:
1. Alcoholic cirrhosis; or
2. Viral hepatitis (including A, B, C, or non-A, non-B); or
3. Autoimmune hepatitis; or
4. Cryptogenic cirrhosis; or
5. Alpha-1 antitrypsin deficiency; or
6. Hemochromatosis; or
7. Protoporphyria; or
8. Wilson's disease; or
9. Non-alcoholic steatohepatitis; or

C. Malignancies such as the following:
1. Primary hepatocellular carcinoma confined to the liver; or
2. Rare, non-hepatocellular malignancies originating in the liver such as hemangioepitheliomas in young adults and hepatoblastomas in children, and hemangioendotheliomas; or
3. Fibrolamellar hepatocellular carcinoma; or
4. Unresectable hilar cholangiocarcinoma; or

D. Vascular Diseases:
1. Budd-Chiari syndrome (congenital hepatic vein thrombosis); or
2. Veno-occlusive disease; or

E. Inborn errors of metabolism; or

F. Trauma and toxic reactions; or

G. Miscellaneous Diseases:
1. Polycystic disease of the liver in patients who have massive hepatomegaly causing obstruction or functional impairment; or
2. Familial amyloid polyneuropathy (Corino de Andrade's disease, paramyloidosis); or
3. Amyloidosis; or
4. Disorders of branch chain amino acids (e.g., Maple syrup urine disease (MSUD), branched chain a-ketoacid dehydrogenase (BCKD); or
5. Fulminant hepatitic failure; or

6. Glycogen storage disease type IV; or
7. Hyperoxaluria; or
8. Steatohepatitis; or
9. Tyrosinemia; or
10. Urea cycle defects.

II. Liver transplantation is considered **not medically necessary** in the following patients:
   A. Patients with hepatocellular carcinoma that has extended beyond the liver; or
   B. Patients with active alcohol and/or substance abuse. (Evidence for abstinence may vary among liver transplant programs, but generally a minimum of three months is required.)

III. Liver transplantation is considered **investigational** in the following patients:
   A. Intrahepatic cholangiocarcinoma; or
   B. Patients with an extrahepatic malignancy, other than those noted above; or
   C. Patients with neuroendocrine tumors metastatic to the liver.

IV. Liver retransplantation may be considered **medically necessary** in patients with one or more of the following diagnoses:
   A. Primary graft nonfunction; or
   B. Hepatic artery thrombosis; or
   C. Chronic rejection; or
   D. Ischemic type biliary lesions after donation after cardiac death; or
   E. Recurrent non-neoplastic disease-causing late graft failure.

V. Liver retransplantation is considered **investigational** in all other situations not described above in Criterion IV.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

BACKGROUND

LIVER TRANSPLANTATION

Liver transplantation is routinely performed as a treatment of last resort for patients with end-stage liver disease. Liver transplantation may be performed with liver donation after a brain or cardiac death or with a liver segment donation from a living donor. Certain populations are prioritized as Status 1A (e.g., acute liver failure with a life expectancy of fewer than seven days without a liver transplant) or Status 1B (pediatric patients with chronic liver disease). Following Status 1, donor livers are prioritized to those with the highest scores on the Model for End-stage Liver Disease (MELD) and Pediatric End-stage Liver Disease (PELD) scales. Due to the scarcity of donor livers, a variety of strategies have been developed to expand the donor pool. For example, a split graft refers to dividing a donor liver into two segments that can be used for two recipients. Living donor liver transplantation (LDLT) is now commonly performed for adults and children from a related or unrelated donor. Depending on the graft size needed for the recipient, either the right lobe, left lobe, or the left lateral segment can be used for LDLT. In addition to addressing the problem of donor organ scarcity, LDLT allows the procedure to be scheduled electively before the recipient's condition deteriorates or serious complications develop. LDLT also shortens the preservation time for the donor liver and decreases disease transmission from donor to recipient.

RECIPIENTS

In March 2019, OPTN and UNOS published its most recent allocation system.[1]

Status 1A Adults

1. The candidate is at least 18 years old at the time of registration
2. The candidate has a life expectancy without a liver transplant of less than 7 days and has at least *one* of the following conditions:
    a. Fulminant liver failure, without pre-existing liver disease and currently in the intensive care unit (ICU), defined as the onset of hepatic encephalopathy within 56 days of the first signs or symptoms of liver disease, and has at least *one* of the following criteria:
        i. Is ventilator dependent
        ii. Requires dialysis, continuous veno-venous hemofiltration (CVVH), or continuous veno-venous hemodialysis (CVVHD)
        iii. Has an international normalized ratio (INR) greater than 2.0
    b. Anhepatic
    c. Primary non-function of a transplanted whole liver within 7 days of transplant, with aspartate aminotransferase (AST) greater than or equal to 3,000 U/L and at least *one* of the following:
        - International normalized ratio (INR) greater than or equal to 2.5
        - Arterial pH less than or equal to 7.30
        - Venous pH less than or equal to 7.25
        - Lactate greater than or equal to 4 mmol/L

    All laboratory results reported for the tests required above must be from the same blood draw taken 24 hours to 7 days after the transplant.

    d. Primary non-function within 7-days of transplant of a transplanted liver segment from a deceased or living donor, evidenced by at least *one* of the following:
        - INR greater than or equal to 2.5
        - Arterial pH less than or equal to 7.30
        - Venous pH less than or equal to 7.25

- Lactate greater than or equal to 4 mmol/L

e. Hepatic artery thrombosis (HAT) within 7-days of transplant, with AST greater than or equal to 3,000 U/L and at least *one* of the following:
   - INR greater than or equal to 2.5
   - Arterial pH less than or equal to 7.30
   - Venous pH less than or equal to 7.25
   - Lactate greater than or equal to 4 mmol/L

All laboratory results reported for the tests required above must be from the same blood draw taken 24 hours to 7 days after the transplant.

Candidates with HAT in a transplanted liver within 14 days of transplant not meeting the above criteria will be listed with a MELD of 40.

f. Acute decompensated Wilson's disease

Status 1A Pediatrics

1. The candidate is less than 18 years old at the time of registration. This includes candidates less than 18 years old at the time of registration, who remain on the waiting list after turning 18 years old, but does not include candidates removed from the waiting list at any time who then return to the waiting list after turning 18 years old.
2. The candidate has at least *one* of the following conditions:
   a. Fulminant liver failure without pre-existing liver disease, defined as the onset of hepatic encephalopathy within 56 days of the first signs and symptoms of liver disease and has at least *one* of the following criteria:
      i. Is ventilator dependent
      ii. Requires dialysis, continuous veno-venous hemofiltration (CVVH), or continuous veno-venous hemodialysis (CVVHD)
      iii. Has an international normalized ratio (INR) greater than 2.0
   b. Diagnosis of primary non-function of a transplanted liver within 7 days of transplant, evidenced by at least *two* of the following:
      i. Alanine aminotransferase (ALT) greater than or equal to 2,000 U/L
      ii. INR greater than or equal to 2.5
      iii. Total bilirubin greater than or equal to 10 mg/dL
      iv. Acidosis, defined as *one* of the following:
         - Arterial pH less than or equal to 7.30
         - Venous pH less than or equal to 7.25
         - Lactate greater than or equal to 4 mmol/L

   All laboratory results reported for any tests required for the primary non-function of a transplanted liver diagnosis above must be from the same blood draw taken between 24 hours and 7 days after the transplant.

   c. Diagnosis of hepatic artery thrombosis (HAT) in a transplanted liver within 14 days of transplant
   d. Acute decompensated Wilson's disease

Status 1B patients

1. The candidate is less than 18 years old at the time of registration. This includes candidates less than 18 years old at the time of registration, who remain on the waiting

list after turning 18 years old, but does not include candidates removed from the waiting list at any time who then return to the waiting list after turning 18 years old.

2. The candidate has *one* of the following conditions:
    a. The candidate has a biopsy-proven hepatoblastoma without evidence of metastatic disease.
    b. The candidate has an organic acidemia or urea cycle defect and a MELD or PELD exception score of 30 points for at least 30 days.
    c. Chronic liver disease with a calculated MELD greater than 25 for adolescent candidates 12 to 17 years old, or a calculated PELD greater than 25 for candidates less than 12 years old, and has at least *one* of the following criteria:
        i. Is on a mechanical ventilator
        ii. Has gastrointestinal bleeding requiring at least 30 mL/kg of red blood cell replacement within the previous 24 hours
        iii. Has renal failure or renal insufficiency requiring dialysis, continuous veno-venous hemofiltration (CVVH), or continuous veno-venous hemodialysis (CVVHD)
        iv. Has a Glasgow coma score (GCS) less than 10 within 48 hours before the status 1B assignment or extension.
    d. Chronic liver disease and is a combined liver-intestine candidate with an adjusted MELD or PELD score greater than 25 according to *Policy 9.1.F: Liver-Intestine Candidates* and has at least *one* of the following criteria:
        i. Is on a mechanical ventilator
        ii. Has gastrointestinal bleeding requiring at least 10 mL/kg of red blood cell replacement within the previous 24 hours
        iii. Has renal failure or renal insufficiency requiring dialysis, continuous veno-venous hemofiltration (CVVH), or continuous veno-venous hemodialysis (CVVHD)
        iv. Has a Glasgow coma score (GCS) less than 10 within 48 hours before the status 1B assignment or extension.

Following Status 1, donor livers will be prioritized to those with the highest scores on MELD (model for end-stage liver disease) or PELD (pediatric end-stage liver disease). MELD and PELD are a continuous disease severity scale based entirely on objective laboratory values. These scales have been found to be highly predictive of the risk of dying from liver disease for patients waiting on the transplant list. The MELD score incorporates bilirubin, prothrombin time (i.e., INR) and creatinine into an equation, producing a number that ranges from 6 to 40. The PELD score incorporates albumin, bilirubin, INR growth failure, and age at listing. Aside from Status 1, donor livers are prioritized to those with the highest MELD or PELD number; waiting time is only used to break ties among patients with the same MELD or PELD score and blood type compatibility. In the previous system, waiting time was often a key determinant of liver allocation, and yet waiting time was found to be a poor predictor of the urgency of liver transplant, since some patients were listed early in the course of their disease, while others were listed only when they became sicker. In the revised allocation system, patients with a higher mortality risk and higher MELD/PELD scores will always be considered before those with lower scores, even if some patients with lower scores have waited longer.[2]

DONORS

Due to the scarcity of donor livers, a variety of strategies have been developed to expand the donor pool. For example, the term “split grafts” refers to dividing a donor liver into two

segments that can be used for two recipients. Living donor liver transplantation (LDLT) is now commonly performed for adults and pediatric populations from a related or unrelated donor. Depending on the graft size needed for the recipient, either the right lobe, left lobe, or the left lateral segment can be used for LDLT. In addition to addressing the problem of donor organ scarcity, LDLT allows the procedure to be scheduled electively, shortens the preservation time for the donor liver, decreases disease transmission and allows time to optimize the recipient's condition pretransplant.

EVIDENCE SUMMARY

Relevant outcomes for studies on liver transplantation (LT) include waiting time duration, dropout rates, survival time, and recurrence. As experience with LT has matured, patient selection criteria have broadened to include a wide variety of etiologies. The most controversial etiologies include viral hepatitis and primary hepatocellular cancer. In the past, the long-term outcomes in patients with primary hepatocellular malignancies were poor (19%) compared to the overall survival of LT recipients. However, recent use of standardized patient selection criteria, such as the Milan criteria (a solitary tumor with a maximum tumor diameter of five cm or less, or up to three tumors that are three cm or smaller and without extrahepatic spread or macrovascular invasion), has dramatically improved overall survival rates. In a systematic review of LT for hepatocellular carcinoma (HCC), Maggs (2012) found five-year overall survival rates ranged from 65% to 94.7% in reported studies.[3] Transplant represents the only curative approach for many of these patients who present with unresectable organ-confined disease and expansion of patient selection criteria. Bridging to transplant, or down-staging of disease, to qualify for LT is frequently studied. Finally, LT cannot be considered curative in patients with locally extensive or metastatic liver cancer, or in patients with isolated liver metastases with extrahepatic primaries.[2]

LIVING DONOR LIVER TRANSPLANTATION: DONOR OUTCOMES

Due to the scarcity of donor organs and the success of living donation, LDLT has become accepted practice. The living donor undergoes hepatectomy of the right lobe, left lobe, or left lateral segment, which is then transplanted into the recipient. Since right hepatectomy involves the resection of 60% to 70% of the total volume of the donor liver, the safety of the donor has been the major concern. The surgical literature suggests that right hepatectomy of diseased or injured livers is associated with mortality rates of about 5%. However, initial reports suggest that right hepatectomy in healthy donors has a lower morbidity and mortality. The Medical College of Virginia appears to have the most extensive experience and has reported the results of their first 40 adult-to-adult LDLTs, performed between June 1998 and October 1999.[4] There were an equal number of related and unrelated donors. Minor complications occurred in seven donors. The outcomes among recipients were similar to those associated with cadaveric donor livers performed during the same period of time. However, in the initial series of 20 patients, four out of five deaths occurred in recipients who were classified as 2A. In the subsequent 20 patients, recipients classified as 2A were not considered candidates for living donor transplant. Other case series have reported similar success rates.[5-7]

Tokodai (2016) published a retrospective review of 56 patients who underwent hepatectomy, between April 2001 and August 2010.[8] Donors were classified as under 50 (average 32) or greater than or equal to 50 (average 58) years of age. The one-, three-, and five-year graft survival rates were 80%, 60%, and 50%, respectively, in the greater than or equal to 50 years of age group compared to the under 50 years of age group with survival rates of 89%, 87%,

and 82%. The authors concluded older patients can undergo hepatectomy safely, but have longer hospital stays and grafts do not survive as long.

Brown (2013) reported on the results of a survey focusing on adult living-related recipients in the United States.[9] The following statistics were reported:

- The survey encompassed 449 adult-to-adult transplantations
- Half of the responding programs already had performed at least one adult-to-adult LDLT, and 32 of the remaining 41 centers were planning to initiate such surgery
- 14 centers had performed more than 10 such transplantations, and these centers accounted for 80% of these transplants
- A total of 45% of those evaluated for living donation subsequently donated a liver lobe; 99% were genetically or emotionally related to the recipient
- Complications in the donor were more frequent in the centers that performed the fewest living-related donor transplantations
- There was one death among the donors, but complications were relatively common (i.e., biliary complications) in 6% and reoperation in 4.5%

Reports of several donor deaths re-emphasize the importance of careful patient selection based in part on a comprehensive consent process and an experienced surgical team.[10-12] In December 2000, the National Institutes of Health convened a workshop on LDLT. A summary of this workshop was published in 2002.[13] According to this document, the risk of mortality to the donor undergoing right hepatectomy was estimated to be approximately 0.2% to 0.5%. Based on survey results, the workshop reported that donor morbidity was common: 7% required re-exploration, 10% had to be re-hospitalized, and biliary tract complications occurred in 7%. The median complication rate reported by responding transplant centers was 21%. The summary report concluded that the incidence and type of complications encountered, and the mortality associated with LDLT in both donors and recipients needs to be determined and compared with that for patients undergoing cadaveric transplantation.

Due to the potential morbidity and mortality experienced by the donor, the workshop also noted that donor consent for hepatectomy must be voluntary and free of coercion; therefore, it was preferable that the donor have a significant long-term and established relationship with the recipient. According to the workshop summary, "At the present time, nearly all centers strive to identify donors who are entirely healthy and at minimal risk during right hepatectomy. As a result, only approximately one third of persons originally interested in becoming a living liver donor complete the evaluation process and are accepted as candidates for this procedure."

Criteria for a recipient of a living-related liver are also controversial, with some groups advocating that living-related donor livers be used only in those most critically ill, while others state that the risk to the donor is unacceptable in critically ill recipients due to the increased risk of postoperative mortality of the recipient. According to this line of thought, living-related livers are best used in stable recipients who have a higher likelihood of achieving long-term survival.[13]

In 2000 the American Society of Transplant Surgeons issued the following statement:[14]

"Living donor transplantation in children has proven to be safe and effective for both donors and recipients and has helped to make death on the waiting list a less common event. Since its introduction in 1990, many of the technical and ethical issues have been addressed and the procedure is generally applied.

The development of left or right hepatectomy for adult-to-adult living donor liver transplantation has been slower. Because of the ongoing shortage of cadaver livers suitable for transplantation, adult-to-adult living donor liver transplantation has been undertaken at a number of centers. While early results appear encouraging, sufficient data is not available to ascertain donor morbidity and mortality rates. There is general consensus that the health and safety of the donor is and must remain central to living organ donation."

LIVING DONOR VERSUS DECEASED DONOR LIVER TRANSPLANT: RECIPIENT OUTCOMES

Few high-quality studies are available regarding recipient outcomes based upon direct comparison of liver transplantation from living and deceased donors.

A systematic review by Gavrilidis (2019) evaluated differences in outcomes between recipients of living-related adult donor and recipients of split liver transplantation from deceased donors.[15] A meta-analysis revealed differences in age distributions for both donors and recipients, with LDLT donors tending to be older than split donors (mean difference 11.12 years, p<0.001) and LDLT recipients tending to be younger than split transplant recipients (mean difference 2.06 years, p<0.001). However, there were no significant differences in postoperative complications, graft survival or overall survival between groups.

Humar (2019) compared outcomes between LDLT (n=245) and DDLT (n=592) at a single center in the U.S. between 2009 and 2019[16] The authors reported superior three-year survival in LDLT recipients (86% vs. 80% for DDLT, p=0.03), as well as shorter hospital stays (11 vs. 13 days, p=0.03) lower likelihood of intraoperative blood transfusion (52% vs 78%, p<0.01) or need for posttransplant dialysis (1.6% vs 7.4%, p<0.01). No significant differences were seen for early reoperation and biliary/vascular complication rates.

Wong (2019) published a retrospective intention-to-treat (ITT) analysis with propensity score matching comparing living and deceased donor LT.[17] The study included data for 375 patients listed for LT between 1995 and 2014: 188 patients in the ITT-DDLT group, and 187 in the ITT-LDLT group. Of these, 122 patients on the DDLT waitlist and 27 on the LDLT waitlist were delisted. Overall survival at one-, three- and five-years was significantly better in the ITT-LDLT group (94.1 vs. 77.5%, 81.4 vs. 48.7% and 75.9 vs. 40.8%, respectively). After propensity score matching, overall and recurrence-free survival were similar between groups.

Przybyszerski (2018) compared outcomes after LDLT and deceased donor liver transplant (DDLT) in a retrospective cohort of pediatric patients.[18] A total of 241 children were included in the study (DDLT n=177, LDLT n=64). Most of the LDLT donors were haplo-identical parents. The study found that LDLT was generally associated with better outcomes than deceased donor LT, including a lower rate of acute cellular rejection (hazard ratio [HR] 0.53, 95% confidence interval [CI] 0.29 to 0.98, p=0.04), chronic rejection (HR 0.12, 95% CI 0.03 to 0.56. p=0.007), and graft loss (HR 0.29, 95% CI 0.10 to 0.88, p=0.03). No difference in mortality by graft type was seen.

Samstein (2017) published a cohort study evaluating complications for recipients receiving DDLT versus LDLT (LDLT).[19] Patients in the study received DDLT (n=471) or LDLT (n=565) from 1998 to 2010 and were followed for up to 10 years post-transplant. The DDLT recipients were found to have higher occurrences of hepatocellular carcinoma, ascites, intra-abdominal bleeding, cardiac complications and pulmonary edema. The LDLT patients had higher biliary-related complications, hepatic artery thrombosis and chronic kidney disease. There was no difference in resolution time, for either group. The authors concluded LDLT outcomes are better than with DDLT, but improvements are needed to lessen complications for both LDLT and DDLT.

Ushigome (2016) published a study evaluating living donor transplants for patients over 60 years of age.[20] Seventy-six adult patients were divided into a greater than 60 years of age group (n=21) or a less than 60 years of age group (n=55). The one-, three-, five-, and 10-year survival rates for the greater than 60 years of age group were 89.9%, 89.9%, 83.0%, and 83.0%, respectively, compared to the less than 60 years of age group with survival rates of 91.1%, 85.2%, 82.8%, and 82.9%. The authors reported no significant differences between the groups' survival rates but noted that the elderly transplant recipients were frailer and needed careful management.

Olthoff (2015) published results from a prospective multicenter National Institutes of Health study comparing recipient outcomes and associated risks from LDLT and DDLT.[21] This was the same cohort evaluated by Samstein (2017), described above. Mortality and graft failure for 1427 liver recipients (963 LDLT and 464 DDLT) enrolled in the Adult-to-Adult Living Donor Liver Transplantation Cohort Study who received transplant between 1998 and 2013, at one of twelve North American centers were analyzed at long-term follow-up (median of 6.7 years). Probability of survival at 10 years was higher for recipients of LDLT then DDLT (70% vs. 64%, respectively). For survival, the adjusted hazard ration for recipients of LDLT was 0.98. LDLT recipients had lower mean model for end-stage liver disease compared to deceased donor recipients (15.5 vs. 20.4, respectively) and had better post-transplant outcomes, regardless of type of donated lobe.

Al Sebayel (2015) published results from a single-center retrospective analysis of survival of recipients of LDLT compared to DDLT in relation to their MELD score.[22] Data was assessed from 222 patients for LDLT and 269 patients with deceased donors. HCV recurrence as a cause of death was significantly higher in recipients of LDLT (p=0.023), but the mortality after one year was significantly higher in recipients of DDLT, (p=0.0072). Overall one, three and five-year survival rates of recipients of LDLT and DDLT were 89%, 85%, and 84%, respectively, for MELD score below 25, and 80%,78%, and 77%, respectively, for MELD score greater than or equal to 25. There were no significant differences in survival of recipients of LDLT and those of deceased donors, regardless of MELD score.

Grant (2013) reported on a systematic review and meta-analysis of 16 studies to compare recipient outcomes between living donor liver transplants and deceased donor liver transplants for HCC.[23] For disease-free survival after living donor liver transplantation, the combined HR was 1.59 (95% CI 1.02 to 2.49) compared to deceased donor liver transplantation. For overall survival, the combined HR was 0.97 (95% CI 0.73 to 1.27). The studies included in the review were mostly retrospective and considered to be of low quality. Further study is needed to determine any differences between living and deceased liver transplantation outcomes for various etiologies.

MALIGNANCIES

The following two issues were the focus of the literature review regarding liver transplant for malignancy: 1) whether selection criteria for hepatocellular carcinoma should be expanded and 2) whether extrahepatic cholangiocarcinoma should be considered an acceptable indication for liver transplantation.

Hepatocellular Carcinoma

Selection Criteria for Hepatocellular Carcinoma

The patient selection criteria for liver transplantation for hepatocellular carcinoma (HCC) have focused mainly on the number and size of tumors. An editorial by Llovet (2006) noted that the Milan criteria are considered the gold standard.[24] The Milan criteria specify that patients may either have a solitary tumor with a maximum tumor diameter of five cm or less, or up to three tumors three cm or smaller. Patients with extrahepatic spread or macrovascular invasion have a poor prognosis. UNOS adopted the Milan criteria, combined with one additional criteria (no evidence of extrahepatic spread or macrovascular invasion), as its liver transplantation criteria. A 2001 paper from the University of California, San Francisco (UCSF), proposed expanded criteria to include patients with a single tumor up to 6.5 cm in diameter, three or fewer tumors with maximum size 4.5 cm and a total tumor size of less than or equal to eight cm.[25] It should be noted that either set of criteria can be applied preoperatively with imaging or with pathology of the explanted liver at the time of intended transplant. Preoperative staging often underestimates what is seen on surgical pathology. To apply pathologic criteria a backup candidate must be available in case preoperative staging is inaccurate. Given donor organ scarcity, any expansion of liver transplant selection criteria has the potential to prolong waiting times for all candidates. Important outcomes in assessing expanded criteria include waiting time duration, death or deselection due to disease progression while waiting (dropout), survival time, and time to recurrence or related outcomes such as disease-free survival. Survival time can be estimated beginning when the patient is placed on the waiting list using the intention-to-treat principal or at the time of transplantation. Llovet (2006) stated that one-year dropout rates for patients meeting Milan criteria are 15% to 30%, and five-year survival rates not reported by intention-to-treat should be adjusted down by 10% to 15%.

Guiteau (2010) reported on 445 patients transplanted for HCC in a multicenter, prospective study in UNOS Region 4.[26] On preoperative imaging, 363 patients met Milan criteria, and 82 patients were under expanded Milan criteria consisting of one lesion less than six cm, equal to or less than three lesions, none greater than five cm and total diameter less than nine cm. Patient, allograft and recurrence-free survival at three years did not differ significantly between patients meeting Milan criteria versus patients under the expanded criteria (72.9% and 77.1%, 71% and 70.2%, and 90.5% and 86.9%, respectively). While preliminary results showed similar outcomes when using expanded Milan criteria, the authors noted their results were influenced by waiting times in Region 4 and that similar outcomes may be different in other regions with different waiting times. Additionally, the authors noted that an HCC consensus conference report on liver allocation in HCC patients does not recommend expanding Milan criteria nationally and encourages regional agreement.[27] The report addressed the need to better characterize the long-term outcomes of liver transplantation for patients with HCC and to assess whether it is justified to continue the policy of assigning increased priority for candidates with early stage HCC on the transplant waiting list in the U.S. Overall, the evidence

base is insufficient to permit conclusions about health outcomes after liver transplantation among patients exceeding Milan criteria and meeting expanded UCSF or other criteria.

Schwartz (2008) argued that selection based exclusively on the Milan criteria risks prognostic inaccuracy due to the diagnostic limitations of imaging procedures and the surrogate nature of size and number of tumors.[28] They predict that evolution of allocation policy will involve the following:

1. The development of a reliable prognostic staging system to help with allocation of therapeutic alternatives;
2. New molecular markers that might improve prognostic accuracy;
3. Aggressive multimodality neoadjuvant therapy to downstage and limit tumor progression before transplant and possibly provide information about tumor biology based on response to therapy; and,
4. Prioritization for transplantation should consider response to neoadjuvant therapy, time on waiting list, suitability of alternative donor sources.

A limited body of evidence is available for outcomes among patients exceeding Milan criteria but meeting UCSF criteria (see table below). The largest series was conducted in 14 centers in France including an intention-to-treat total of 44 patients based on preoperative imaging at the time of listing, and a subset of 39 patients meeting pathologic UCSF criteria.[29] The median waiting time was 4.5 months, shorter than the typical six to twelve months in North America. Dropouts composed 11.4%. The post-transplant overall patient five-year survival of 63.6% was more favorable than the intention-to-treat probability of 45.5% but less favorable than among larger numbers of patients meeting Milan criteria. Similar findings were seen for disease-free survival and cumulative incidence of recurrence. Three centers in Massachusetts included ten patients beyond pathologic Milan criteria but within UCSF criteria.[30] Two-year survival post-transplant was 77.1%, with two patients dying and eight alive after a median of 32 months. A group of 74 patients meeting preoperative Milan criteria had a two-year survival probability of about 73%, but it is inadvisable to compare different preoperative and pathologic staging criteria.

From the series of patients from which the expanded UCSF criteria was developed, 14 satisfied those criteria on pathology but exceeded the Milan criteria.[31] UCSF investigators did not provide survival duration data for this subgroup but noted that two patients died. Although the French series suggested that outcomes among patients exceeding Milan criteria and meeting UCSF criteria are worse than for patients meeting Milan criteria, it is unclear if the latter group still achieves acceptable results. A benchmark of 50% five-year survival has been established in the liver transplant community. The French study met this by post-transplant pathologic staging results (63.6%) and fell short by preoperative intention-to-treat results (45.5%). United States centers have published data for only 24 patients exceeding Milan criteria and meeting UCSF criteria; survival and recurrence data are very sparse. Overall, the evidence base is insufficient to permit conclusions about health outcomes after liver transplantation among patients exceeding Milan criteria and meeting expanded UCSF criteria.

Several groups have worked on identifying predictors of survival and recurrence of disease. Ioannou (2008) analyzed UNOS data pre- and post-adoption of the MELD allocation system finding a six-fold increase in recipients with hepatocellular carcinoma and that survival in the MELD era was similar to survival to patients without HCC.[32] The subgroup of patients with larger (three to five cm) tumors, serum alpha-fetoprotein level equal to or greater than 455

mg/mL, or a MELD score equal to or greater than 20, however, had poor transplantation survival. A cancer recurrence prediction scoring system was developed by Chan (2008), based on a retrospective review and analysis of liver transplants at two centers to determine factors associated with recurrence of HCC.[33] Of 116 patients with findings of hepatocellular carcinoma in their explanted livers, 12 developed recurrent hepatocellular carcinoma. Four independent significant explant factors were identified by stepwise logistic regression: size of one tumor greater than 4.5 cm, macroinvasion, and bilobar tumor were positive predictors of recurrence, and the presence of only well-differentiated HCC was a negative predictor. Points were assigned to each factor in relation to its odds ratio. The accuracy of the method was confirmed in two validation cohorts.

Table 1. Outcomes Among Patients with Hepatocellular Carcinoma Exceeding Milan Selection Criteria and Meeting UCSF Criteria

Study	Outcome	Group	Probability (%)			
			n	1yr	2yr	5yr
Decaens (2006)[29] 14 centers in France, Meeting Milan criteria (Milan+). Exceeding Milan criteria, meeting UCSF criteria (Milan-/UCSF+)	Intention-to-treat, preoperative					
	Overall patient survival	Milan+	279			60.1
		Milan-/UCSF+	44			45.5
	Cumulative incidence of recurrence	Milan+				20.2
		Milan-/UCSF+				27.1
	Disease-free survival	Milan+				60.4
		Milan-/UCSF+				47.8
	Post-transplant, pathologic (p)					
	Overall patient survival	pMilan+	184			70.4
		pMilan-/pUCSF+	39			63.6
	Cumulative incidence of recurrence	pMilan+				9.4
		pMilan-/pUCSF+				16.5
	Disease-free survival	pMilan+				7.02
		pMilan-/pUCSF+				62.7
	Milan-/UCSF+ median waiting time 4.5 mo (0.1-20.4); 5/44 dropouts (11.4%)					
Sotiropoulos (2006)[34] Essen, Germany. Unclear if criteria preoperative or pathologic.	Milan-/UCSF+, n=4, 1 patient died at 20 mo, 3 patients alive at median follow-up 57 mo.					
Leung (2004)[30] 3 centers in Massachusetts, Meeting preoperative Milan criteria (Milan+)	Post-transplant overall patient survival	Milan+	74	85.9	~73	50.9
		pMilan-/pUCSF+	10		77.1	
	2 patients died at 3 and 22 months, 8 patients alive after median 32 mo follow-up (6.6-73.5)					
Yao (2002)[31] University of California, San Francisco	Post-transplant overall patient survival	pMilan+	46	91	81	72
	pMilan-/pUCSF+, n=14, 2 patients died, 8 alive but no information on survival duration, 1 patient retransplanted 5 mo after initial transplant					

The use of extended Milan criteria, to include other factors, has recently become an area of investigation. Tosco (2015) conducted a prospective study that recruited 233 patients with HCC according to their proposed total tumor volume (TTV, ≤115 cm^3)/alpha-fetoprotein (AFP, ≤400 ng/mL) score.[35] The Milan group was modified to include only patients with AFP <400 ng/mL (n=195); these patients were compared to patients beyond Milan, but within TTV/AFP (n=38), with an average follow-up of 34 ± 25 months. Risk of dropout was higher for patients beyond Milan (42.1%), than for those within Milan (25.1%, p = 0.033), and intent-to-treat survival was lower in patients beyond Milan (53.8% vs. 71.6% at four years, p<0.001). Post-transplant, patients within Milan criteria and those beyond Milan had similar recurrence rates (4.5% vs. 9.4%, p=0.138) and post-transplant survivals (78.7% vs. 74.6% at four years,

p=0.932). The investigators concluded that expanding the Milan criteria may lead to increased risk of drop-out but does not impact overall post-transplant survival.

Liver Transplantation versus Liver Resection for Hepatocellular Carcinoma

Liver transplantation is the gold standard treatment for HCC meeting Milan criteria in decompensated livers such as Child-Pugh class B or C (moderate to severe cirrhosis). Liver resection is generally used for early HCC in livers classified as Child-Pugh class A.[36] Additionally, current UNOS criteria indicate a liver transplant candidate must not be eligible for resection.[1] However, the best treatment approach for early HCC in well-compensated livers is controversial.

Schoenberg (2017) published a systematic review and meta-analysis of 54 retrospective studies (n=13,794) comparing liver resection (n=7,990) with transplantation (n=5,804) in patients with HCC.[37] At one-year follow-up, survival rates were higher in those receiving resection (86.17%) than in those receiving liver transplant (80.58%) (OR 1.19, 95% CI 0.99 to 1.43, p=0.07). At five-year follow-up, survival rates were better for those who received transplantation (61.26%) than for those receiving surgery (51.9%, OR 0.62, 95% CI 0.50 to 0.76, p<0.001). When a subgroup of patients with early HCC (eight studies) was analyzed, one-year follow-up showed comparable survival rates between surgically-treated patients (92.14%), and transplanted patients (90.38%) (OR 0.97, 95% CI 0.63 to 1.50, p=0.89). At five years, transplanted patients had a significantly higher survival rate (66.67%) than surgically treated patients (60.35%, OR=0.60, 95% CI 0.45 to 0.78, p<0.001). Review limitations included a high level of heterogeneity between studies analyzed.

Chapman (2015) conducted a retrospective analysis of outcomes of liver transplant compared to resection in 1765 HCC patients treated across five U.S. centers.[38] There were 884 patients who underwent resection and 881 who underwent transplantation. Of the resected patients, 248 (28.1%) were eligible for transplantation, according to the MILAN criteria; which were compared with 496 transplant patients, matched based on year of transplantation and tumor status. Five- and 10-year survival rates were significantly higher in transplant patients, compared to resected patients eligible for transplant (74% vs. 53% and 54% vs. 22% respectively, p<0.001). The investigators concluded that although transplantation results in better long-term survival, resection will likely remain a standard therapy in selected patients with HCC due to limited donor availability.

Zheng (2013) reported on a meta-analysis of 62 cohort studies (n=10,170 total patients) comparing liver transplantation to liver resection for HCC.[39] Overall one-year survival was similar between procedures (OR 1.08, 95% CI 0.81 to 1.43, p=0.61). However, three- and five-year overall survival significantly favored liver transplantation over resection (OR 1.47, 95% CI 1.18 to 1.84, p<0.001, and OR 1.77, 95% CI 1.45 to 2.16, p<0.001, respectively). Disease-free survival in liver transplant patients was 13%, 29%, and 39% higher than liver resection patients at one, three, and five years, respectively (p<0.001). Recurrence rates were also 30% lower in liver transplantation than resection (OR 0.20, CI 0.15 to 0.28, p<0.001). While liver transplantation outcomes appear favorable compared to liver resection, a shortage of donor organs may necessitate liver resection as an alternative to liver transplantation.

Salvage Liver Transplantation after Liver Resection for Hepatocellular Carcinoma

In patients who have a recurrence of HCC after primary liver resection, salvage liver transplantation has been considered a treatment alternative to repeat hepatic resection,

chemotherapy or other local therapies such as radiofrequency ablation, transarterial chemoembolization percutaneous ethanol ablation or cryoablation. Several systematic reviews have evaluated the evidence on outcomes of salvage transplant compared to primary transplant.

Yadav (2018) published a systematic review and meta-analysis comparing salvage liver transplant (SLT) and primary LT for individuals with hepatocellular carcinoma.[40] Twenty retrospective studies (10 of which were also included in Murali [2017], described below) with a total of 9,879 patients were included in the analysis. One-year overall survival was better for SLT (74.30%) than primary LT (OR 0.86, 95% CI 0.75 to 0.98, p=0.03). SLT also had higher three- (55.69% and 59.07%, respectively; OR 0.85, 95% CI 0.76 to 0.96, p=0.01) and five-year (48.67% and 52.32%, respectively; OR 0.85, 95% CI 0.76 to 0.96, p=0.009) overall survival than primary LT. One- (OR 0.86, 95% CI 0.75 to 0.99, p=0.03), three- (OR 0.56, 95% CI 0.39 to 0.81, p=0.002), and five-year DFS (OR 0.75, 95% CI 0.66 to 0.86, p<0.001) were worse for primary LT (70.03%, 74.08%, and 47.09%, respectively) than for SLT (67.69%, 57.02%, and 41.27%, respectively). There was no significant difference between the two groups for postoperative biliary complications (p=0.19) or sepsis (p=0.68). No limitations to the analysis were reported.

Murali (2017) published a systematic review and meta-analysis comparing primary LT to locoregional therapy with curative intent (CLRT) followed by SLT.[41] Forty-eight studies with 9,835 patients were included in the review, which found that five-year overall survival and disease-free survival were worse for the CLRT compared with primary LT (OR for overall survival 0.59, 95% CI 0.48 to 0.71, p<0.01), but there was no significant difference between primary LT and CLRT followed by SLT. However, only 32.5% of patients who had disease recurrence after CLRT received SLT, so disease-free survival was worse with CLRT-SLT.

A systematic review of 14 non-randomized comparative studies was published by Zhu (2013) (n=1,272 for primary transplant and n=236 for salvage).[42] Overall survival at one, three, and five years, and disease-free survival at one and three years were not significantly different between groups. Disease-free survival, however, was significantly lower at five years in SLT compared to primary transplantation (OR 0.62, 95% CI 0.42 to 0.92, p=0.02). There was insufficient data to evaluate outcomes in patients exceeding Milan criteria but in patients meeting Milan criteria, survival outcomes were not significantly different suggesting SLT may be a viable option in these patients.

Chan (2013) systematically reviewed 16 non-randomized studies (n=319) on SLT after primary hepatic resection for HCC.[43] The authors found overall and disease-free survival outcomes with SLT were similar to reported primary LT outcomes. The median overall survival for SLT patients was 89%, 80% and 62% at one, three, and five years, respectively. Disease-free survival was 86%, 68% and 67% at one, three, and five years, respectively. SLT studies had median overall survival rates of 62% (range 41 to 89%) compared to a range of 61% to 80% in the literature for primary LT. Median disease-free survival rates for SLT were 67% (range 29% to 100%) compared to a range of 58 to 89% for primary liver transplantation. Given a limited donor pool and increased surgical difficulty with salvage liver transplantation, further studies are needed. UNOS criteria indicate LT candidates with HCC who subsequently undergo tumor resection must be prospectively reviewed by a regional review board for the extension application.

In a meta-analysis, Li (2012) compared primary LT to SLT (liver transplantation after liver resection) for HCC.[44] Included in the meta-analysis were 11 case-controlled or cohort studies totaling 872 primary LTs and 141 SLTs. Survival rates of patients who exceeded the Milan criteria at one, three and five years were not significantly different between the two groups (one-year OR 0.26, 95% CI 0.01 to 4.94, p=0.37, three-year OR 0.41, 95% CI 0.01 to 24.54, p=0.67, and five-year OR 0.55, 95% CI 0.07 to 4.48, p=0.57).

Adenomatosis

Chiche (2016) published a prospective study that evaluated data from the European Liver Transplant Registry (ELTR) for 49 patients who had LT for liver adenomatosis (LA) between January 1, 1986 and July 15, 2013.[45] LA is a rare benign disease that does not affect liver function. It therefore does not increase the MELD score used to determine who should receive a transplant. The most prevalent concern is fear of malignant transformation and severe bleeding. The authors concluded LA is a rare indication for LT and can be handled non-surgically or through other surgical approaches. LT for LA carries an increased risk of morbidity/mortality, and criteria are critical to aid in transplant selection.

Cholangiocarcinoma

Reports on LT for cholangiocarcinoma (CCA), or bile duct carcinoma, generally distinguish between intrahepatic and extrahepatic tumors, the latter including hilar or perihilar tumors. Recent efforts have focused on pretransplant downstaging of disease with neoadjuvant radiochemotherapy. Relevant outcomes included waiting time duration, dropout rates, survival time, and recurrence.

A meta-analysis by Cambridge (2021) assessed survival following neo-adjuvant chemoradiation and orthotopic LT for unresectable perihilar CCA in 20 studies (total n=428).[46] Pooled one-, three-, and five-year overall survival rates following LT for patients who completed neoadjuvant therapy were 82.8% (95% CI 73.0 to 90.8%), 65.5% (95% CI 48.7% to 80.5%), and 65.1% (95% CI 55.1% to 74.5%), respectively. For those without neoadjuvant therapy, survival rates were lower at 71.2% (95% CI 62.2% to 79.4%), 48.0% (95% CI 35.0% to 60.9%), and 31.6% (95% CI 23.1% to 40.7%), respectively. Pooled recurrence at three years with neoadjuvant treatment was 24.1% (95% CI 17.9% to 30.9%), while three-year recurrence without neoadjuvant treatment was 51.7% (95% CI 33.8% to 69.4%).

Lunsford (2018) evaluated neoadjuvant chemotherapy followed by LT in a small, prospective case series of patients with locally advanced, unresectable, intrahepatic CCA at a single center.[47] Of the 21 patients referred between 2010 and 2017, 12 were accepted and six had undergone LT. Three of the transplants were from deceased donors and three were from living donors. All six patients survived to one year after transplant, and five patients survived to three and five years. Three had disease recurrence during follow-up.

Hildebrand (2016) published a multi-center retrospective cohort study to evaluate risk factors, recurrence of biliary strictures, and impact on survival after LT, for patients with primary sclerosing cholangitis (PSC).[48] PSC is a progressive cholestatic disease with inflammation and fibrotic strictures within the hepatic or extrahepatic bile ducts. Progression leads to biliary cirrhosis, recurrent episodes of septic cholangitis, or CCA. The only cure is LT. This study evaluated 2,170 transplant patients with prior PSC. LT was performed at 10 German transplant centers from January 1990 to December 2006. One-, five-, and 10-year recipient survival was 90.7%, 84.8%, and 79.4%, respectively, and one-, five-, and 10-year graft survival was 79.1%,

69.0%, 62.4%. Biliary strictures were found in 36.1% of the recipients after an average of 3.9 years, and recurrent PSC was found in 20.3% of the recipients after 4.6 years post-LT. MELD and Mayo risk score parameters, particularly INR, were higher in patients with biliary stricture after LT. Donor age was also a risk factor for developing strictures after LT.

Gu (2012) reported on a systematic review and meta-analysis of 14 clinical trials on LT for CCA.[49] Overall one-, three-, and five-year pooled survival rates from 605 study patients were 0.73 (95% CI 0.65 to 0.80), 0.42 (95% CI 0.33 to 0.51), and 0.39 (95% CI 0.28 to 0.51), respectively. When patients received adjuvant therapies preoperatively, one-, three-, and five-year pooled survival rates improved and were 0.83 (95% CI 0.57 to 0.98), 0.57 (95% CI 0.18 to 0.92), and 0.65 (95% CI 0.40 to 0.87), respectively.

Darwish Murad (2012) reported on 287 patients from 12 transplant centers treated with neoadjuvant therapy for perihilar CCA followed by LT.[50] Intent-to-treat survival (after a loss of 71 patients before liver transplantation) was 68% at two years and 53% at five years, and recurrence-free survival rates post-transplant were 78% at two years and 65% at five years. Survival time was significantly shorter for patients who had a previous malignancy or did not meet UNOS criteria by having a tumor size greater than 3 cm, metastatic disease, or transperitoneal tumor biopsy. ($p<0.001$).

Panjala (2011) published results from a small case series of 22 patients with CCA treated with neoadjuvant chemoradiotherapy and subsequent LT.[51] Estimated rates of one, two, and three year survival, were 90%, 70%, and 63%, respectively, calculated based upon survival after a median follow-up of 601 days. Smaller tumors and those in the earliest stages of disease were associated with the most promising outcomes.

Among the various publications, the Mayo Clinic in Minnesota had the most favorable results.[52, 53] Between 1993 and 2006, 65 patients underwent LT for unresectable perihilar CCA or had perihilar tumor due to primary sclerosing cholangitis. Unresectable patients underwent neoadjuvant radiochemotherapy. One-year survival was 91% and five-year survival was 76%. In a series of 38 patients from the Mayo Clinic, cumulative recurrence was 0% at one year, 5% at three years, and 13% at five years.

The University of California, Los Angeles (UCLA)/Cedars-Sinai reported on 25 cases of both intrahepatic and extrahepatic CCA.[54] One-year survival was 71% and 3-year survival was 35%. The University of Pittsburgh found one-year survival of 70% and 18% five-year survival among 20 patients with intrahepatic CCA.[55] A German study of 24 patients reported the poorest results.[56]

The European Liver Transplant Registry reported that, among 186 patients with intrahepatic CCA, one-year survival was 58% and five-year survival was 29%.[57] In 169 patients with extrahepatic CCA, the probabilities were 63% and 29%. The Cincinnati Transplant Registry reported on 207 patients with either intrahepatic or extrahepatic CCA, finding a one-year survival of 72% and a five-year survival of 23%.[58] The multicenter report included 36 patients with hilar tumors and 23 with peripheral intrahepatic disease.[59] One-year survival was 82% and 77%, while five-year survival was 30% and 23%, respectively. Crude recurrence rates were 53% and 36% for extrahepatic and intrahepatic CCA, respectively. The German center at Hannover found a crude recurrence rate of 63%.[56]

Table 2. Outcomes Among Patients with Cholangiocarcinoma

Study	Outcome	Group	n	Probability (%)			
				1yr	2yr	3yr	5yr
Pascher (2003)[30] European Liver Transplant Registry	Overall patient survival	IH-CCA	186	58		38	29
		EH-CCA	169	63		38	29
Meyer (2000)[31] Cincinnati Transplant Registry unresectable CCA, cholangiohepatoma, incidental median follow-up 23 mo (<1-96)	Overall patient survival	IH/EH-CCA	207	72	48		23
Robles (2004)[34] Multiple Centers in Spain 03/88-09/01; hilar or peripheral CCA; unresectable, postoperative recurrent, or incidental	Overall patient survival	Hilar CCA	36	82		53	30

	Crude recurrence rate: 15/24 (63%)						
CCA: cholangiocarcinoma; EH: extrahepatic; IH: intrahepatic							

Heimbach (2018) reviewed the published outcomes of the combined protocol in the context of data on outcomes for surgical resection, and concluded that outcomes of neoadjuvant chemoradiotherapy with subsequent LT for patients with early-stage hilar CCA, which is unresectable, or arising in the setting of PSC are comparable to outcomes for patients with hepatocellular carcinoma and other chronic liver diseases, and superior to resection.[60] Intraoperative challenges attributable to the neoadjuvant therapy were described, including severe inflammatory changes and dense fibrosis. The author suggested that key principles for centers considering use of the combined protocol include a multidisciplinary approach, pretransplant staging, inclusion of only patients without lymph node metastasis, replacement of irradiated vessels (when possible), and monitoring for postoperative vascular complications.

Wu (2008) described an extensive surgical procedure combined with radiotherapy.[61] The authors retrospectively reviewed their experience with surveillance and early detection of CCA

and en bloc total hepatectomy-pancreaticoduodenectomy-orthotopic liver transplantation (OLT-Whipple) in a small series of patients with early-stage CCA complicating PSC. Surveillance involved endoscopic ultrasound and endoscopic retrograde cholangiopancreatography and cytological evaluation. Patients diagnosed with CCA were treated with combined extra-beam radiotherapy, lesion-focused brachytherapy, and OLT-Whipple. CCA was detected in eight of the 42 patients followed up according the surveillance protocol between 1988 and 2001, and six patients underwent OLT-Whipple. One died at 55 months after transplant of an unrelated cause without tumor recurrence, and five are without recurrence at 5.7 to 10.1 years.

Section Summary

Treatment benefit of liver transplant has been demonstrated for select patients with CCA and evidence on patients with perihilar CCA have shown reasonable survival rates at five years. However, current evidence regarding five-year survival rates for intrahepatic CCA are less certain as most studies which demonstrated lower overall survival rates reported on a combined intra- and extra-hepatic patient population.

Pediatric Hepatoblastoma

Hepatoblastoma is a rare malignant primary solid tumor of the liver that occurs in children. Treatment consists of chemotherapy and resection; however, tumors aren't often discovered until they are unresectable. In cases of unresectable tumors, LT with pre- and/or post-chemotherapy is a treatment option with reports of good outcomes and high rates of survival.[62] UNOS guidelines list non-metastatic hepatoblastoma as a condition eligible for pediatric LT.[1]

Hamilton (2017) reported on 376 children with hepatoblastoma requiring liver transplantation; this was part of a larger cohort of 544 children receiving a liver transplant from 1987 to 2012, as recorded in the United Network for Organ Sharing database.[63] The five-year patient survival rate after liver transplant for hepatoblastoma was 73%, with five-year graft survival rate of 74%. Recurrent or metastatic disease was the most common (57%) cause of death for this population.

Barrena (2011) reported on 15 children with hepatoblastoma requiring LT.[64] Overall survival after liver transplant was 93.3 (±6.4%) at one-, five- and 10-years. Malek (2010) reported on liver transplantation results for 27 patients with primary liver tumor identified from a retrospective review of patients treated between 1990 and 2007.[65] Tumor recurrence occurred in one patient after LT and overall survival was 93%. Browne (2008) reported on 14 hepatoblastoma patients treated with LT. Mean follow-up was 46 months with overall survival in 10 of 14 patients (71%).[66] Tumor recurrence caused all four deaths. In the 10 patients receiving primary LT, nine survived while only one of four patients transplanted after primary resection survived (90% vs. 25%, p=0.02).

Metastatic Neuroendocrine Tumors

Neuroendocrine tumors (NETs) are relatively rare neoplasms that are generally slow growing but rarely cured when metastatic to the liver. Treatment options to control or downstage the disease include chemotherapy and debulking procedures, including hepatic resection. In select patients with non-resectable, hormonally active liver metastases refractory to medical therapy, LT has been considered as an option to extend survival and minimize endocrine symptoms.

Moris (2017) published a systematic review on LT for the treatment of NETs with liver metastases.[67] There were 64 studies deemed eligible for inclusion in the review, including four studies using registry data and three multicenter studies. The authors reported an overall recurrence rate ranging from 31.3% to 56.8%, with a five-year survival of 63%. Factors that were associated with worse survival included >50% liver tumor involvement, higher Ki67 (a disease marker) and pancreatic NETs (compared to gastrointestinal NETs).

Sher (2015) conducted a retrospective analysis on LT outcomes of 85 patients with NETs, assessing data from a North American multicenter database.[68] One, three, and five-year patient survival rates were 83%, 60%, and 52%, respectively. These rates are similar to those reported in larger studies. Overall, 40 of 85 patients died, with 20 of 40 deaths due to recurrent disease. In multivariable analysis, predictors of poor overall survival included large vessel invasion (p=0.001), and extent of extrahepatic resection at liver transplant (p=0.015). The investigators reported that the survival outcomes are high enough to merit LT in this patient population.

Fan (2014) reported on a systematic review of 46 studies on LT for NET liver metastases of any origin.[69] A total of 706 patients were included in the studies reviewed. Reported overall five-year survival rates ranged from 0 to 100%, while five-year disease-free survival rates ranged from 0% to 80%. In studies with more than 100 patients, the five-year overall survival rate and disease-free survival rate averaged about 50% and 30%, respectively. Frequent and early NET recurrences after LT were reported in most studies.

Mathe (2011) conducted a systematic review of the literature to evaluate patient survival after LT for pancreatic NETs.[70] Data from 89 transplanted patients from 20 clinical studies were included in the review. Sixty-nine patients had primary endocrine pancreatic tumors, nine patients had carcinoids, and 11 patients were not further classified. Survival rates at one-, three-, and five-years were 71%, 55%, and 44%, respectively. The mean calculated survival rate was 54.45 (±6.31) months, and the median calculated survival rate was 41 months (95% CI 22 to 76 months).

Gedaly (2011) reported on a retrospective analysis of LT conducted on 150 patients with metastatic NETs.[71] Survival rates at one-, three-, and five-years were similar to those reported in the systematic analysis above: 81%, 65%, and 49%, respectively. No significant differences were seen in rates of patient survival between patients with metastatic NETs compared with those with hepatocellular carcinoma. Because longer wait times were associated with improved health outcomes, the authors suggested allowing for disease stabilization before attempting transplantation.

Mazzaferro (2007) performed a literature review to establish transplant selection criteria for patients with metastatic neuroendocrine tumors.[72] Eight studies were reviewed between 1970 and 2006, and all but one study reported either poor or limited five-year survival outcomes. Suboptimal patient selection was reported as the cause for the lower rates of long-term survival. However, the authors reported outcomes for 24 patients who were selected for transplant using the Milan criteria,[73] and found a high five-year survival rate of 77%. Although, the utilization of these criteria to select optimal transplantation candidates in patients with non-resectable metastatic neuroendocrine tumors is promising, the data is limited to a small sample (n=24), from a single study. Larger, long-term studies are required to validate the usefulness of the Milan criteria in improving five-year survival rates for this unique patient population.

Section Summary

While there may be centers that perform LT on select patients with NETs, further studies are needed to determine appropriate selection criteria. Few studies are available, and the quality is limited by their retrospective nature and heterogeneous populations.

HIV POSITIVE RECIPIENTS

The subgroup of HIV positive LT recipients was historically controversial due to the long-term prognosis for HIV positivity, and the impact of immunosuppression on HIV disease. HIV candidates for LT are frequently co-infected with hepatitis B (HBV) or HCV, and viral co-infection can further exacerbate drug-related hepatotoxicities.

Cooper (2011) conducted a systematic review to evaluate LT in patients co-infected with HIV and hepatitis.[74] The review included 15 cohort studies and 49 case series with individual patient data. The survival rate of patients was 84.4% (95% CI 81.1% to 87.8%) at 12 months. Patients were 2.89 (95% CI 1.41 to 5.91) times more likely to survive when HIV viral load at the time of transplantation was undetectable compared to those with detectable HIV viremia.

Terrault (2012) reported on a prospective, multicenter study to compare LT outcomes in three groups: patients with both HCV and HIV (n=89), patients with only HCV (n=235), and all transplant patients age 65 or older.[75] Patient and graft survival reductions were significantly associated with only one factor: HIV infection. At three years, patient and graft survival rates were significantly better in the HCV-only group (79%, 95% CI 72% to 84%, and 74%, 95% CI 66% to 79%, respectively) than in the group with both HIV and HCV infection (60%, 95% CI 47% to 71%, and 53%, 95% CI 40% to 64%, respectively).

Current, OPTN policy permits HIV-positive transplant candidates.[1]

The American Society of Transplantation (2019) published a guideline on solid organ transplantation in HIV-infected patients.[76] For liver transplants, the following criteria for transplantation are suggested:

- Cluster of differentiation 4 (CD4) count >100 cells/mL with no history of AIDS-defining illnesses such as opportunistic infection or malignancy or CD4 count >200 cells/mL for at least 3 months
- Undetectable HIV viral load while receiving antiretroviral therapy or a detectable HIV viral load in patients with intolerance to antiretroviral therapy that can be suppressed posttransplant
- Documented compliance with a stable antiretroviral therapy regimen
- Absence of active opportunistic infection and malignancy
- Absence of chronic wasting or severe malnutrition
- Appropriate follow-up with providers experienced in HIV management and ready access to immunosuppressive medication therapeutic drug monitoring

The guideline authors note that patients with a previous history of progressive multifocal leukoencephalopathy, chronic interstitial cryptosporidiosis, primary central nervous system lymphoma, or visceral Kaposi's sarcoma were excluded from studies of solid organ transplantation in HIV-infected patients. Patients with HIV and concomitant controlled HBV

infection may be considered for transplant. Caution is recommended in HCV-coinfected patients who have not been initiated on direct acting antiviral therapy.

Section Summary

While HIV infection reduced three-year survival rates after liver transplantation in patients also infected with HCV, there were still a majority of patients experiencing long-term survival. Overall, survival rates are relatively high for patients with viral loads are low at the time of transplantation.

NONALCOHOLIC STEATOHEPATITIS

Nonalcoholic steatohepatitis (NASH) is a condition where fat build up in the liver causes inflammation of the liver. LT is a treatment option for patients with NASH who progress to liver cirrhosis and failure.

In a systematic review and meta-analysis, Wang (2014) evaluated nine studies comparing LT outcomes in patients with and without NASH.[77] Patients with NASH had similar one-, three- and five-year survival outcomes after liver transplantation as patients without NASH. Patients with NASH also had lower graft failure risk than those without NASH (OR 0.21, 95% CI 0.05 to 0.89, p=0.03). However, NASH LT patients had a greater risk of death related to cardiovascular disease (OR 1.65, 95% CI 1.01 to 2.70, p=0.05) and sepsis (OR 1.71, 95% CI 1.17 to 2.50, p=0.006) than non-NASH liver transplant patients. Given the relatively equivocal survival rates compared to transplant patients without NASH, transplant in patients with NASH appear to be of benefit.

Cholankeril (2017) published a retrospective cohort analysis of records from 2003 to 2014 in the United Network Organ Sharing and Organ Procurement and Transplantation Network database to evaluate the frequency of NASH-related liver transplantation.[78] In all, 63,061 patients underwent liver transplant from 2003 to 2014. NASH accounted for 17.38% of liver transplants in 2014. During the observation period, liver transplants secondary to NASH increased by 162.0%, a greater increase than either HCV (33.0% increase) and alcoholic liver disease (55.0% increase). Five-year survival posttransplant in patients who had NASH (77.81%, 95% CI 76.37% to 79.25%) was higher than patients who had HCV (72.15%, 95% CI 71.37 to 72.93, p<0.001). Patients with NASH also demonstrated significantly higher posttransplant survival than patients with HCV (HR 0.75, 95% CI 0.71 to 0.79, p<0.001).

Section Summary

The evidence on LT for hepatocellular disease includes case series, registry studies, and systematic reviews. Long-term survival rates in patients with viral hepatitis are significant in a group of patients who have no other treatment options. Also, survival can be improved by eradication of hepatitis virus before transplantation. For patients with NASH, a 2013 systematic review has indicated that overall survival rates are similar to other indications for LT.

VIRAL HEPATITIS

The presence of HBV and HCV have been controversial indications for liver transplantation because of the high potential for recurrence of the virus and subsequent recurrence of liver disease. However, in a review of registry data, Belle (1995) have indicated a long-term survival rate (seven years) of 47% in HBV virus-positive transplant recipients, which is lower than that seen in other primary liver diseases such as primary biliary cirrhosis (71%) or alcoholic liver

disease (57%).[2] Recurrence of HCV infection in transplant recipients, who are not treated pretransplant, has been nearly universal, and 10% to 20% of patients will develop cirrhosis within five years.[79]

Historical data demonstrating inferior survival in transplant recipients with HCV is not applicable to the current treatment landscape with the availability of direct acting antiviral agents, which are associated with sustained virological response rates over 95%.[80] Timing the receipt of direct acting antiviral agents either before or after transplantation is still controversial and the decision should be individualized based the presence of compensated or decompensated disease, Model for End-Stage Liver Disease (MELD) score, current quality of life, and the proportion of HCV-positive donors in the local and regional areas.

ELDERLY DONORS AND RECIPIENTS

Elderly Donors

Gao (2019) evaluated trends in long-term outcomes for LT with donors aged 60 years and above, using data from the OPTN/UNOS database.[81] There were 14,796 adult LT between 1990 and 2014 included in the analysis. There was a steady increase in the number of transplants from older donors found during the first 15 years of period, followed by a leveling off. There were significant improvements in the unadjusted five-year graft and patient survival over time ($p<0.0001$), as well as a reduction in the survival difference between older and younger grafts ($p<0.0001$).

A prospective study by Cascales-Campos (2018) assessed LT outcomes for those with donors aged 80 years and above (n=36) compared to those with donors under 65 years of age (n=283). They reported no significant differences in graft survival and overall survival.[82]

Paterno (2016) published a study that evaluated the outcome of LT from elderly donors.[83] Data from January 2007 to December 2011 was evaluated for patients who received a transplant from donors aged 70 years and older (n=540) or from patients younger than 60 years of age (n=10,473). The authors stated transplants from elderly donors in patients who meet criteria (i.e., no HCV and not on dialysis) had good outcomes and survival rates, but slightly lower graft survival.

A similar study by Dasari (2017) with 4,376 LT recipients compared outcomes for those receiving grafts from deceased donors over 70 years of age (n=880) and below 70 years of age (n=3,496).[84] In this study, graft and patient survival were similar between groups at one year, but there was better graft and patient survival at three and five years in the older donor group.

Elderly Recipients

Chen (2016) published a population-based cohort study that reported age-related LT mortality for patients in Taiwan.[85] Data were collected for patients receiving transplants from July 1, 1998 to December 31, 2012, and patients were followed until the end of the study or death. The authors stated the older a recipient, the higher risk of mortality, particularly for those with comorbidities.

Section Summary

Liver transplants for elderly recipients or from elderly donors can have positive health outcomes. More studies are needed to further identify survival rates and risks of mortality.

RETRANSPLANTATION

A registry analysis of pediatric retransplantation patients from Australia and New Zealand was published by Jeffrey (2020).[86] Between 1986 and 2017, 142 retransplantations in children were performed. Survival was higher in retransplantations performed between 2001 and 2017 compared with those performed between 1986 and 2001 ($p<0.001$), with 5-, 10-, and 15-year patient survival rates of 87%, 87%, and 71%, respectively, for the procedures between 2001 and 2017. There were no significant associations between survival and graft type, cause of graft failure, or number of transplants.

Agüero (2016) published an international cohort study that evaluated retransplantation for HIV patients who had HBV or HCV coinfection.[87] Thirty-seven patients with HBV or HCV coinfection underwent retransplant, with a survival rate of 80%. The authors concluded that patients coinfected with HBV or HCV, without HCV RNA had acceptable outcomes.

Abdelfattah (2015) reported on a retrospective cohort of 466 LT patients, 16 of whom underwent retransplantation.[88] The 16 retransplant patients were divided into those which had retransplantation within 30 days of the primary transplant, and those which had retransplantation more than 30 days after. Although the investigators stated that, overall patient and graft survival were lower after liver retransplant than primary liver transplant, and these outcomes were better in late than early liver retransplant; the study populations in the comparator groups was too small to draw meaningful conclusions. Studies of larger sample size are needed.

Bellido (2012) reported on a retrospective cohort study of 68 consecutive adult liver retransplantations using registry data.[89] Survival probability using Kaplan-Meier curves with log-rank tests to compare 21 urgent versus 47 elective retransplantations were calculated. Overall survival rates were significantly better in patients undergoing urgent procedures (87%), which were mostly due to vascular complications than elective procedures (76.5%) related to chronic rejection.

Remiszewski (2011) examined factors influencing survival outcomes in 43 liver retransplantation patients.[90] When compared to primary LT patients, retransplantation patients had significantly lower six-year survival rates (80% vs. 58%, respectively, $p=0.0001$). The authors also reported low negative correlations between survival time and time from original transplantation until retransplantation and between survival time and patient age. Survival time and cold ischemia time showed a low positive correlation.

Hong (2011) reported on a prospective study of 466 adults to identify risk factors for survival after liver retransplantation.[91] Eight risk factors were identified as predictive of graft failure, including age of recipient, MELD score greater than 27, more than one prior liver transplant, need for mechanical ventilation, serum albumin of less than 2.5 g/dL, donor age greater than 45 years, need for more than 30 units of packed red blood cells transfused intraoperatively, and time between prior transplantation and retransplantation between 15 and 180 days. The authors propose this risk-stratification model can be highly predictive of long-term outcomes after adult liver retransplantation and can be useful for patient selection.

Section Summary

Recent data regarding liver retransplantation suggest survival rates are not as good as with initial transplantation; however, overall survival rates appear to meet the benchmark of 50% five-year survival.

PRACTICE GUIDELINE SUMMARY

In December 2010, 10 international liver diseases or transplantation societies held an international consensus conference on liver transplantation for HCC.[92] Consensus criteria for selecting candidates for LT were developed at the conference. Milan criteria were recommended for use as the benchmark for patient selection and as the basis for comparison with other suggested criteria for selecting non-HCC patients. The Milan criteria set limits on the size and quantity of tumors and have been shown to be an independent prognostic factor for outcomes after LT.[92, 93] Panel members did refer to several studies which indicated that in some circumstances, the Milan criteria may be modestly expanded for patients who do not have HCC. It was warned, however, that expanding Milan criteria could result in a variety of outcomes and that patients, "…would need to achieve 5-year survival of 60% or higher to prevent a substantial decrement to the life-years available to the entire population of candidates for liver transplantation."[92] In addition, candidates for LT should also have a predicted survival of five years or more. The consensus criteria indicate alpha-fetoprotein concentrations may be used with imaging to assist in determining patient prognosis.

With respect to liver retransplantation, the consensus criteria issued a weak recommendation indicating retransplantation after graft failure of a living donor transplant for HCC is acceptable in patients meeting regional criteria for a deceased donor liver transplant. A strong recommendation was issued indicating liver retransplantation with a deceased donor for graft failure for patients exceeding regional criteria is not recommended. And the consensus criteria issued a strong recommendation that liver retransplantation for recurrent HCC is not appropriate. However, a de-novo HCC may be treated as a new tumor and retransplantation may be considered even though data to support this are limited.

AMERICAN ASSOCIATION FOR THE STUDY OF LIVER DISEASES (AASLD)

Evaluation for Liver Transplantation

The AASLD issued separate updated, evidence-based guidelines for evaluating pediatric[94] and adult[95] patients for LT. These guidelines update the 2005 guidelines[96] which addressed all ages. While the disease categories are similar for adult and pediatric (below 18 years of age) patients, separate guidelines were considered warranted because of differences between these age groups in specific etiologies and outcomes. Furthermore, the AASLD guidelines indicate patients should be assessed by a transplantation center to determine whether LT is appropriate. While the AASLD guidelines indicate LT may be appropriate in patients with CCA and metastatic NETs, these recommendations and many of the recommendations in the AASLD guidelines are based on opinion.

- In 2014 the AASLD in conjunction with the American Society of Transplantation (AST) and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition issued evidence-based guidelines for the evaluation of pediatric patients for liver transplantation.[94] Each of the 93 recommendations was classified for strength of recommendation and quality of evidence. Strength of recommendation 1 and 2 is defined as a strong or weak recommendation, respectively. Quality of evidence A, B, or C is

defined as high, moderate, or low quality, respectively. Contact of or referral to a liver transplant center was recommended for any of the following indications:

  - Acute liver failure or acute decompensation of an established liver disease (*Strength of recommendation 1; quality of evidence A [1-A])*
  - Liver-based metabolic crises refractory to medical and/or surgical therapy *(1-B)*
  - Unresectable hepatoblastoma or hepatocellular carcinoma *(1-B)*
  - Biliary atresia patients with total bilirubin > 6 mg/dL beyond 3 months post-hepatoportoenterostomy (*1-B*); liver transplant evaluation should be considered in these patients if total bilirubin remains between 2-6 mg/dL. *(1-B)*
  - Anticipate referral for evaluation for children with chronic liver disease and evidence of deteriorating liver function (i.e., poor weight gain, growth failure, variceal hemorrhage, intractable ascites, recurrent cholangitis, or episodes of spontaneous bacterial peritonitis, pruritus, advancing encephalopathy, and/or uncorrectable coagulopathy *(1-B)*

- The 2013 AASLD/ATS guideline for evaluation of adults for LT state that LT is indicated for acute or chronic liver failure when the limits of medical therapy have been reached.[95] The following are some of the included recommendations:

  - Consideration for liver transplantation is recommended for acute liver failure complications of cirrhosis, liver-based metabolic conditions with systemic manifestations, and systemic complications of chronic liver disease (i.e., hepatopulmonary syndrome; portopulmonary hypertension)
  - Liver transplant in combination with neoadjuvant chemoradiation for early-stage unresectable peri-hilar cholangiocarcinoma *(1-B)*.
  - Intrahepatic cholangiocarcinoma is a listed contraindication to liver transplant
  - Extrahepatic malignancy is a contraindication to liver transplant
  - Live donor transplant should be considered only when a deceased donor is unlikely to become available within a reasonable time frame for the recipient's liver disease

Long-term Management after Liver Transplant

The AASLD has also issued joint evidence-based guidelines with the AST for management of pediatric[97] and adult[98] patients following successful LT. Numerous recommendations are included and each is graded for strength of recommendation and quality of the supporting evidence. The stated intent of the guidelines is to provide flexible, preferred approaches to the diagnostic, therapeutic, and preventive aspects of care.

The 2013 guideline for pediatric (age 0 to 18 years) post-LT patients includes 54 recommendations.[97] "Pediatric liver transplant has dramatically changed the prognosis for many infants and children with liver failure and metabolic disease. As survival increases, long-term maintenance resources exceed perioperative care requirements. The most common indication for LT in children is biliary atresia which accounts for 50% of all children requiring transplant in the U.S. and 74% in Europe."

The 2012 AASLD/AST practice guideline for adults after LT includes 93 recommendations.[98] "LT is the treatment of choice for patients with decompensated cirrhosis, acute liver failure, small hepatocellular carcinomas (HCCs), or acute liver failure…long-term survivors are at risk of early death and increased morbidity. The purpose of this guideline is to assist in the management of adult recipients of LT, identify the barriers to maintaining their health, and

make recommendations on the ways to best prevent or ameliorate these barriers. This guideline focuses on management beyond the first 90 days after transplantation."

Alcohol-Associated Liver Disease

The AASLD (2019) guideline on alcohol-associated liver disease provides recommendations on the timing of referral and selection of candidates for liver transplant.[99] The guidance notes that the patient's history of addiction to alcohol is a primary driver in selecting appropriate candidates for liver transplantation. Clinical characteristics that should trigger an evaluation and consideration for liver transplant include decompensated alcohol-associated cirrhosis, Child-Pugh-Turcotte class C cirrhosis, or a MELD-Na score ≥21. Additionally, the guideline notes that candidate selection "should not be based solely on a fixed interval of abstinence" and instead a formal psychological evaluation can help stratify patients into higher- or lesser-risk strata for relapse.

NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)

The NCCN guidelines on hepatobiliary cancers (v1.2022) recommend referral to a liver transplant center or bridge therapy for patients with HCC meeting United Network of Organ Sharing criteria of a single tumor measuring 2 to 5 cm, or two to three tumors 3 cm or less with no macrovascular involvement or extrahepatic disease.[36] Patients should be referred to the transplant center. Patients should be referred to the transplant center before the biopsy. In patients who are ineligible for transplant and in select patients with Child-Pugh class A or B liver function with tumors that are resectable, the NCCN indicates resection is the preferred treatment option; locoregional therapy may also be considered. Patients with unresectable HCC should be evaluated for liver transplantation; if the patient is a transplant candidate, then referral to a transplant center should be given or bridge therapy should be considered. These are level 2A recommendations based on lower-level evidence and uniform consensus.

The NCCN guidelines on neuroendocrine and adrenal tumors (v1.2022) indicate that liver transplantation for neuroendocrine tumor metastases in the liver is considered investigational despite "encouraging" five-year survival rate.[100]

SUMMARY

There is enough research to show that liver transplantation can improve survival for patients with irreversible, end-stage liver failure due to certain conditions. Clinical guidelines based on research recommend liver transplantation for some people with irreversible, end-stage liver failure. Therefore, liver transplantation may be considered medically necessary in patients who meet the policy criteria.

There is enough research to show that liver transplantation does not improve health outcomes for patients with hepatocellular carcinoma that has extended beyond the liver, or for patients with active alcohol and/or substance abuse. Therefore, liver transplantation is considered not medically necessary for these patients.

There is not enough research to show that liver transplantation improves survival for patients with intrahepatic cholangiocarcinoma, extrahepatic malignancy other than those noted in the policy criteria, or neuroendocrine tumors metastatic to the liver. Therefore, liver

transplantation is investigational for these populations when the policy criteria are not met.

RETRANSPLANTATION

There is enough research to show that liver retransplantation improves survival for pediatric and adult patients for primary graft nonfunction, hepatic artery thrombosis, chronic rejection, ischemic type biliary lesions after donation after cardiac death, or recurrent non-neoplastic disease-causing late graft failure. Therefore, liver retransplantation may be considered medically necessary in patients with one of these diagnoses who meet the policy criteria. There is not enough research to show that liver retransplantation improves survival in patients for other conditions. Therefore, liver retransplantation is investigational when the policy criteria are not met.

CODES

Codes	Number	Description
CPT	47133	Donor hepatectomy (including cold preservation) from cadaver donor
	47135	Liver allotransplantation; orthotopic; partial or whole, from cadaver or living donor, any age
	47140	Donor hepatectomy (including cold preservation), from living donor; left lateral segment only (segments II and III)
	47141	Donor hepatectomy (including cold preservation), from living donor; total left lobectomy (segments II, III and IV)
	47142	Donor hepatectomy (including cold preservation), from living donor; total right lobectomy (segments V, VI, VII and VIII)
	47143	Backbench standard preparation of cadaver donor whole liver graft prior to allotransplantation, including cholecystectomy, if necessary, and dissection and removal of surrounding soft tissues to prepare the vena cava, portal vein, hepatic artery, and common bile duct for implantation; without trisegment or lobe split
	47144	Backbench standard preparation of cadaver donor whole liver graft prior to allotransplantation, including cholecystectomy, if necessary, and dissection and removal of surrounding soft tissues to prepare the vena cava, portal vein, hepatic artery, and common bile duct for implantation; with trisegment split of whole liver graft into two partial liver grafts (i.e., left lateral segment (segments II and III) and right trisegment (segments I and IV through VIII))
	47145	Backbench standard preparation of cadaver donor whole liver graft prior to allotransplantation, including cholecystectomy, if necessary, and dissection and removal of surrounding soft tissues to prepare the vena cava, portal vein,

Codes	Number	Description
		hepatic artery, and common bile duct for implantation; with lobe split of whole liver graft into two partial liver grafts (i.e., left lobe (segment II, III, and IV) and right lobe (segments I and V through VIII)
	47146	Backbench reconstruction of cadaver or living donor liver graft prior to allotransplantation; venous anastomosis, each
	47147	Backbench reconstruction of cadaver or living donor liver graft prior to allotransplantation; arterial anastomosis, each

Medical Policy Manual Transplant, Policy No. 06

Pancreas Transplant

Effective: November 1, 2023

Next Review: August 2024
Last Review: September 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Transplantation of a normal pancreas is a treatment method for patients with diabetes.

MEDICAL POLICY CRITERIA

Note: Islet cell transplantation is considered in a separate medical policy (see Cross References).

I. Pancreas transplant may be considered **medically necessary** when both of the following (A. and B.) are met:
   A. Candidates must meet both of the following general criteria:
      1. Adequate cardiopulmonary status; and
      2. Documentation of patient compliance with medical management.
   B. Transplant for any of the following indications:
      1. A combined pancreas-kidney transplant in diabetic patients with uremia; or
      2. Pancreas transplant after a prior kidney transplant in patients with insulin-dependent diabetes mellitus (IDDM); or

3. Pancreas transplant alone in patients with documentation of any of the following conditions, which persist despite optimal medical management:
    a. Severely disabling and potentially life-threatening hypoglycemia unawareness as evidenced by chart notes or emergency room visits; or
    b. Potentially life-threatening labile diabetes as evidenced by documentation of erratic blood glucose levels and hemoglobin A1c equal to or greater than 8% or hospitalization for diabetic ketoacidosis.

II. Pancreas retransplantation may be considered **medically necessary** after one failed primary pancreas transplant.

III. Pancreas transplantation that does not meet Criterion I. or II. is considered **not medically necessary.**

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

MULTIPLE TRANSPLANTS

Although there are no standard guidelines regarding multiple pancreas transplants, the following information may aid in case review:

- If there is early graft loss resulting from technical factors (e.g., venous thrombosis), a retransplant may generally be performed without substantial additional risk.
- Long-term graft losses may result from chronic rejection, which is associated with increased risk of infection following long-term immunosuppression, and sensitization, which increases the difficulty of finding a negative cross-match. Some transplant centers may wait to allow reconstitution of the immune system before initiating retransplant with an augmented immunosuppression protocol.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant
- Pre-transplant evaluation including pulmonary status and pertinent co-morbidities and treatments
- Failed primary pancreas transplant

CROSS REFERENCES

1. Islet Cell Transplantation, Transplant, Policy No. 13

BACKGROUND

Pancreas transplantation can restore glucose control, and is intended to prevent, halt, or

reverse the secondary complications of insulin-dependent Type 1 diabetes mellitus (IDDM). Achievement of insulin independence with resultant decreased morbidity and increased quality of life is the primary health outcome of pancreas transplantation. While pancreas transplantation is generally not considered a life-saving treatment, in a small subset of patients who experience life-threatening complications from IDDM, pancreas transplantation could be considered lifesaving. In addition to the immune rejection issues common to all allograft transplants, autoimmune destruction of beta cells has been observed in the transplanted pancreas, presumably from the same mechanism responsible for type 1 diabetes.[1]

Pancreas transplantation occurs in several different scenarios such as:

1. Patient with type 1 diabetes with renal failure who may receive a cadaveric simultaneous pancreas/kidney transplant (SPK)
2. Patient with type 1 diabetes who may receive a cadaveric or living-related pancreas transplant after a kidney transplantation (pancreas after kidney, i.e., PAK)
3. Patient with non-uremic type 1 diabetes with specific severely disabling and potentially life-threatening diabetes related problems who may receive a pancreas transplant alone (PTA).

PTA has also been investigated in patients following total pancreatectomy for chronic pancreatitis. The experience with SPK transplants is more extensive than that of other transplant options.

The approach to retransplantation varies according to the cause of failure. Surgical/technical complications such as venous thrombosis are the leading cause of pancreatic graft loss among patients with diabetes. Graft loss from chronic rejection may result in sensitization, increasing both the difficulty of finding a cross-matched donor and the risk of rejection of a subsequent transplant. Each center has its own guidelines based on experience; some transplant centers may wait to allow reconstitution of the immune system before initiating retransplant with an augmented immunosuppression protocol.

EVIDENCE SUMMARY

SIMULTANEOUS PANCREAS-KIDNEY TRANSPLANT

The U.S.-based Organ Procurement and Transplant Network (OPTN) reported a one-year patient survival rate of 97.5% (95% confidence interval [CI] 96.9% to 98.0%) for primary simultaneous pancreas/kidney transplant (SPK) procedures performed between 2008 and 2015.[2] Three- and five-year patient survival rates were 94.8% (95% CI 93.9% to 95.5%) and 88.9% (95% CI 87.8% to 89.9%), respectively.

Martin-Gonzalez (2023) published a retrospective observational study was conducted in two cohorts of SPK recipient patients that underwent surgery between 2001 and 2021.[3] The two cohorts represented an initial protocol (cohort 1; n=32) and an updated protocol (cohort 2; n=23). Average survival was 2546 days (95% CI: 1902-3190) for cohort 1 and 2540 days (95% CI: 2100-3204) for cohort 2 ($p > 0.05$). Pancreatic graft failure-free survival had an average of 1705 days (95% CI: 1037-2373) in cohort 1, lower than the average in cohort 2 (2337 days; 95% CI: 1887-2788) ($p = 0.016$). Similarly, renal graft failure-free survival had an average of 2167 days (95% CI: 1485-2849) in cohort 1, lower than the average in cohort 2 (2583 days; 95% CI: 2159-3006) ($p = 0.017$).

Barlow (2017) analyzed U.K. registry data that compared outcomes in patients with type 1 diabetes and end-stage renal disease who had SPK transplants (n=1739) with live donor kidney transplants (n=370).[4] In multivariate analysis, there was not a significant association between type of transplant and patient survival (HR [hazard ratio] 0.71, 95% CI 0.47 to 1.06; p=0.095). SPK recipients with a functioning pancreas graft had significantly better overall survival than those with a living donor kidney transplant (p<0.001).

Pancreas transplant has been found to improve mortality in patients with type 1 diabetes. Van Dellen (2014) reported a retrospective analysis of data on 148 SPK patients and a wait-list control group of 120 patients.[5] The study also included 33 patients who had PAK and 11 PTA patients. All patients had uncomplicated type 1 (insulin dependent) diabetes. Overall mortality was 30% (30/120 patients) on the waiting list and patients who underwent transplantation had a mortality rate of 9% (20/193 patients); the difference between groups was statistically significant (p<0.001). One-year mortality was 13% (n=16) on the waiting list and 4% (n=8) in the transplant group (p<0.001).

There are some data on outcomes in patients with type 2 compared with type 1 diabetes. Sampaio (2011) published an analysis of data from the United Network for Organ Sharing (UNOS) database.[6] The investigators compared outcomes in 6,141 patients with type 1 diabetes and 582 patients with type 2 diabetes who underwent SPK between 2000 and 2007. In adjusted analyses, outcomes were similar in the two groups. After adjusting for other factors such as body weight; dialysis time; and cardiovascular comorbidities, type 2 diabetes was not associated with an increased risk of pancreas or kidney graft survival or mortality compared to type 1 diabetes.

Mora (2010) described the long-term outcome of 12 patients 15 years following SPK transplant.[7] Metabolic measures of glucose control were measured at 1, 5, 10, and 15 years following the procedure. Of this subset of patients, six (50%) had non-diabetic glucose challenge tests. Basal serum insulin levels declined over this period as well, from 24 mU/L to 16 mU/L at 1 and 15 years, respectively. The authors concluded that in a select group of patients whose pancreatic graft continued to function after 15 years, some glycemic control continued, albeit in a diminished fashion. It should be noted that this represented a small fraction of the 367 patients receiving the SPK transplant at this single center (12 of 367 SPK; 3.3%). The number of allograft survivals at five or more, and 10 or more years in this study was 43 (11.7%) and 28 (7.6%), respectively.

The improved glycemic control that may occur in SPK transplant patients, principally in those with labile disease while on medical therapy alone, is purported to reduce risk of complications from diabetes. Davenport (2009) published results of a registry review (n=58) on cardiovascular risk factors in an Irish study of SPK transplant recipients.[8] Glycosylated hemoglobin values fell from a mean of 8.1 to 5.2 (p<0.0001) from pre-transplant levels. Similar statistically significant declines were seen in total cholesterol, triglycerides, and creatinine. Systolic and diastolic blood pressures were likewise improved but with a greater range of pre- and post-transplant variability. These endpoints are commonly accepted as surrogates for cardiovascular risk. The authors compared both a surgical method (bladder vs. enteric drainage) and mode of immunosuppression (cyclosporine vs. tacrolimus) on changes to blood pressure and cholesterol. No significant differences were found in either measure based on surgical drainage method, nor did immunosuppressive therapy have an impact on blood pressure reduction. Cholesterol reduction was greater in the cyclosporine than the tacrolimus group (-1.3 to -0.2, respectively), favoring the less contemporary strategy. The authors noted

that this was in contrast to other recently published studies favoring both enteric drainage and tacrolimus. While this single arm study suggested beneficial cardiovascular effects from transplant, other factors such as rejection rates were more likely to influence the conditions under which transplantations took place.

PANCREAS AFTER KIDNEY TRANSPLANT[9]

Parajuli (2019) described a single center's experience with 635 pancreas and kidney transplant patients (611 SPK, 24 PAK).[10] Transplants were performed between 2000 and 2016. The mean length of time between kidney transplant and pancreas transplant was 23.8 months in the PAK group. Pancreas rejection rates at one-year post-transplant were 4% and 9% with PAK and SPK respectively. During the entire study period, PAK patients were more likely to experience pancreas rejection (38% vs. 16%; p=0.005). Kidney and pancreas graft survival rates did not differ between groups at one year or at last follow-up. Pancreas graft survival rates for PAK and SPK at one year were 100% and 89%, respectively (p=0.09). Death-censored pancreas graft failure rates for PAK and SPK at last follow-up were 13% and 25%, respectively (p=0.17). Patient survival at last follow-up was similar between groups (71% with PAK vs. 68% with SPK; p=0.79).

Gruessner (2016) reported updated patient survival rates for pancreas after kidney (PAK) transplants. According to UNOS and International Registry data, patient survival after PAK from 2010 to 2014 was 97.9% after one year and 94.5% after three years.[11] This compares with one-year and three-year patient survival rates for 2005 to 2009 of 96.4% and 93.1%, respectively.

PAK transplantation allows the uremic patient the benefits of a living-related kidney graft, if available, and the benefits of a subsequent pancreas transplant that is likely to result in improved quality of life compared to a kidney transplant alone. Uremic patients for whom a cadaveric kidney graft is available, but a pancreas graft is not simultaneously available benefit similarly from a later pancreas transplant. Based on international pancreas registry data, at five years post-transplant, the patient survival rate after PAK is 83%.[12]

Bazerbachi (2012) reviewed a single center’s experience with PAK and synchronous pancreas-kidney (SPK) transplantations.[13] Between 2002 and 2010, 172 pancreas transplants were performed in diabetic patients; 123 SPK and 49 PAK. The median length of time between kidney and pancreas transplantation in the PAK group was 4.8 years. Graft and patient survival rates were similar in the two groups. Death-censored pancreas graft survival rates for SPK and PAK were 94% and 90% at one year, 92% and 90% at three years, and 85% and 85% at five years (all respectively, p=0.93). Patient survival rates (calculated beginning at the time of pancreas transplantation) in the SPK versus PAK groups were 98.3% and 100% after one year, 96.4% and 100% after three years, and 94.2% and 100% after five years (all respectively, p=0.09).

Fridell (2009) reported a retrospective review (n=203) of a single center’s experience with PAK and SPK since 2003, when current induction/tacrolimus immunosuppressive strategies became standard.[14] Of the cases studied, 61 (30%) were PAK and 142 (70%) were SPK. One-year patient survival rates were 98% and 95% (PAK and SPK, respectively; p=0.44). Pancreas graft survival rates at one year were observed to be 95% and 90%, respectively (p=0.28). The authors conclude that in the modern immunosuppressive era, PAK should be considered as an acceptable alternative to SPK in candidates with an available living kidney donor.

Kleinclauss (2009) retrospectively examined data from diabetic kidney transplant recipients (n=307) from a single center and compared renal graft survival rates in those who subsequently received a pancreatic transplant to those who did not.[15] The comparative group was analyzed separately depending on whether they were medically eligible (KTA-E) for pancreas transplant, but chose not to proceed for financial or personal reasons, or were ineligible (KTA-I) for medical reasons. The KTA-I (n=57) group differed significantly at baseline from both the PAK group (n=175) and the KTA-E group (n=75) with respect to age, type of diabetes and dialysis experience; kidney graft survival rates were lower than either of the other groups, with 1-, 5-, and 10-year rates of 75%, 54%, and 22%, respectively (p<0.0001). The PAK and KTA-E groups were similar in age, race, type of diabetes, and dialysis experience. The authors compared 1-, 5-, and 10-year kidney graft survival rates in PAK patients with those in the KTA-E group: 98%, 82%, and 67% versus 100%, 84%, and 62%, respectively, and concluded that the subsequent transplant of a pancreas after a living donor kidney transplant did not adversely affect patient or kidney graft survival rates.

PANCREAS TRANSPLANT ALONE[9]

Boggi (2021) reported results of a single-center cohort study of 66 patients with type 1 diabetes who received PTA.[16] After 10 years of follow-up, patient survival was 92.4%. Of these patients surviving to 10 years, 57.4% had optimal graft function (defined as normoglycemia and insulin independence) and 3.2% had good graft function (defined as HbA1c <7%, no severe hypoglycemia, >50% reduction in insulin requirements, and restoration of clinically significant C-peptide production). Four patients (6.0%) developed end-stage renal failure (stage 5, estimated glomerular filtration rate [eGFR] < 15 ml/min/1.73 m2), and 2 additional patients (3.0%) showed stage 4 kidney failure (eGFR 15-30 ml/min/1.73 m2) at the 10-year posttransplant assessment.

Gruessner and Gruessner (2016) reported updated patient survival rates for PTA.[11] According to UNOS and the International Registry data, for the period of 2010 to 2014, patient survival after PTA was 96.3% after one year and 94.9% after three years. This compares with one-year and three-year patient survival rates of 97.5% and 93.3% for 2005 to 2009, respectively.

According to international registry data one-year graft function increased from 51.5% in 1987-1993 to 77.8% in 2006-2010 (p<0.0001).[12] One-year immunologic graft loss remains higher (6%) after PTA than PAK (3.7%) or SPK (1.8%). In carefully selected IDDM patients with severely disabling and potentially life-threatening complications due to hypoglycemia unawareness and labile diabetes that persists despite optimal medical management, the benefits of PTA were judged to outweigh the risk of performing pancreas transplantation with subsequent immunosuppression. The majority of patients undergoing PTA are those with either hypoglycemic unawareness or labile diabetes. However, other exceptional circumstances may exist where non-uremic IDDM patients have significant morbidity risks due to secondary complications of diabetes (e.g., peripheral neuropathy) that exceed those of the transplant surgery and subsequent chronic immunosuppression. Because there is virtually no published evidence regarding outcomes of medical management in this very small group of exceptional diabetic patients, it is not possible to generalize about which circumstances represent appropriate indications for pancreas transplantation alone. Case-by-case consideration of each patient's clinical situation may be the best option for determining the balance of risks and benefits.

Noting that nephrotoxic immunosuppression may exacerbate diabetic renal injury after PTA,

Scalea (2008) reported a single institutional review of 123 patients who received 131 PTA for development of renal failure.[17] Mean graft survival was 3.3 years (range, 0 to 11.3), and 21 patients were lost to follow-up. Mean estimated glomerular filtration rate (eGFR) was 88.9 pre-transplantation versus 55.6 post-transplantation, with mean follow-up of 3.7 years. All but 16 patients had a decrease in eGFR, and mean decrement was 32.1 mg/min/1.73. Thirteen developed end-stage renal disease, which required kidney transplantation at a mean of 4.4 years. The authors suggested that patients should be made aware of the risk and only the most appropriate patients offered PTA. Future updates of this policy will continue to follow this clinical topic.

PANCREAS RETRANSPLANTATION[18]

Parajuli (2019) compared outcomes among SPK patients who did or did not receive pancreas retransplantation after isolated pancreas graft failure.[19] Among 109 SPK patients with pancreas graft failure, 25 underwent pancreas retransplantation and 84 did not. Mean follow-up time after pancreas graft failure was longer among patients who underwent pancreas retransplantation (7.6 years vs. 4.6 years). Rates of death-censored kidney graft failure at last follow-up were lower among patients who underwent pancreas retransplantation (24% vs. 48%; p=0.04). However, given the retrospective nature of the study, selection bias may have influenced the observed outcomes. Patient survival was not significantly different between groups. Among patients who underwent retransplantation, one-year pancreas graft survival was 84%.

Rudolph (2015) reported higher graft survival rates, but not patient survival rates, after primary transplant.[20] A total of 2145 pancreas transplants were performed, 415 (19%) of which were retransplants. Death-censored graft survival at one year was 88.2% in initial transplants and 75% in retransplants (p=0.06).

Fridell (2015) reported on 441 initial transplants and 20 late transplants.[21] One-year graft survival rates were 92% after initial transplant and 90% after retransplant (p=0.48). Similarly, one-year patient survival rates were 96% after initial transplants and 95% after retransplants (p=0.53).

Siskind (2015) published the largest comparative study to date which included long-term outcomes for 1149 retransplant patients and 19,705 primary transplant patients.[22] Patient data was collected from the UNOS database (1996-2012) and PAK, PTA, PWK and SPK patients were included in the analysis. Adjusted patient survival rates were compared at 1-, 3-, 5-, 10-, and 15-year follow-up. Analysis of 30-day retransplantation outcomes was not performed due to small sample size. Graft survival was significantly worse in the retransplant group compared to primary transplant at all follow-up points, for all transplant types:

Table 1: Graft Survival

Graft Survival	Primary Transplant, %	Retransplant, %	P
1 year	85.44	37.16	<0.0001
3 year	76.86	21.93	<0.0001
5 year	69.23	14.45	<0.0001
10 year	52.26	2.79	<0.0001
15 year	36.96	0.17	<0.0001

Table 2: Patient Survival

Patient Survival	Primary Transplant, %	Retransplant, %	P
1 year	94.83	98.99	<0.0001
3 year	90.20	96.67	<0.0001
5 year	85.41	93.19	<0.0001
10 year	71.85	79.80	<0.0001
15 year	58.86	54.93	<0.0001

Authors speculated that the improved survival rates in the retransplantation group could be attributed to retransplantation of the kidney with the pancreas versus pancreas alone; however, subgroup analysis did not support this hypothesis. These study findings significantly differ from previous nonrandomized comparative studies which have indicated pancreas retransplantation has comparable graft survival rates to primary transplant.

The OPTN has reported data on transplants performed between 2008 and 2015.[2] Patient survival rates after repeat transplants were similar to survival rates after primary transplants. For example, the one-year survival rate was 91.0% (95% CI, 88.7% to 92.8%) after a primary pancreas transplant and 96.4% (95% CI, 92.1% to 98.4%) after a repeat pancreas transplant. The numbers of patients transplanted were not reported, but OPTN data stated that 663 patients were alive one year after primary transplant and 154 after repeat transplants. The three-year patient survival rate was 87.5% (95% CI, 85.1% to 89.6%) after primary transplants and 91.2% (95% CI, 86.2% to 94.4%) after repeat transplants. The five-year patient survival rate was 79.9% (95% CI, 77.4% to 82.2%) after primary transplants and 83.7% (95% CI, 78.2% to 88.0%) after repeat transplants. The one-year graft survival rate was 81.8% (95% CI, 78.9% to 84.3%) after primary pancreas transplant and 77.7% (95% CI, 70.8% to 83.1%) after repeat transplant.

Data are similar for patients receiving SPK transplants, but follow-up data are only available on a small number of patients who had repeat SPK transplants, so estimates of survival rates in this group are imprecise. Three-year patient survival rate was 94.8% (95% CI, 93.9% to 95.5%) after primary SPK transplant and 87.9% (95% CI, 73.4% to 94.8%) after a repeat SPK transplant. The number of patients living 3 years after transplant was 2871 after a primary combined procedure and 36 after a repeat combined procedure.

Seal (2014) reported on 96 consecutive PTA patients treated at a single center in Canada; 78 were initial transplants, and 18 were retransplants.[23] Pancreas graft survival was similar for primary transplants and retransplants at one year (88% vs 100%, p=0.88) and three years (85% in both groups, p=0.99). Patient survival rates were also similar in the two groups at one year (96% and 100%, p=0.95) and three years (93% and 100%, p=0.93).

Buron (2013) reported on their experience with pancreas retransplantation in France and Geneva.[24] Between 1976 and 2008, 568 pancreas transplants were performed at two centers, including 37 repeat transplants. Patient survival after a repeat pancreas transplant was 100% after one year and 89% after five years. Graft survival was 64% at one year and 46% at five years. Among the 17 patients who underwent a second transplant in a later time period i.e., between 1995 and 2007, graft survival was 71% at one year and 59% at five years. In this more recently transplanted group, graft survival rates were similar to primary pancreas transplants which was 79% at one year and 69% at five years.

Studies for pancreatic retransplantation are limited to retrospective reviews and non-randomized feasibility studies. The evidence for graft and patient survival following the first retransplantation of the pancreas following PAK, PTA, or SPK transplantation has shown

outcomes similar to primary transplantation.[20, 25-29] No clinical trials were found that reported survival outcomes following more than one retransplantation.

HIV+ TRANSPLANT RECIPIENTS

The Organ Procurement Transfer Network (OPTN) permits HIV test positive patients as organ candidates if permitted by the transplant hospital.[25]

The American Society of Transplantation (2019) published a guideline on solid organ transplantation in HIV-infected patients.[30] For kidney-pancreas transplants, the following criteria for transplantation are suggested:

- Cluster of differentiation 4 count >200 cells/mL for at least 3 months (insufficient data to recommend for or against transplantation in patients with counts >100 cells/mL and no history of opportunistic infection)
- Undetectable HIV viral load while receiving antiretroviral therapy
- Documented compliance with a stable antiretroviral therapy regimen
- Absence of active opportunistic infection and malignancy
- Absence of chronic wasting or severe malnutrition
- Appropriate follow-up with providers experienced in HIV management and ready access to immunosuppressive medication therapeutic drug monitoring
- The guideline authors note that patients with a previous history of progressive multifocal leukoencephalopathy, chronic interstitial cryptosporidiosis, primary central nervous system lymphoma, or visceral Kaposi's sarcoma were excluded from studies of solid organ transplantation in HIV-infected patients. Patients with HIV and concomitant controlled hepatitis B infection may be considered for transplant. Caution is recommended in hepatitis C-coinfected patients who have not been initiated on direct acting antiviral therapy.

A retrospective analysis of all deceased donor pancreas transplants performed in the U.S. between 1988 and 1999 revealed that since the mid-1990's allograft half-lives ranged from eight to nine years for PTA transplants to nearly 13 years for SPK transplants.[31] The data indicates that insulin-independence with functioning grafts can been achieved for longer than 20 years.

AGE

In the past 5 to 10 years, several analyses of outcomes by patient age group have been published and there is now general agreement among experts that age should not be a contraindication; however, age-related comorbidities are important to consider when selecting patients for transplantation.

Siskind (2014) used data from the United Network for Organ Sharing (UNOS) database to publish the largest study of pancreas outcomes by recipient age.[32] Investigators included all adult patients who received SPK or PTA between 1996 and 2012 (n=20,854). There were 3160 patients between the ages of 50 and 59 years, and 280 patients age 60 or older. Overall, Kaplan-Meier survival analysis found statistically significant differences in patient survival ($p<0.001$) and graft survival ($p<0.001$) among age categories. Graft survival was lowest in the 18- to-29 age group at 1, 5, and 10 years, which the authors noted might be due to early immunological graft rejection due to more robust immune responses. However, 10 and 15 year graft survival was lowest in the 60 and older age group. Patient survival rates decreased with increasing age, and the differential between survival in older and younger ages increased with

longer follow-up intervals. Lower survival rates in patients 50 and older could be due in part to comorbidities at the time of transplantation. Also, as patient age, they are more likely to die from other causes. Still, patient survival at 5 and 10 years was relatively high, as shown in Table 3.

Table 3: Patient Survival by Age Group[32]

	Age 18-29, %	Age 30-39, %	Age 40-49, %	Age 50-59, %	Age 60+, %
1 year	95.4	96.0	94.9	93.3	91.0
5 years	86.3	87.8	85.7	81.6	71.4
10 years	73.5	76.8	71.8	61.5	42.5

Shah (2013) reviewed data on 405 patients who underwent PTA between 2003 and 2011.[33] One-year patient survival was 100% for patients younger than age 30, 98% for patients age 30 to 39 years, 94% for patients 40 to 49 years, 95% for patients 50 to 59 years and 93% for patients age 60 or older. There was not a statistically significant difference in the rate of patient survival by age (p=0.38). Findings were similar for one-year graft survival; there was not a statistically significant difference in outcomes by age of the transplant recipients (p=0.10).

Afaneh (2011) reviewed data on 17 individuals at least 50-years-old and 119 individuals younger than 50 who had a pancreas transplant at a single institution in the U.S.[34] The two groups had similar rates of surgical complications, acute rejection and non-surgical infections. Overall patient survival was similar. Three- and five-year survival rates were 93% and 90% in the younger group and 92% and 82% in the older group.

Schenker (2011) in Germany compared outcomes in 69 individuals at least 50-years-old and 329 individuals younger than 50 years who had received a pancreas transplant.[35] Mean duration of follow-up was 7.7 years. One-, five-, and 10-year patient and graft survival rates were similar in the two groups. For example, the five-year patient survival rate was 89% in both groups. The five-year pancreas grant survival rate was 76% in the older group and 72% in the younger group. The authors of both studies, as well as the authors of a commentary accompanying the Schenker article,[36] agreed that individuals age 50 years and older are suitable candidates for pancreas transplantation.

PRACTICE GUIDELINE SUMMARY

AMERICAN DIABETES ASSOCIATION

The American Diabetes Association (ADA) Position Statement made the following recommendations on kidney and pancreas transplantation for patients with type 1 diabetes:[37]

- “Consider solid organ pancreas transplantation simultaneously with kidney transplantation in patients with type 1 diabetes who have an indication for kidney transplantation and are poorly controlled with large glycemic excursions. (B)”
- “Consider solid organ pancreas transplantation after kidney transplantation in adult patients with type 1 diabetes who have already received a kidney transplant. (C)”
- “Judiciously consider solid organ pancreas transplantation alone in adults with type 1 diabetes, unstable glucose control, hypoglycemia unawareness, and an increased risk of diabetes-related mortality, who have attempted all of the more traditional approaches to glycemic control and have remained unsuccessful, yet are judged responsible enough to manage the antirejection medication regimen, risks, and follow-up required with an organ transplant. (C)”

ORGAN PROCUREMENT AND TRANSPLANTATION NETWORK

The Board of Directors of the Organ Procurement and Transplantation Network (OPTN) issues an updated comprehensive list of transplant related policies regularly, most recently June 2023.[25]

Each candidate registered on the pancreas waiting list must meet *one* of the following requirements:

- Be diagnosed with diabetes
- Have pancreatic exocrine insufficiency
- Require the procurement or transplantation of a pancreas as part of a multiple organ transplant for technical reasons

Each candidate registered on the kidney-pancreas waiting list must meet *one* of the following requirements:

- Be diagnosed with diabetes
- Have pancreatic exocrine insufficiency, with renal insufficiency

In addition, waiting time criteria indicated that for kidney-pancreas transplant candidates 18 years and older, candidates must meet *all* of the following conditions:

1. The candidate is registered for a kidney-pancreas.
2. The candidate qualifies for kidney waiting time according to *Policy 8.4: Waiting Time*.
3. The candidate is on insulin.

The OPTN policy also delineated pancreas, kidney-pancreas, and islet allocation, classifications, and rankings.

SUMMARY

SIMULTANEOUS PANCREAS-KIDNEY TRANSPLANTATION (SPK)

There is enough research to show that simultaneous pancreas kidney (SPK) improves outcomes (e.g., normalizes insulin production and kidney function, improves quality of life, and improves diabetic complications) for patients with diabetes. Therefore, SPK transplantation for patients with diabetes may be medically necessary when policy criteria are met.

PANCREAS AFTER KIDNEY TRANSPLANT (PAK)

There is enough research to show that pancreas after kidney transplant (PAK) improves health outcomes for patients with diabetes. The International Pancreas Transplant Registry provides information that PAK improves health outcomes in some patients with diabetes who have previously received a successful kidney transplant. Therefore, PAK transplantation for patients with diabetes may be considered medically necessary when policy criteria are met.

PANCREAS TRANSPLANT ALONE (PTA)

There is enough research to show that pancreas transplantation improves health outcomes including quality of life and reduce short complications for patients with diabetes. Therefore,

pancreas transplantation for patients with diabetes that have conditions which persist after optimal medical management may be considered medically necessary when policy criteria are met.

RETRANSPLANTATION

There is enough research to show that the health outcomes for pancreas retransplantation recipients appear similar to those reported for initial transplants. Therefore, retransplantation after one failed primary pancreas transplant may be considered medically necessary when policy criteria are met.

There is not enough research to show that a third or subsequent pancreas transplant improves health outcomes and there are documented safety concerns. Therefore, a third or subsequent pancreas transplant including simultaneous kidney-pancreas transplant, pancreas after kidney transplant, or pancreas alone transplant are considered not medically necessary when policy criteria are not met.

Medical Policy Manual Transplant, Policy No. 08

Lung and Lobar Lung Transplant

Effective: June 1, 2023

Next Review: March 2024
Last Review: April 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

A lung transplant consists of replacing all or part of diseased lungs with healthy lung(s). Transplantation is an option for patients with end-stage lung disease.

MEDICAL POLICY CRITERIA

I. Lung transplantation may be considered **medically necessary** for carefully selected patients with irreversible, progressively disabling, end-stage pulmonary disease unresponsive to maximum medical therapy.

II. A lobar lung transplant from a living or deceased donor may be considered **medically necessary** for carefully selected patients with end-stage pulmonary disease.

III. Lung or lobar lung retransplantation after a failed lung or lobar lung transplant may be considered **medically necessary** in patients who meet either criterion I or II.

IV. Lung or lobar lung transplantation is considered **not medically necessary** in all other situations.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

End-stage pulmonary disease may include, but is not limited to, the following diagnoses:

- Alpha-1 antitrypsin deficiency
- Bilateral bronchiectasis
- Bronchiolitis obliterans
- Bronchopulmonary dysplasia
- Chronic obstructive pulmonary disease
- Cystic fibrosis (both lungs to be transplanted)
- Eisenmenger's syndrome
- Emphysema
- Eosinophilic granuloma
- Idiopathic/interstitial pulmonary fibrosis
- Lymphangiomyomatosis
- Postinflammatory pulmonary fibrosis
- Primary pulmonary hypertension
- Pulmonary hypertension due to cardiac disease
- Recurrent pulmonary embolism
- Sarcoidosis
- Scleroderma

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

CROSS REFERENCES

BACKGROUND

End-stage lung disease may be the consequence of a number of different conditions. The most common indications for lung transplantation are chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis, cystic fibrosis, alpha-1 antitrypsin deficiency, and idiopathic pulmonary arterial hypertension. Prior to the consideration for transplant, patients should be receiving maximal medical therapy, including oxygen supplementation, or surgical options, such as lung-volume reduction surgery for COPD. Lung or lobar lung transplantation is an option for patients with end-stage lung disease despite these measures.

A lung transplant refers to single-lung or double-lung replacement. In a single-lung transplant, only one lung from a deceased donor is provided to the recipient. In a double-lung transplant, both the recipient's lungs are removed and replaced by the donor's lungs. In a lobar transplant, a lobe of the donor's lung is excised, sized appropriately for the recipient's thoracic dimensions, and transplanted. Donors for lobar transplant have primarily been living-related

donors, with one lobe obtained from each of two donors (e.g., mother and father) in cases for which bilateral transplantation is required. There are also cases of cadaver lobe transplants. Combined lung-pancreatic islet cell transplant is being studied for patients with cystic fibrosis.[1]

Potential recipients who are 12 years of age and older are ranked according to the Lung Allocation Score (LAS).[2] A score may range between 1 and 100 and incorporates predicted survival after transplantation and predicted survival on the waiting list; the LAS takes into consideration the patient's disease and clinical parameters. Waiting list incorporates the LAS, geography, and blood type classifications. Children younger than age 12 years old receive a priority for lung allocation. Under this system, children younger than 12 years old with respiratory lung failure and/or pulmonary hypertension who meet criteria are considered "priority 1" and all other candidates in the age group are considered "priority 2." A lung review board has the authority to adjust scores on appeal for adults and children.

EVIDENCE SUMMARY

Due to the nature of the population, there are no randomized controlled trials (RCTs) that compare lung transplantation with alternatives. Systematic reviews are based on case series and registry data. The extant RCTs compare surgical technique, infection prophylaxis, or immunosuppressive therapy and are not germane to this policy. Therefore, the following is a summary of the evidence based on registries, case series, and expert opinion.

SURVIVAL

The Registry of the International Society for Heart and Lung Transplantation (ISHLT) contains data from 49,453 adult recipients who received lung transplantation (including lung retransplantation) through June 30, 2015, at 134 transplant centers.[3] A total of 55,795 lung transplants were performed, of which 53,522 (95.9%) were primary transplants and 2,273 (4.1%) were retransplants. The overall median survival of patients who underwent lung transplantation was 5.8 years. Estimated unadjusted survival rates were 89% at three months, 80% at one year, 65% at five years, and 32% at 10 years. Patients who survived a year after primary transplantation had a median survival of 8.0 years. In the first 30 days after transplantation, the major reported causes of mortality were graft failure (24.5%) and non-cytomegalovirus (CMV) infections (19.1%), while non-CMV infections became the major cause of death for the remainder of the first year. Beyond the first year, the most common reported causes of mortality were obstructive bronchiolitis/bronchiolitis obliterans syndrome (OB/BOS), graft failure, and non-CMV infections. Beyond 10 years post-transplant, the major causes of mortality were OB/BOS (21.5%), non-CMV infection (16.5%) and non-lymphoma malignancy (13.7%).

The ISHLT registry contains a total of 2,229 pediatric lung transplants performed through 2014.[4] Most transplants (73%) were done in older children between the ages of 11 to 17 years. Median survival in children who underwent lung transplantation was 5.4 years, similar to survival in adults (mean survival, 5.7 years). However, median survival in children was lower (2.2 years) than in adults (5.6 years) for single-lung transplants.

Black (2014) published results from an analysis of lung transplants using data from the United Network for Organ Sharing's (UNOS) Scientific Registry of Transplant Recipients from 1994 to June 2012.[5] The goal of the analysis was to evaluate how survival was affected in patients who had a high lung allocation score (LAS) and received a single versus a double lung

transplant. In all, there were 8,778 patients identified; however, just 8,050 had a LAS less than 75, and 728 has a LAS greater than or equal to 75. Kaplan-Meier survival curves stratified by high and low LAS, and by single versus double lung transplants, showed a significant decrease in survival ($p<0.001$) in those with a high LAS who received a single lung transplant when compared with those with a high LAS who received a double lung transplant. The authors, that despite a higher operative morbidity, patients who had a high LAS did substantially better in terms of survival if two lungs were transplanted rather than only one, with a larger difference in survival than for patients with a lower LAS.

Yu (2019) compared double-lung with single-lung transplantations for outcomes of survival, pulmonary function, surgical indicators, and complications in a meta-analysis of 30 studies (n=1,980 recipients of single-lung transplants and n=2,112 recipients of double-lung transplants).[6] Overall survival, in-hospital mortality, and postoperative complications besides bronchiolitis obliterans syndrome were similar between the two groups. Recipients of double-lung transplants had lower rates of bronchiolitis obliterans syndrome, better postoperative lung function, improved long-term survival, while recipients of single-lung transplants spent less time in surgery, postoperative intensive care unit, and postoperative hospital stay.

Thabut (2009) reported on a comparison of patients undergoing single- and double-lung transplantation for idiopathic pulmonary fibrosis.[7] A retrospective review was conducted of 3,327 patients with data in the UNOS registry. More patients underwent single-lung as compared to double-lung transplant (64.5 vs. 35.5%, respectively). Median survival time was greater for the double-lung group at 5.2 years (95% CI 4.3 to 6.7 years) versus 3.8 years (95% CI 3.6 to 4.1 years, $p<0.001$). After adjustment for baseline differences, however, survival times were not statistically different. The authors concluded that overall survival did not differ between the two groups: single-lung transplants offered improved short-term survival but long-term harm, whereas double-lung transplant increased short-term harm but was associated with a long-term survival benefit. Later, Black (2014) reported on the LAS and single- versus double-lung transplant in 8,778 patients (8,050 had an LAS less than 75 and 728 had an LAS of 75 or higher).[5] A significant decrease in survival was seen in single-lung transplant patients with a high LAS compared with double-lung transplant patients with a high LAS, even though operative morbidity was higher ($p<0.001$).

Hayanga (2016) analyzed lung transplantation data from the UNOS registry between 2005 and 2013.[8] Survival was analyzed in relation to the annual volume of lung transplants performed at each center: less than 20, 20-29, 30-39, and 40 or more. During the study period, 13,506 adults underwent lung transplantation. Approximately 40% of the transplants were performed in centers with a volume of 40 or more, with the remaining transplants spread relatively equally across lower volume center groups. Both one- and five-year patient survival tended to increase with increasing volume, but the authors noted that it was a relatively small effect.

Kistler (2014) reported on a systematic review of the literature on waitlist and posttransplant survival for idiopathic pulmonary fibrosis.[9] Estimated median survival of idiopathic pulmonary fibrosis patients posttransplantation is estimated at 4.5 years and is lower than other underlying pretransplant diagnoses. From ISHLT and the Organ Procurement and Transplantation Network (OPTN) data, one-year survival ranged from 75% to 81%; three-year, 59% to 64%, and five-year, 47% to 53%. Limited data were available on posttransplant morbidity outcomes.

Taimeh (2016) reported on post-lung transplant survival in 695 patients with pulmonary sarcoidosis in the U.S.[10] Survival in this group was similar to that of non-sarcoid lung recipients, and in a multivariate analysis, sarcoidosis was not associated with higher mortality. In the sarcoidosis group, LAS and double lung transplantation were both associated with improved survival.

PATIENT SELECTION

Based on concern that the LAS may prioritize lung transplant candidates with a poor expected survival benefit from the procedure, Li (2019) analyzed data from the UNOS registry (n=21,157) to determine whether there was a LAS threshold above which the score did not predict increasing survival benefit.[11] The results of this analysis indicated that the greatest benefit was seen for recipients with scores between 70 and 79 (n=365), with a hazard ratio of death after undergoing transplantation relative to remaining on the waitlist of 0.2 (95% CI 0.1 to 0.3). Survival for patients with LAS scores above this range was not significantly increased. The authors noted that the survival benefit threshold for patients with cystic fibrosis was quite a bit lower, at a score of approximately 50.

Shafii (2014) reported on a retrospective evaluation of the LAS and mortality in 537 adults listed for lung transplantation, and 426 who underwent primary lung transplantation between 2005 and 2010.[12] Patients on the waitlist who had a higher LAS had a higher rate of mortality ($p<0.001$). In the highest quartile of LAS, ranging from 47 to 95, within one year of listing, there was a 75% mortality rate. Higher LAS was also associated with early posttransplant survival ($p=0.05$) but not late posttransplant survival ($p=0.4$). When other predictive factors of early mortality were accounted for, pretransplant LAS was not independently related to posttransplant mortality ($p=0.12$).

Russo (2011) analyzed a dataset of 6,082 patients who received a lung transplant between May 4, 2005 and May 4, 2009 in order to describe outcomes and estimate the survival benefit based upon patient lung allocation score.[13] Authors found that although lower priority patients comprise the majority of transplants, mid-priority groups with LAS of 50 to 79, seemed to achieve the greatest survival benefit from transplantation (2.81 to 3.49 years). Patients with the highest and lowest LAS score achieved the least survival benefit; however, it was noted that patients with high allocation scores were expected to have worse survival and that patients with lower LAS had the lowest risk of death on the waiting list. Data suggested that transplant centers may be justified in considering patients for lung transplantation who had a mid-range allocation scores before patients with the highest and lowest scores.

Yusen (2010) reviewed the effect of the LAS on lung transplantation by comparing statistics for the period before and after its implementation in 2005.[14] Other independent changes in clinical practice, which may affect outcomes over the same period of time, include variation in immunosuppressive regimens, an increased supply of donor lungs, changes in diagnostic mix, and increased consideration of older recipients. Deaths on the waiting list declined following implementation of the LAS system, from approximately 500 per 5,000 patients to 300 per 5,000 patients. However, it is expected that implementation of the LAS affected patient characteristics of transplant applicants. One-year survival post-transplantation did not improve after implementation of the LAS system: patient survival data before and after are approximately 83%. More recently, Shafii (2014) reported on a retrospective evaluation of the LAS and mortality in 537 adults listed for lung transplantation and 426 who underwent primary lung transplantation between 2005 and 2010.[12] Patients on the waitlist who had a higher LAS

had a higher rate of mortality (p<0.001). In the highest quartile of LAS, ranging from 47 to 95, within one year of listing, there was a 75% mortality rate. Higher LAS was also associated with early posttransplant survival (p=0.05) but not late posttransplant survival (p=0.4). When other predictive factors of early mortality were accounted for, pretransplant LAS was not independently related to posttransplant mortality (p=0.12).

Gries (2010) published results from a study on pre-transplant characteristics of 10,128 patients from the Organ Procurement and Transplantation Network (OPTN) database were examined to understand how well LAS post-transplant survival model parameters predict one- and five-year survival.[15] Authors concluded that the LAS system and pre-transplant characteristics in general did not predict long term one- or five-year survival better than chance.

Kozower (2008) performed a retrospective cohort study using data from five academic medical centers to evaluate the impact of the LAS on short-term outcomes after lung transplantation.[16] (The LAS was implemented in May 2005 by the OPTN.) This score changed lung allocation from a system based on waiting time to an algorithm based on the probability of survival for one year on the transplant list and survival one-year post-transplantation. Results were compared for 170 patients who received transplants based on the new lung allocation scores (May 4, 2005 to May 3, 2006) with those of 171 patients who underwent transplants the preceding year before implementation of the scoring system. Waiting time decreased from 681 to 445.6 days (p<0.001). Recipient diagnoses changed, with an increase (15% to 25%) in idiopathic pulmonary fibrosis cases and decreases in emphysema (46% to 34%) and cystic fibrosis (23% to 13%). Hospital mortality and one-year survival were the same between groups (5.3% vs. 5.3% and 90% vs. 89%, respectively). Presumably due to increased severity of illness, the incidence of primary graft dysfunction and postoperative intensive care unit length of stay increased in the year after implementation of the scoring system; graft dysfunction grew from 14.8% (24/170) to 22.9% (39/171); (p=0.04) and length of stay rose from 5.7 to 7.8 days.

PEDIATRIC CONSIDERATIONS

A retrospective cohort study from 150 centers worldwide was conducted by Nelson (2021).[17] The results compared outcomes of 2232 pediatric patients with or without cystic fibrosis that underwent lung transplantation between 1990 and 2017. The primary outcomes were all-cause mortality and graft failure at timepoints of 30 days, one year, five years, and 10 years. The proportion of patients undergoing lung transplantation without cystic fibrosis is increasing where nearly half of primary pediatric lung transplantations are performed for other indications. These patients without cystic fibrosis were younger, more commonly receiving intensive care, were on inotropes and/or extracorporeal membrane oxygenation (ECMO). Mortality was higher for non-cystic fibrosis patients after 30 days compared to patients with cystic fibrosis. A diagnosis of pulmonary arterial hypertension was also a risk factor for pediatric patients without cystic fibrosis at one and five years. However, long-term survival was higher in these patients without cystic fibrosis comparatively.

Paraskeva (2018) analyzed survival rates of adolescent lung transplant recipients using data from the ISHLT registry.[18] Patients between 10 and 24 years old represented 9% of the registry data (n=2,319) and they were compared with both old and young cohorts. Overall survival in the adolescent cohort was 65% at three years, which was similar to that observed in adults between 50 and 65 years of age, but significantly lower than the three-year survival

rate among the pediatric subgroup (73%, p=0.006) and adults 25 to 34 years old (75%, p<0.001) and 35 to 49 years old (71%, p<0.001). Within the adolescent group, patients between 15 and 19 years of age had the poorest survival rates at three years (59%) compared with 10- to 14-year year old patients (73%, p<0.001) and 20- to 24-year old patients (66%, p<0.001). The registry study was biased toward inclusion of North American data and potential data entry errors or missing data. There were no data reported on cause of mortality, differences in regimens, or rates of graft dysfunction between the groups.

Benden (2012) reviewed pediatric lung transplants that have been reported to the international registry.[19] Pediatric patients are defined as those younger than 18 years of age. The authors noted an increase in the number of pediatric lung transplants in recent years; there were 126 transplants in 2010 compared to 73 in 2000. In contrast to adult patients, the most common indication for pediatric patients was cystic fibrosis, accounting for 54% of lung transplants in 6- to 11-year-olds and 72% of lung transplants in 12- to17-year-olds that occurred between 1990 and June 2011. Survival has improved in the recent era, and five-year survival is not significantly different from adult recipients. The half-life, estimated time at which 50% of recipients have died, was 4.7 years for children and 5.3 years for adults. For children receiving allografts between 2002 and June 2010, the five-year survival rate was 54% and seven-year survival was 44%. Patients aged 1 to 11 years had a significantly better survival rate than those between the ages of 12 and 17 years (half-life of 6.2 years and 4.3 years, respectively). In the first year after lung transplantation, non-CMV infection and graft failure were the two leading causes of death. Bronchiolitis obliterans syndrome was the major cause of death beyond three years after transplantation.

Moreno (2016) compared survival and clinical outcomes in pediatric and adult lung transplantation for cystic fibrosis at a single institution.[20] There were 120 patients included in the study: 50 children and 70 adults, who underwent 111 bilateral, four lobar, four combined and one unilateral lung transplant. Overall survival for children at five, ten, and 15 years was 57, 45, and 35% vs, 67, 55, and 43% for adults, respectively (p=0.32). Pediatric patients were significantly more likely than adults to have used cardiopulmonary bypass (56% vs. 28%, p=0.002), have acute rejection episodes (1.4 ± 0.7 vs. 1.2 ± 0.8, p=0.004), and stay longer in intensive care (20 ± 19 vs. 10 ± 9 days, p=0.006). The authors noted that pediatric cystic fibrosis patients presenting for lung transplant tend to have a worse status than adult patients, which might explain some of these differences.

Mangiameli (2016) reported on outcomes of pediatric lung transplantation at a center in France, with a focus on sex matching of donors and recipients.[21] In this study, which included 58 patients below age 18, the 30-day mortality was 10% and survival at one, five, and 10 years was 81%, 60%, and 57%, respectively. Among these patients, female sex and sex mismatching were associate with poor prognosis, with female recipients of male-donated organs having particularly poor outcomes.

A study by Fraser (2019) used information from the UNOS database to examine the role of size mismatch in preadolescent lung transplantation.[22] There were 540 patients included in the analysis, which found that one-year mortality was higher for patients with height and weight mismatching, and for predictive total lung capacity ratios less than 0.9 (p=0.017)

POTENTIAL CONTRAINDICATIONS

Malignancy

Concerns regarding a potential recipient's history of cancer have been based on the observation of significantly increased incidence of cancer in kidney transplant patients.[23] For renal transplant patients who had a malignancy treated prior to transplant, the incidence of recurrence ranged from zero to more than 25%, depending on the tumor type.[24, 25] However, it should be noted that the availability of alternative treatment strategies informs recommendations for a waiting period following high-risk malignancies: in renal transplant, a delay in transplantation is possible due to dialysis; end-stage lung disease patients may not have an option to defer.

A 2012 study reported on outcomes in patients with lung cancer who were lung transplant recipients.[26] Ahmad and colleagues identified 29 individuals in the UNOS database who underwent lung transplantation for advanced bronchoalveolar carcinoma (BAC). These patients represented 0.13% of the 21,553 lung transplantations during the study period. BAC and general lung transplant recipients had similar survival rates: the 30-day mortality rate was 7% versus 10% (p=0.44) and five-year survival rate was 50% versus 57% (p=0.66), respectively.

Human Immunodeficiency Virus (HIV)

The current Organ Procurement Transplantation Network (OPTN) policy permits HIV-positive transplant candidates.[27] The 2020 US Public Health Service guideline also allows for transplantations in HIV-positive recipients with proper screenings and effective regimens for HIV infections.[28]

Other Infections

Infection with *Burkholderia cenocepacia* is associated with increased mortality in some transplant centers, a factor that may be considered when evaluating overall risk for transplant survival.[29]

A 2016 analysis of international registry data found that non-CMV infection is a major cause of mortality within 30 days of lung transplant in adults.[3] A total of 655 (19%) of 3,424 deaths after transplants between January 1990 and June 2015 were due to non-CMV infection. Only three (0.1%) of the deaths were due to CMV infection.

Wojarski (2018) assessed the impact of bacterial infection on mortality in 97 lung transplant patients from a single center between 2004 and 2016.[30] The mean hospitalization time was 57 days, and 67 patients had a total of 120 episodes of bacterial infection. The most common sources of infection were *Pseudomonas aeruginosa* (27%), followed by *Acinetobacter baumannii* (21%), and *Stenotrophomonas maltophilia* (11%). There were 39 patients who developed bronchiolitis obliterans syndrome. *A. baumannii* infection was associated with decreased survival, while treatment with mammalian target of rapamycin inhibitors was linked to increased survival.

Lobo (2013) reported on 13 lung transplant patients with *Mycobacterium abscessus* in cystic fibrosis.[31] Survival rates were 77%, 64% and 50% after transplant at one, three, and five years, respectively. These results were not significantly different when compared to 154 cystic fibrosis patients treated with lung transplantation who did not have *M. abscessus* (p=0.8).

Shields (2012) reported on infections in 596 consecutive lung transplant recipients treated at a single center occurring in the first 90 days after transplantation.[32] A total of 109 patients

(18%) developed 138 *Staphylococcus aureus* (*S. aureus*) infections. The most common type of infection was pneumonia (66 of 138, 48%) followed by tracheobronchitis (36 of 138, 26%) and bacteremia (17 of 138, 12%). Thirteen of 109 (12%) of patients with *S. aureus* infection died within 90 days of the onset of infection. The one-year mortality rate was higher for patients with *S. aureus* pneumonia (19 of 66, 29%) but not *S. aureus* tracheobronchitis (8 of 36, 22%) compared with uninfected patients (85 of 487, 17%).

Pinney (2011) published results from a retrospective review of invasive fungal infection rates in lung transplantation patients without cystic fibrosis treated at a single center.[33] Patients were followed for a median of 34 months. Invasive fungal infections were identified in 22 of 242 (9.1%) patients. *Aspergillus* infections were most common, occurring in 11 of 242 (4.5%) of patients. There were also seven cases (3%) of *Candida* infection. Survival rates did not differ significantly in patients with invasive fungal infections compared to the entire cohort of patients. For example, three-year survival was 50% among patients with invasive fungal infection and 66% in the entire cohort (p=0.66). The authors did not compare survival in patients with invasive fungal infections to survival only in those without invasive fungal infections.

In a study published by Murray (2008), multivariate Cox survival models assessing hazard ratios (HRs) were applied to 1,026 lung transplant candidates and 528 transplant recipients.[34] Of the transplant recipients, 88 were infected with *Burkholderia*. Among transplant recipients infected with *Burkholderia cenocepacia,* only those infected with nonepidemic strains (n=11) had significantly greater post-transplant mortality than uninfected patients (HR 2.52, 95% CI 1.04 to 6.12, p=0.04). Transplant recipients infected with *Burkholderia gladioli* (n=14) also had significantly greater post-transplant mortality than uninfected patients (HR 2.23, 95% CI 1.05 to 4.74, p=0.04). When adjustments for specific species/strains were included, lung allocation scores of *Burkholderia multivorans*-infected transplant candidates were comparable to uninfected candidate scores, and scores for patients infected with non-epidemic *B. cenocepacia* or *B. gladioli* were lower. In a smaller study of 22 patients colonized with *Burkholderia cepacia* complex who underwent lung transplantation in two French centers, the risk of death by univariate analysis was significantly higher for the eight patients infected with *B. cenocepacia* than for the other 14 colonized patients (11 of whom had *B. multivorans*).[35]

Coronary Artery Disease (CAD)

Castleberry (2013) reported on a retrospective cohort study of lung transplantation with concurrent CAB or preoperative percutaneous coronary intervention (PCI).[36] Out of 898 lung transplants performed during the period between 1997 and 2010, 49 patients also had concurrent CAB and 38 patients had preoperative PCI. All of the intervention groups, including revascularization, had similar rates of perioperative mortality, overall unadjusted survival and adjusted HR for cumulative risk of death. Postoperative major adverse cardiac event rates were also similar among groups, although postoperative length of stay, intensive care unit time and need for ventilator support increased in patients receiving concurrent CAB with lung transplantation.

Sherman (2011) reported on outcomes in 27 patients with CAD at a single center who underwent lung transplantation and coronary revascularization.[37] Patients needed to be otherwise considered good candidates for transplantation and have discrete coronary lesions (at least 50% in the left main artery or at least 70% in other major vessels) and preserved

ejection fraction. Thirteen patients had single-lung transplantation and 14 had double-lung transplantation. Outcomes were compared with a control group of 81 patients without CAD who underwent lung transplantation; patients were matched for age, diagnosis, lung allocation score and type of procedure. During a mean follow-up of three years, nine of 27 (33%) patients with CAD and 28 of 81 (35%) without CAD died (p=0.91). Bronchiolitis obliterans and infection were the primary causes of death. There was no significant difference between groups in a composite outcome of adverse cardiac events (defined as acute coronary syndrome, redo revascularization or hospital admissions for congestive heart failure), p=0.80.

LOBAR LUNG TRANSPLANTATION

Several case series have reported outcomes after lobar lung transplants in both children and adults.

Eberlein (2017) published a systematic review of studies on lobar lung transplantation from deceased donors.[38] Reviewers identified nine studies comparing outcomes after lobar lung or lung transplant, all of which were single-center retrospective cohort studies. Seven studies were conducted in Europe, one in Australia, and one in North America. One-year survival reported in individual studies ranged from 50% to 100% after lobar lung transplant and from 72% to 88% after conventional lung transplant. In a pooled analysis of data from eight studies, lobar lung transplant recipients (n=284) had a significantly higher risk of one-year mortality than lung transplant recipients (n=2,777) (relative risk [RR] 1.85, 95% CI 1.52 to 2.25, p<0.001, I^2=0%).

Date (2014) reported on a retrospective study comparing 42 living-donor lobar lung transplants and 37 cadaveric lung transplants.[39] Survival rates at one and three years were not significantly different between the groups (89.7 and 86.1% vs 88.3 and 83.1%, respectively, p=0.55), despite living-donor lobar lung transplant patients having poorer health status preoperatively.

Slama (2014) reported on a comparison of outcomes in 138 cadaveric lobar lung transplants (for size discrepancies) to 778 patients who received cadaveric whole-lung transplants, 239 of whom had downsizing by wedge resection of the right middle lobe and/or the left lingula.[40] Survival in the lobar lung transplant group at one and five years was 65.1% and 54.9% versus 84.8% and 65.1% in the whole lung and downsized by wedge resection group (p<0.001). The lobar lung transplantation group experienced significantly inferior early postoperative outcomes, but in patients who were successfully discharged, survival rates were similar to standard lung transplantation (p=0.168).

In 2012, a program in Japan reported on 14 critically ill patients who had undergone single living-donor lobar lung transplants; there were ten children and four adults.[41] Patients were followed for a mean 45 months. The three-year survival rate was 70% and the five-year survival was 56%. Severe graft dysfunction occurred in four patients. Mean forced vital capacity (FVC) was found to be lower in patients experiencing severe graft dysfunction compared to the other patients, mean FVC was 54.5% and 66.5%, respectively. The authors stated that this suggests size mismatching in the patients with severe graft dysfunction. The same year, Inci (2012) published data on 23 patients in Switzerland who received bilateral lobar lung transplants.[42] The mean age was 41 years (range 13 to 66 years). Survival at one and two years was 82% and 64%, respectively; survival rates were comparable with 219 patients who underwent bilateral lung transplantation during the same period (p=0.56).

A review article by Date (2015) stated that, as of 2011, approximately 400 living-donor lobar lung transplants have been performed worldwide.[39] Procedures in the U.S. decreased after 2005 due to changes in the lung allocation system. The author stated that size matching between donor and recipient is important and that, to some extent, size mismatching (oversized or undersized grafts) can be overcome by adjusting surgical technique.

Several studies reported on lobar lung transplantation from living donors. For example, Barr (2005) reported on experience performing living donor lobar lung transplants in the U.S.[43] Ninety patients were adults and 43 were children. The primary indication for transplantation (86%) was cystic fibrosis. At the time of transplantation, 67% of patients were hospitalized and 20% were ventilator dependent. Overall recipient actuarial survival at one, three and five years was 70%, 54% and 45%, respectively. There was not a statistically significant difference in actuarial survival between adults and children who underwent transplantation. Moreover, survival rates were similar to the general population of lung transplant recipients. The authors also reported that rates of postoperative pulmonary function in patients surviving more than three months post-transplant were comparable to rates in cadaveric lung transplant recipients.

RETRANSPLANTATION

Registry data and case series reports have demonstrated favorable outcomes with lung retransplantation in certain populations, such as in patients who meet criteria for initial lung transplantation.[44-47]

OPTN reported data on lung transplants performed between 2008 and 2015.[48] Patient survival rates after repeat transplants were lower than primary transplants, but a substantial number of patients survived. For example, one-year patient survival was 87.9% (95% CI 87.2% to 88.7%) after a primary lung transplant and 76% (95% CI 70.9% to 80.2%) after a repeat transplant. Five-year patient survival was 55.9% (54.7% to 57.2%) after a primary lung transplant and 33.8% (28.5 to 39.1%) after repeat transplant.

The ISHLT registry contains data on 2,273 retransplantations performed through June 2015 (4.4% of all lung transplantations during this period).[3] The major causes of death in the first 30 days after retransplantation were graft failure and non-CMV infection, followed by multiorgan failure, cardiovascular causes and technical factors related to the transplant procedure. Beyond the first year, the most common reported causes of mortality were OB/BOS, graft failure, and non-CMV infections.

Biswas Roy (2018) published a single-center retrospective study comparing survival outcomes in 29 patients who received retransplantation for chronic lung allograft dysfunction with 390 patients receiving primary lung transplant at the same center.[49] Patients receiving retransplantation had significantly higher use of extracorporeal membrane oxygenation support for severe primary graft dysfunction (p=0.019) and underwent cardiopulmonary bypass and re-exploration for bleeding (p=0.019) more frequently than patients receiving primary transplantation (p=0.029). At one-year follow-up, 89.7% of primary transplant patients were living, as were 89.2% of retransplantation patients. At five-year follow-up, a greater percentage of the retransplantation group had survived, compared with the primary transplantation group (64.3% vs 58.2%), although the difference was not statistically significant. While high LAS and extended hospital length of stay were both identified as independent mortality risk factors, retransplantation was not (HR 1.58, 95% CI 0.31 to 8.08, p=0.58). Study limitations included its single-center, retrospective design, the potential selection bias for younger patients, and the

small size of the retransplantation group. Further, follow-up data at three and five years were incomplete for some patients, and patients who were refused retransplantation were not considered in the analyses. However, for appropriately selected patients, retransplantation after chronic lung allograft dysfunction resulted in one- and five-year survival rates comparable to those seen after primary lung transplantation.

Thomas (2015) published results from a retrospective study that compared patient survival after lung retransplantation (LRTx) to primary lung transplantation (LPTx) in the U.S. using data from the UNO registry between 2004 and 2013.[50] A total of 582 LRTx and 13,673 LPTx recipients were included in the analysis. The median survival after LRTx was 2.6 years compared with 5.6 years after LPTx. One-year, three-year, and five-year survival rates were, respectively, 71.1%, 46.3%, and 34.5% for LRTx, and 84.3%, 66.5%, and 53.3% for LPTx ($p<0.001$). On multivariate analysis, patients who had LRTx after a greater than one-year interval survived longer (RR 0.53, 95% CI 0.34% to 0.88%, p=0.008). Lower survival was associated with single-lung transplantations (RR 1.49, 95% CI 1.06% to 2.07%, p=0.021), transplantations done between 2009 and 2013 (RR 1.40, 95% CI 1.01% to 1.94%, p=0.041), multiple retransplantations (RR 2.55, 95% CI 1.14% to 5.72%, p=0.023), and recipients requiring pre-transplantation ventilator support.

Kilic (2013) evaluated data on 390 adult lung retransplantation patients from the UNOS database.[45] Patients received lung retransplantation during the period May 2005 to December 2010, which was after the LAS selection criteria were implemented. Patients with reduced functional status were found to have poorer outcomes than patients with better functional status prior to retransplantation. Using the Karnofsky scale to stratify patients into functional status groups, the authors found the overall one-year survival of 56% for patients requiring total assistance before retransplantation was significantly lower than the overall one-year survival of 82% for patients who only required some assistance before retransplantation ($p<0.001$). The one-year mortality rate after risk adjustment was also increased significantly for patients requiring total assistance prior to retransplantation (odds ratio 3.72, p=0.02). While additional patient selection criteria may be useful for lung retransplantation, current LAS criteria are now used.

PRACTICE GUIDELINE SUMMARY

INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION

In 2021, the International Society for Heart and Lung Transplantation published updated consensus-based guidelines on the selection of lung transplant candidates.[51]

"Lung transplantation should be considered for adults with chronic, end-stage lung disease who meet all the following general criteria:

1. High (>50%) risk of death from lung disease within 2 years if lung transplantation is not performed.
2. High (>80%) likelihood of 5-year post-transplant survival from a general medical perspective provided that there is adequate graft function."

The guideline also notes risk factors to be considered in the evaluation of transplant candidates, along with pediatric and disease-specific considerations.

The 2021 guideline update briefly addressed lung **retransplantation**, with the consensus statement noting that "The outcomes after re-transplants are inferior compared to first lung transplants, particularly if the re-transplant is done within the first year after the original transplant or for patients with restrictive allograft syndrome (RAS) [...] In the pre-transplant evaluation of such patients, particular emphasis should be focused on understanding the possible reasons for the graft failure, such as alloimmunization, poor adherence, gastroesophageal reflux, or repeated infections".

In 2015, the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation (ISHLT) published an update to their 2006 consensus-based guidelines on selection of lung transplant candidates.[52, 53] The guidelines state:

> "… there is general agreement that referral to a lung transplant program should occur early in patients who have a lung disease that is amenable to transplantation. None of the parameters listed in this document informing on the timing of referral or listing should be used in isolation. Instead, the entire clinical situation of the patient should be considered. However, early referral does give the transplant program maximal flexibility in performing the formal evaluation and in making the second more important step—placing the patient on the active waiting list. Listing a patient for a lung transplant is an explicit acknowledgement that a patient has a limited life expectancy without a transplant and an expectation that the risk-to-benefit ratio favors lung transplantation rather than conventional medical treatment."

For lung retransplantation, the guidelines state:

> "Lung retransplantation accounts for a small percentage of lung transplants performed annually. However, its frequency has increased in recent years. The criteria for candidate selection for lung retransplantation generally mirror the criteria used for selection for initial lung transplantation. Survival after lung retransplantation may have improved over time but remains inferior to survival seen after initial transplantation. For the individual patient, retransplantation should be analyzed as a time-dependent survival risk factor. Consideration must also be given to ethical issues surrounding lung allocation to retransplantation candidates."

AMERICAN THORACIC SOCIETY/EUROPEAN RESPIRATORY SOCIETY/JAPANESE RESPIRATORY SOCIETY/LATIN AMERICAN THORACIC ASSOCIATION

Evidence-based recommendations from the American Thoracic Society and three international respiratory/thoracic societies were published in 2011 for the diagnosis and management of patients with idiopathic fibrosis.[54] For appropriately selected patients with idiopathic pulmonary fibrosis, the group recommended lung transplantation (strong recommendation, low-quality evidence). An updated to this document was published in 2015 in which the committee did not make a recommendation regarding single versus bilateral lung transplantation in patients with idiopathic fibrosis.[55] The committee stated that "it is unclear whether single or bilateral lung transplantation is preferential for long-term outcomes".

GLOBAL INITIATIVE FOR CHRONIC OBSTRUCTIVE LUNG DISEASE

In 2017 the Global Initiative for Chronic Obstructive Lung Disease (GOLD) committee members performed a literature search and developed guidelines regarding the diagnosis, management and prevention of chronic obstructive pulmonary disease.[56] The committee

suggested that in carefully selected patients with COPD, lung transplantation has been shown to improve quality of life and functional capacity. The guidelines state:

> "In selected patients with very severe COPD and without relevant contraindications, lung transplantation may be considered. … Criteria for referral for lung transplantation include COPD with progressive disease, not a candidate for endoscopic or surgical lung volume reduction, BODE index of 5 to 6, Pco_2 greater than 50 mm Hg or 6.6 kPa and/or Pao_2 less than 60 mm Hg or 8 kPa, and FEV_1 less than 25% predicted."

These recommendations were made on the basis of evidence collected from observational studies; however, randomized controlled trials are unlikely in this patient population.

SUMMARY

There is enough research to show that lung transplantation can improve survival in certain patients and thus may be considered medically necessary for patients when the policy criteria are met. It may be the only option for some patients with end-stage lung disease.

There is enough research to show that lung retransplantation can improve survival and may be the only option for patients with failed lung transplantation. Therefore, lung retransplantation may be considered medically necessary in selected patients who meet criteria for lung transplantation.

Lung or lobar lung transplantation or retransplantation is considered not medically necessary in all other situations when the policy criteria are not met.

Medical Policy Manual Transplant, Policy No. 09

Small Bowel, Small Bowel/Liver, and Multivisceral Transplant

Effective: April 1, 2024

Next Review: January 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Small bowel transplants are performed to treat intestinal failure in patients that require total parenteral nutrition (TPN) and are having serious TPN complications.

Small bowel/liver transplantation is performed in people that have both intestinal and liver failure, and may be combined with the transplantation of other portions of the digestive tract and accessory organs, including the, duodenum, jejunum, ileum, pancreas, or colon. When the small bowel and liver are transplanted in conjunction with other gastrointestinal organs, the procedure is referred to as a multivisceral transplant.

MEDICAL POLICY CRITERIA

I. A small bowel transplant using cadaveric intestine may be considered **medically necessary** for adults and children when ALL of the following are met (A. – E.):

   A. Adequate cardiopulmonary status; and

   B. Documentation of patient compliance with medical management; and

   C. Intestinal failure characterized by the loss of absorption and the inability to maintain protein-energy, fluid, electrolyte, or micronutrient balance; and

   D. Long-term dependence on total parenteral nutrition (TPN); and

E. One or more of the following severe complications due to TPN:

1. TPN intolerance to the point that multiple and prolonged hospitalizations are required to treat TPN-related complications; or
2. The development of progressive but reversible liver failure; or
3. Inability to maintain venous access.

II. A small bowel transplant using a living donor may be considered **medically necessary** when a cadaveric intestine is not available for transplantation and Criterion I. is met.

III. A small bowel/liver transplant or multivisceral transplant may be considered **medically necessary** for adults and children when all of the following are met (A. – B.)

A. Criterion I. is met; and

B. There is evidence of impending end-stage liver failure.

IV. A small bowel retransplant may be considered **medically necessary** after a failed small bowel transplant.

V. A small bowel/liver or multivisceral retransplant may be considered **medically necessary** after a failed primary small bowel/liver or multivisceral transplant.

VI. A small bowel transplant is considered **not medically necessary** for patients with intestinal failure who are able to tolerate TPN.

VII. A small bowel transplant is considered **not medically necessary** if Criterion I, II, or IV is not met.

VIII. A small bowel/liver, or multivisceral transplant is considered **not medically necessary** if Criterion III or V is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Diagnosis and Indication for transplant

BACKGROUND

Intestinal failure is a serious medical condition which results from surgical resection, congenital defect, or disease-associated loss of absorption and is characterized by the inability to

maintain protein-energy, fluid, electrolyte, or micronutrient balance.[1] Short bowel syndrome, one type of intestinal failure, is a condition in which the absorbing surface of the small intestine is inadequate due to extensive disease or surgical removal of a large portion of small intestine. Etiologies of short bowel syndrome include: volvulus, atresias, necrotizing enterocolitis, gastroschisis, desmoid tumors, and trauma. Patients with short bowel syndrome are unable to obtain adequate nutrition from enteral feeding and become dependent upon total parenteral nutrition (TPN). Patients with complications from TPN, such as catheter-related mechanical problems, infections, hepatobiliary disease, and metabolic bone disease, may be considered candidates for small bowel transplant.

Small bowel/liver transplantation is transplantation of an intestinal allograft in combination with a liver allograft, either alone or in combination with one or more of the following organs: stomach, duodenum, jejunum, ileum, pancreas, or colon. Small bowel transplants are typically performed in patients with intestinal failure (IF) due to functional disorders (e.g., impaired motility) or short bowel syndrome (SBS), defined as an inadequate absorbing surface of the small intestine due to extensive disease or surgical removal of a large portion of small intestine. In some instances, short bowel syndrome is associated with liver failure, often due to the long-term complications of total parenteral nutrition (TPN). These patients may be candidates for a small bowel/liver transplant or a multivisceral transplant, which includes the small bowel and liver with one or more of the following organs: stomach, duodenum, jejunum, ileum, pancreas, and/or colon. A multivisceral transplant is indicated when anatomic or other medical problems preclude a small bowel/liver transplant, and the patient requires removal of all of the native gastrointestinal tract and replacement with a multivisceral graft.

Intestinal transplants, including multivisceral and small intestine/liver, represent a small minority of all solid organ transplants. In 2022 and 2023, 82 and 87 intestinal transplants, respectively, were performed in the United States, all of which were from deceased donors. In 2023, 27 multivisceral transplants involving the small intestine/liver/pancreas were performed. Small intestine/liver transplant is rare, with only one performed in 2022 and zero in 2023.[2]

EVIDENCE SUMMARY

Ideally, for intestinal transplant to be considered as a replacement for total parenteral nutrition (TPN), head-to-head comparisons of transplantation versus TPN are needed, preferably in well-designed randomized controlled trials (RCTs). Further, for chronic conditions such as intestinal failure, comparative trials with long-term follow-up are necessary in order to determine the durability of any beneficial treatment effects, and to establish guidelines regarding the timing of intestinal transplant. In order to establish the net benefit of using living donors versus cadaveric intestinal transplant for treatment of intestinal failure, clinical trials that compare these therapies are needed, and the impacts on health outcomes for both the donors and recipients must be considered.

The current literature on small bowel transplantation included the following general observations:

- The importance of timely referral for intestinal transplantation was emphasized to avoid the necessity of combined liver and intestine transplantation.
- While outcomes continue to improve, obstacles to long-term survival remain. Recurrent and chronic rejections and complications of immunosuppression are significant issues in bowel transplantation.

- It has been suggested that improvements in survival over the last 10–15 years may justify removing the restriction of intestinal transplantation to patients who have severe complications of TPN.[3] However, as noted by Vianna in their report on the status of intestinal transplantation, no randomized trials compare intestinal transplantation to long-term parenteral nutrition, and optimal timing for earlier transplantation has not been established.[4]

- People with high morbidity from TPN appear to have better outcomes with transplant, but it is unknown whether ongoing home-based TPN or intestinal transplant is superior. Randomized controlled trials comparing the two forms of IF management have not been performed, primarily owing to small numbers of people with IF.[5]

REGISTRY DATA

The most recent published report from the international Intestinal Transplant Registry (ITR) reported on 4103 total intestinal transplants between January 1985 and December 2018. Of these, 2096 transplants were performed in children. Transplant subtypes are: small bowel only (1842), small bowel and liver (1251), multivisceral (small bowel, liver, stomach: 810), and modified multivisceral (small bowel and stomach: 200).[6] Improvements in the management of IF, both with and without intestinal transplant have led to a sharp reduction in the annual number of intestinal transplants being performed. Intestinal transplant volume decreased from a peak of 270 in 2008 to fewer than 50 in 2018.[5, 6] Participation in this registry was considered to be nearly 100% of all intestinal transplants performed in the world since April 1985. The following trends were identified[7]:

- Regional practices and outcomes are now similar worldwide.
- Current actuarial patient survival rates at one-, five-, and 10-years post-transplant are 76%, 56%, and 43%, respectively.
- Outcomes of intestinal transplantation improved modestly over the past decade, but rates of graft loss beyond one year have not improved.
- The reasons for late graft loss have been difficult to identify due to the low case volumes at most centers.
- Better function was found in intestinal grafts that included a colon segment and/or a liver component.

Better graft survival was also seen in patients who waited at home for intestinal transplant, used induction immune-suppression therapy, and had rapamycin maintenance therapy.

SYSTEMATIC REVIEWS

This policy was initially based on 1995 and 1999 BlueCross BlueShield Association Technology Evaluation Center (TEC) assessments.[8, 9] The 1995 assessment concluded that in children, small bowel transplant was associated with improved survival compared to TPN. This assessment also concluded that in adults, the outcomes for small bowel transplant were worse than those associated with TPN.

The 1999 TEC assessment reevaluated the data on adults, specifically focusing on the probability of adult patient and graft survival with small bowel transplant compared to TPN, and whether successful outcome of small bowel transplant improves health outcomes or reduces adverse outcomes.[9] The assessment reported that bowel transplants in adults produce patient survival rates from 27%-58% at 4 or 5 years. Graft survival rates (and presumably

independence from TPN) range from 13%-30%. It is unknown whether this represents a net benefit to these patients, since some patients may survive for long periods of time on TPN. The TEC assessment also indicated that some patients with increasingly severe TPN-associated complications may face a high probability of impending mortality such that the risk of continued medical management is higher than the risk of transplantation. However, at this point in time, it is not possible to predict which patients will survive longer on TPN versus small bowel transplant.

In 2010, Sudan published a systematic review of current literature on long-term outcomes after intestinal transplantation.[10] The author noted that intestinal transplantation has become standard therapy for patients with life-threatening complications from parenteral nutrition therapy. Data from current single-center series indicate a 1-year patient survival rate of 78-85% and a 5+ year survival rate of 56-61%. With respect to pediatric intestinal transplant patients, the majority achieve normal growth velocity at two years post-transplant. However, oral aversion is a common problem; tube feedings are necessary in 45% of children. Sudan also noted that parental surveys of quality of life in pediatric transplant patients have shown that intestinal transplant patients appear to have modestly improved quality of life compared to patients remaining on TPN and slightly worse than matched school-age controls without intestinal disease.

RANDOMIZED CONTROLLED TRIALS

No RCTs were identified that compared intestinal transplantation with ongoing parenteral nutrition with or without subsequent small bowel/liver or multivisceral transplantation.

NONRANDOMIZED STUDIES

Despite the lack of RCTs, isolated small bowel transplantation has become an accepted alternative to continued total parenteral nutrition (TPN) to avoid the need for multivisceral transplantation in carefully selected patients with intestinal failure who are developing severe complications related to total parenteral nutrition (TPN).

The following is a summary of non-randomized trials that are representative of the available data on small bowel, small bowel/liver, and multivisceral transplantation, and post-transplantation complications.

Living Donor

The literature related to living-related intestinal transplant consists of small case reports of 1 to 11 patients in which different lengths of the ileum or jejunum were used.[11-18] While there appeared to be minimal complications to the donors, of the cases reported a significant number of recipients remained on TPN for at least part of their nutrition while others remain healthy and off TPN.

Ueno reported on 21 intestinal transplant patients that underwent transplantation between 1996 and 2012 at one of five institutions.[19] Twelve transplants came from living donors. All but one patient received an isolated small bowel transplant for intestinal failure. The overall 1- and 5- year survival rates were 86% and 68%, respectively. In the 15 patients who underwent transplantation after 2006, 1-year survival was 92% and 5-year survival was 83%.

Gangemi and Benedetti published a literature review of living donor small bowel transplantation reports from 2003 to 2006; all of the reports listed Benedetti as author.[20] The

authors commented that, “Due to the excellent result in modern series of deceased donor bowel transplantation, widespread use of the procedure [living donor] should not be recommended, in consideration of the potential risks to donor. Furthermore, few centers have acquired the necessary experience with the procedure.” Benedetti also reported outcomes from four children and seven adults who underwent 12 living-related small bowel transplantations between 1998 and 2004.[21] All donors were reported to have had uneventful recovery following removal of up to 40% of the small intestine. The three-year patient survival was 82%, with graft survival of 75%. Longer follow-up from the earlier cases was not reported.

Complications

Post-transplant lymphoproliferative disorders (PTLD) are a potentially life-threatening complication of the immunosuppression required for solid organ transplant. PTLD is associated with exposure to Epstein-Barr virus (EBV). Chang (2022) performed a retrospective single-institution study of pediatric solid organ transplant recipients to determine risk factors associated with post-transplant EBV DNAemia and PTLD.[22] The study included 275 patients, of whom 20 had multivisceral transplant and 10 had intestinal transplant. Other transplant types were liver, lung, kidney, and heart. Intestinal and multivisceral transplants patients were over-represented in PTLD cases. Intestinal transplants comprised 2% of the total study population but 21% of PTLD cases. Multivisceral transplant recipients represented 3% of the study population but 14% of PTLD cases. While high post-transplant EBV DNAemia levels were a strong risk factor for PTLD ($p<0.0001$), the study found that PTLD incidence in intestinal and multivisceral transplant recipients was not explained by EBV DNAemia levels. Transplant type did not correlate with EBV DNAemia ($p=0.14$).

Santarsieri (2022) published data describing PTLD incidence and outcomes from 5365 solid-organ and hematopoietic stem cell transplants over a 20-year period in the United Kingdom.[23] Multivisceral transplants were defined as intestinal transplant, with or without simultaneous transplant of other abdominal organs. The study included both adult and pediatric cases with the median age at transplant of 52 years (range 0.8 to 79.5 years). In addition to multivisceral transplant, other transplant types were kidney, pancreas, liver, hematopoietic stem cell, heart, lung (single, bilateral, and heart-lung), and simultaneous kidney and pancreas (SPK). A total of 225 cases of PTLD were documented. It was noted that multivisceral transplant follow-up time was the shortest because the procedure was initiated after other transplant types. Despite shorter follow-up, the incidence of PTLD was highest in multivisceral transplant cases. Out of a total of 113 multivisceral transplant cases, 21 (18.6%) were diagnosed with PTLD, which was notably higher than the overall PTLD incidence of 5.9% in all transplant types.

Clouse (2019) reported on the incidence of graft-versus-host disease (GVHD) following intestine transplant at a single center.[24] Of the 236 transplants performed between 2003 and 2015, 37 patients (16%) developed GVHD. Mortality was 54% within one year of diagnosis for these patients. An increased risk of GVDH was seen with liver inclusion and increasing graft volume.

Spence (2020) published on the development of intra-abdominal infections within two years following intestinal and multivisceral transplants in adults at a single center.[25] There were 103 patients that were included, who underwent transplantations between 2003 and 2015, and 46 of these (43%) had intra-abdominal infections with the two-year follow-up. The median time to infection was 23 days post-transplant. Six patients also had concurrent blood stream

infections. While patients with intra-abdominal infections had longer hospital stays than those without (median 35 days vs. 23 days, p=0.0012), there was no difference in all-cause mortality.

A report of thrombotic and hemorrhagic complications associated with visceral transplantation was published by Raveh (2018).[26] Data from 48 adult transplantations (32 multivisceral, 10 isolated intestinal, and six modified multivisceral) between 2010 and 2017 were reviewed retrospectively. There were eight patients who experience intraoperative intracardiac thrombosis (ICT)/pulmonary embolism (PE), all of whom were undergoing multivisceral transplants. Postoperative bleeding complications at one month were found in 11% of multivisceral transplants, 20% of isolated intestinal transplants, and 17% of modified multivisceral transplants.

Danziger-Isakov (2018) evaluated the epidemiology and outcomes of inpatient respiratory virus infection in pediatric patients following solid organ transplant at nine U.S. transplant centers.[27] Among the 42 patients who underwent intestine/multivisceral transplantation, respiratory virus infection occurred in 38%, the highest rate by transplant type. Respiratory virus infection was associated with younger age at transplant.

Vo (2018) reported on the risk of invasive pneumococcal infections among pediatric patients receiving liver-small bowel-pancreas transplants at a single center.[28] Of the 122 patients who underwent this procedure between 2008 and 2016, nine patients experienced 12 invasive pneumococcal infections. The median time to first infection following transplant was three years (range 0.8 to 5.8 years), and the mortality rate was 22%. The authors noted that all patients were on prophylactic oral penicillin and the majority had received at least one dose of pneumococcal conjugate vaccine.

Nagai (2016) reported on cytomegalovirus (CMV) infection after intestinal or multivisceral transplantation at a single center in the US.[29] A total of 210 patients had in intestinal transplant, multivisceral transplant or modified multivisceral transplant between January 2003 and June 2014. The median length of follow-up was 2.1 years. A total of 34 patients (16%) developed CMV infection a median of 347 days after transplantation. Nineteen patients had tissue invasive CMV disease. CMV infection was significantly associated with rejection (odds ratio 2.6, p<0.01) and adversely affected patient survival (hazard ratio 2.7, p<0.001). A report from another center in the US, 16 of 85 (19%) patients undergoing intestinal or multivisceral transplantation developed CMV infection a mean of 139 days (range 14 to 243 days) postoperatively.[30]

Wu (2016) investigated the incidence and risk factors of acute antibody-mediated rejection (ABMR) among patients undergoing intestinal transplantation (n=175).[31] Acute ABMR was diagnosed by: clinical evidence; histologic evidence of tissue damage; focal or diffuse linear C4d deposition; and circulating anti-human leukocyte antigen antibodies. Of the 175 intestinal transplants, 58% were liver-free grafts, 36% included a liver graft, and 6.3% were retransplantations. Eighteen cases of acute ABMR were identified: 14 (14%) among the patients undergoing first liver-free transplantation, two (3%) among patients undergoing liver/small bowel transplantations, and two (18%) among the patients undergoing retransplantation. Graft failure occurred in 67% of patients with acute ABMR. The presence of a donor-specific antibody and a liver-free graft were associated with the development of acute ABMR.

In 2016, Limketkai published a retrospective study on mortality and graft rejection rates in 1115 cases of intestinal transplants performed from May 1990 through June 2014.[32] Of these, 142

transplants were done for Crohn's disease (CD). Transplants were rejected in 33.3% of patients without CD and 36.9% of patients with CD. The actuarial risk of death for patients with CD at one, five, and ten years post-transplant 22.5%, 50.3%, and 59.7%, respectively. Patients without CD had similar mortality risks.

In a case series by Cromvik (2016), five of 26 patients (19%) were diagnosed with GVHD after intestinal or multivisceral transplantation at a center in Sweden.[33] Risk factors for GVHD were malignancy as a cause of transplantation and neoadjuvant chemotherapy or brachytherapy before transplantation.

A 2015 retrospective review reported a number of parameters for intestinal and multivisceral transplants performed on Nordic patients between 1998 and 2013.[34] Twenty out of the 29 patients (69%) received liver-containing allografts. Nineteen of them were multivisceral grafts, including the stomach, the pancreaticoduodenal complex, the liver and the small intestine. The remaining liver-containing allograft was a combined liver and intestinal graft with a segmental pancreas. Three of eight patients with a spleen included in their multivisceral graft developed GVHD. One patient with GVHD and manifestations with skin rash later developed post-transplant lymphoproliferative disorder (PTLD).

In 2014, Calvo Pulido reported on 21 adults who underwent intestinal transplantation; 17 were isolated small bowel transplants.[35] Thirteen patients (62%) experienced renal failure; the etiology included high ileostomy output, immunosuppression and medical treatment.

In 2013, Boyer reported that 7 of 12 children who had an isolated small bowel transplant had renal function complications at some point after surgery.[36] Prior to treatment, all of the patients had normal renal functioning.

Florescu have published several articles retrospectively reviewing complications in a cohort of 98 pediatric patients. Twenty-one of these children (21.4%) had an isolated small bowel transplant; the remainder had combined transplants. These articles include a 2012 study that reported that 68 of the 98 patients (69%) developed at least one episode of bloodstream infection.[37] Among the patients with an isolated small bowel transplant, the median time to infection for those who became infected was 4.5 months (95% confidence interval [CI]: 2.4 to 6.7 months). Also in 2012, the researchers reported that 7 of 98 patients (7%) developed cytomegalovirus (CMV) disease; only one of these had an isolated small bowel transplant.[38] A 2010 study by this group retrospectively reported on the incidence of fungal infection after pediatric small bowel transplantation among patients treated between 2003 and 2007 at a single center.[39] The average length of follow-up was not reported. A total of 25 of 98 cases reviewed (26%) developed at least one episode of fungal infection; Candida infection was most common. During the study period, the mortality rate did not differ significantly between patients who did and did not develop a fungal infection (32.3% vs. 29.8%, respectively), but the authors stressed the importance of better screening tools to identify and prevent fungal infections.

As noted previously, Sudan reported oral aversion to be a common problem in pediatric patients with tube feedings necessary in 45% of children following small bowel transplantation.[10]

A 2012 retrospective review focused on the rate of kidney dysfunction, a recognized complication after non-renal solid organ transplantation, in 33 multivisceral and 15 isolated small bowel transplant patients.[40] A significant decline in kidney function was reported in 46% of patients at one year following transplantation. A significant correlation was found for patient

age, pretransplant serum creatinine, estimated GFR (eGFR) at post-transplant day 30, 90, 180, and 270, and tacrolimus level at post-transplant day seven. Lesser decline was found in pediatric patients and patients with multivisceral transplantation compared with adults or isolated small bowel transplantation.

A 2012 retrospective review reported on bloodstream infections among 98 children younger than age 18 years with small bowel/combined organ transplants.[37] Seventy-seven (79%) patients underwent small bowel transplant in combination with a liver, kidney, or kidney-pancreas, and 21 had an isolated small bowel transplant. After a median follow-up of 52 months, 58 (59%) patients remained alive. The one-year survival rate was similar in patients with combined small bowel transplant (75%) and those with isolated small bowel transplant (81%). In the first year after transplantation, 68 patients (69.4%) experienced at least one episode of bloodstream infection. The one-year survival rate for patients with bloodstream infections was 72% compared to 87% in patients without bloodstream infections (p=0.056 for difference in survival in patients with and without bloodstream infections).

Wu (2011) reported on complications after small bowel and multivisceral transplantation in 241 patients who underwent intestinal transplantation.[41] Of these, 147 (61%) had multivisceral transplants, 65 (27%) had small bowel transplants and 12% had small bowel/liver transplants. There were 151 children (63%) and 90 adults. A total of 22 patients (9%) developed graft-versus-host disease (GVHD). Children younger than five years old were more likely to develop GVHD; the incidence in this age group was 16 of 121 (13.2%) compared to 2 of 30 (6.7%) in children between 5 and 18 years and 9 of 90 (4.4%) in adults over 18 years. Among diseases, patients with intestinal atresia were more likely to develop GVHD than those with other conditions (22.2% vs. 2.6%, respectively, p=0.03).

Transplant Recipients with Tumors

Duchateau (2022) published a systematic review of reported experiences of combined liver-intestinal and multivisceral transplantation (MvTx) for neuroendocrine tumors (NET) extending beyond the liver.[42] Fourteen single-center and three multi-center retrospective studies reported on one combined liver-intestinal and 38 MvTx for NET and nine previously unreported MvTx were added to the analysis by the authors. Overall patient survival up to 51.2% was found with recurrence of 35%, which is similar to recurrence after liver transplantation for NET. In addition, the authors reported that patients with NET with diffuse abdominal presentation, normally considered a contraindication, may benefit from radical resection and MvTx. Additional studies to optimize post-transplant management are needed.

Cruz (2011) published results from a small case series (n=10) of patients with intra-abdominal desmoid tumors secondary to familial adenomatous polyposis who underwent multivisceral transplant.[43] All patients were able to discontinue home parenteral nutrition by an average 30 days after transplant. Estimated survival was 80% at five years, and desmoid tumors reoccurred in one patient 15 months after transplantation. However, conclusions from this study are limited by the small sample size and the lack of a comparison group, factors which do not allow for the isolation of transplant as a causative factor in patient health outcomes.

Retransplantation

Evidence for the use of retransplantation to treat individuals who have failed intestinal transplantations includes several case series, mostly from single institutions. One case series analyzed records from the United Network for Organ Sharing database.[44] Among the case

series described in Table 1, reasons for retransplantation include: acute rejection, chronic rejection, CMV, liver failure, lymphoproliferative disorder, and graft dysfunction. Survival rates for retransplantation are listed in Table 2.

Table 1. Summary of Key Case Series Characteristics for Retransplantation

Author (Year)	Location	N	Median Age (Range), y	Interventions		Follow-Up, (Range), mo

Survival Outcomes

The published literature consists of case series, mainly reported by single centers in the United States and Europe. Tables 3 and 4 summarize the characteristics and results of the case series, respectively. Many case series have included isolated small bowel transplantations.

Reasons for transplantations were mainly short bowel syndrome. Other reasons included congenital enteropathies and motility disorders. Most common outcomes reported were survival rates and weaning off TPN. Several studies have presented survival rates by type of transplantation, while others have combined all types of transplants when reporting survival rates. When rates were reported by type of transplant, isolated transplantations had higher survival rates than multivisceral transplants (see Table 4).

Several investigators have reported higher survival rates in transplants conducted more recently than those conducted earlier.[44, 48, 50] Reasons for improved survival rates in more recent years have been attributed to the development of more effective immunosuppressive drugs and the learning curve for the complex procedure.

Authors of these series, as well as related reviews, have observed that while outcomes have improved over time, recurrent and chronic rejection and complications of immunosuppression continue to be obstacles to long-term survival. A separate discussion of complications follows the evidence tables.

Table 3. Summary of Key Case Series Characteristics for Transplantations

Author (Year)	Location	N	Median Age (Range), y	Interventions		Follow-Up (Range)
				Treatment	n

HIV POSITIVE TRANSPLANT RECIPIENTS

This subgroup of recipients has long been controversial due to the long term prognosis for HIV positivity and the impact of immunosuppression on HIV disease. Although HIV positive transplant recipients may be a research interest of some transplant centers, the minimal data regarding long term outcomes in these patients consist primarily of case reports and abstract presentations of liver and kidney recipients. Nevertheless, some transplant surgeons would argue that HIV positivity is no longer an absolute contraindication to transplant due to the advent of highly active antiretroviral therapy (HAART), which has markedly changed the natural history of the disease.

The Organ Procurement and Transplantation Network (OPTN) considers HIV+ organ candidates to be acceptable recipients "if permitted by the transplant hospital. Care of HIV test positive organ candidate and recipients should not deviate from general medical practice."[58]

PRACTICE GUIDELINE SUMMARY

AMERICAN GASTROENTEROLOGICAL ASSOCIATION (AGA)

In 2022, The American Gastroenterological Association published a clinical practice update on the management of short bowel syndrome (SBS) that includes best practice advice on referral for intestinal transplantation.[59] The update is focused on adult patients. In general, early referral for transplant is recommended to avoid the need for simultaneous liver transplant, which leads to increased mortality risk while on the waiting list. Referral for intestinal transplant is recommended for:

- People with SBS-IF and onset of TPN failure. Patients with SBS-IF who have high morbidity or low acceptance of TPN should be considered for referral to transplant individually.

Transplant referral is also suggested for certain patients who do not meet criteria for TPN failure:

- Post-operative referral for patients with large abdominal desmoid tumors.
- Patients with severe dysmotility syndromes who have no prospect of weaning from TPN.

XIV INTERNATIONAL SMALL BOWEL TRANSPLANT SYMPOSIUM WORKING GROUP CRITERIA FOR PLACEMENT ON A WAITLIST FOR INTESTINAL TRANSPLANTATION

In 2020, Kaufman published an update of the 2001 American Society of Transplantation Indications.[5] The new guidance was developed by a multidisciplinary team of providers and is based on practice advances since 2001 that have led to improved management of SBS both with and without small bowel transplant.

Criteria for placement on a waitlist for intestinal transplantation:

- Evidence of advanced or progressive intestinal failure-associated liver disease
    - Hyperbilirubinemia >75 µmol/L[b] (4.5 mg/dL) despite intravenous lipid modification strategies that persists for >2 months.
    - Any combination of elevated serum bilirubin, reduced synthetic function (subnormal albumin or elevated international normalized ratio), and laboratory indications of portal hypertension and hypersplenism, especially low platelet count, persisting for >1 month in the absence of a confounding infectious event(s).
- Thrombosis of:
    - 3 out of 4 discrete upper body central veins (left subclavian and internal jugular, right subclavian and internal jugular) or
    - Occlusion of a brachiocephalic vein in children (in adults, this criterion should be evaluated in a case-by-case basis).
- Live-threatening morbidity in the setting of indefinite parenteral nutrition dependence of either anatomical or functional cause, as suggested by:
    - In children, 2 admissions to an intensive care unit (after initial recovery from the event resulting in intestinal failure) because of cardiorespiratory failure (mechanical ventilation or inotrope infusion) due to sepsis or other complication of intestinal failure
    - In adults, on a case-by-case basis.
- Invasive intra-abdominal desmoids in adolescents and adults
- Acute diffuse intestinal infarction with hepatic failure
- Failure of first intestinal transplant

SUMMARY

There is enough research to show that small bowel transplant from a living donor does not improve health outcomes in certain patient populations except when a cadaveric intestine is not available. Therefore, small bowel transplant from a living donor is considered not medically necessary in all other situations except when a cadaveric intestine is not available and is indicated.

There is enough research to show that small bowel transplants can improve health outcomes in certain patients with intestinal failure with serious complications from total parenteral nutrition (TPN). Therefore, isolated small bowel transplant may be considered medically necessary in patients that meet the policy criteria.

There is enough research to show that small bowel transplant does not improve health outcomes in patients with intestinal failure who are able to tolerate TPN. Therefore, small bowel transplant may be considered not medically necessary for these patients.

There is enough research to show that small bowel retransplant improves health outcomes in patients that have had a failed small bowel transplant. Therefore, for patients with failed small bowel transplant, retransplant may be considered medically necessary.

There is enough research to show that small bowel transplant from a living donor does not improve health outcomes in certain patient populations except when a cadaveric intestine is not available. Therefore, small bowel transplant from a living donor is considered not medically necessary in all other situations except when a cadaveric intestine is not available and is indicated.

There is enough research to show that small bowel/liver and multivisceral transplant and retransplant can improve survival in certain patients. Therefore, these procedures may be considered medically necessary for patients with intestinal failure who have been managed with long-term total parenteral nutrition and who have developed evidence of impending end-stage liver failure. Transplants or retransplants are considered not medically necessary when the policy criteria are not met.

Medical Policy Manual Transplant, Policy No. 13

Islet Transplantation

Effective: July 1, 2023

Next Review: March 2024
Last Review: May 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Islet cells are responsible for producing insulin, which is necessary for the regulation of blood glucose levels. Following islet transplantation, it is proposed that the beta cells in the transplanted islets will begin to make and release insulin.

MEDICAL POLICY CRITERIA

I. Autologous pancreas islet cell transplantation may be considered **medically necessary** as an adjunct to a total or near total pancreatectomy in patients with chronic pancreatitis.

II. Autologous pancreas islet cell transplantation for all other indications is considered **investigational**.

III. Allogeneic and xeno islet cell transplantation for any diagnosis are considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- Diagnosis and indication for transplant

BACKGROUND

CHRONIC PANCREATITIS

Although the incidence of chronic pancreatitis is rising, it is still a relatively rare condition, affecting an estimated seven to eight new people out of every 100,000 people each year.[1] Some patients with chronic pancreatitis may experience intractable pain that can only be relieved with a total or near-total pancreatectomy. However, the pain relief must be balanced against the certainty that the patient will be rendered an insulin-dependent diabetic. Autologous islet cell transplantation, also called islet autotransplantation (IAT), has been investigated as a technique to prevent this serious morbidity.

TYPE 1 DIABETES

Glucose control is a challenge for individuals with type 1 diabetes. Failure to prevent disease progression can lead to long-term complications such as retinopathy, neuropathy, nephropathy, and cardiovascular disease.[2]

ISLET TRANSPLANTATION

In autologous islet transplantation during the pancreatectomy procedure, islet cells are isolated from the resected pancreas using enzymes, and a suspension of the cells is injected into the portal vein of the patient's liver. Once implanted, the beta cells in these islets begin to make and release insulin.

Allogeneic islet cell transplantation is normally conducted as a stand-alone procedure among patients with type 1 diabetes. Islet cells, harvested from a deceased donor's pancreas, are processed and injected into the recipient's portal vein.

Allogeneic islet cell transplantation potentially offers an alternative to whole-organ pancreas transplantation to treat type 1 diabetes, restore normoglycemia and ultimately reduce or eliminate the long-term complications of diabetes, such as retinopathy, neuropathy, nephropathy, and cardiovascular disease. However, a limitation of islet cell transplantation is that two or more donor organs are usually required for successful transplantation, and only pancreases rejected for whole-organ transplant are typically used for islet transplantation. Due to limited islet cell supply, allogeneic islet cell transplantation is recommended only for patients with frequent and severe metabolic complications who have consistently failed to achieve control with insulin-based management. In 2000, a modified immunosuppression regimen increased the success of allogeneic islet transplantation. This regimen was developed in Edmonton, Canada and is known as the "Edmonton protocol."

While most of the published research to date involves the transplantation of allogeneic human islet cells, there is also interest in xenotransplantation, using porcine islet cells.

REGULATORY STATUS

The U.S. Food and Drug Administration regulates human cells and tissues intended for implantation, transplantation, or infusion through the Center for Biologics Evaluation and Research, under Code of Federal Regulation title 21, parts 1270 and 1271. Allogeneic islet cells are included in these regulations.

EVIDENCE SUMMARY

AUTOLOGOUS ISLET CELL TRANSPLANT AS AN ADJUNCT TO PANCREATECTOMY

Autologous islet cell transplantation as an adjunct to pancreatectomy or near total pancreatectomy among patients with chronic pancreatitis has been investigated since 1977. Since then, the experience has grown slowly with incremental improvements in the islet cell isolation process. The focus of this section is on systematic reviews.

Systematic Reviews

Zhang (2020) published a systematic review and meta-analysis of 17 studies that reported clinical outcomes following total pancreatectomy with islet transplant in patients with chronic pancreatitis.[3] Most studies were single-center, small case series from the United States. The median age was 53 years. Insulin independence was 33.29% (95% CI 27.77 to 39.05; I^2=32.3%) at one year (eight studies). Mortality at 30 days was 1.32% (95% CI 0.68 to 2.16; I^2=0.0%) and mortality at one year was 2.54% (95% CI 1.32 to 4.16; I^2=17.6%).

Kempeneers (2019) published a systematic review of studies examining pain, endocrine function, or quality of life outcomes in patients with chronic pancreatitis undergoing total pancreatectomy with islet transplantation.[4] A total of 15 studies met the inclusion criteria. All included studies were retrospective and observational. The median age was 41 years. Pooled insulin free rate was 30% (95% confidence interval [CI] 20% to 43%) at one year (four studies). The pooled mortality rate was 2% (95% CI 1% to 4%) at 30 days (11 studies) and 4% at one year (six studies). At one year, 63% (95% CI 46% to 77%, I^2=89%) of patients were opioid free (six studies, 657 patients). An analysis revealed a high risk for publication bias among the included studies, which could have led to an overestimation of the true affect.

In 2015, Wu published a systematic review of studies on islet transplantation after total pancreatectomy for chronic pancreatitis.[5] Studies could use any type of design but needed to include at least five patients or have a median follow-up of at least six months. Twelve studies with a total of 677 patients met the review's inclusion criteria. The mean age of the patients was 38 years and mean duration of pancreatitis was 6.6 years. A meta-analysis of the insulin independence rate at one year (five studies, 362 patients) was 28.4% (95% CI 15.7% to 46.0%). At two years, the pooled insulin independence rate (three studies, 297 patients) was 19.7% (95% CI 5.1% to 52.6%). The pooled 30-day mortality rate (11 studies) was 2.1% (95% CI 1.2% to 3.8%). Long-term mortality data were not pooled.

In 2012, Bramis searched for studies reporting on patients who had been treated with total, subtotal or completion pancreatectomy followed by islet autotransplantation.[6] Case series were included if they included more than five individuals and reported outcomes for

consecutive patients. A total of 72 full-text articles were reviewed, and five studies were found to meet inclusion criteria. The postoperative insulin independence rate in the five studies ranged from 10% (mean follow-up of eight years) to 46% (mean follow-up of five years). In the study with the longest follow-up, the insulin independence rate was 28% at ten years. Two studies reported postoperative morphine use with a decrease in morphine use of 116 mg and 55 mg, respectively.

A 2011 systematic review by Dong included studies regardless of design or sample size.[7] After reviewing 84 studies, 15 observational studies were found to meet eligibility criteria. There were 11 studies of total pancreatectomy, two studies of partial pancreatectomy, and two studies that included both types of surgery. Sample sizes in individual studies ranged from three to 173 patients. Thirteen studies included patients with chronic pancreatitis, and two included patients with benign pancreatic tumors. The pooled 30-day mortality was 5% (95% CI 2 to 10%), and the cumulative mortality at one year (reported by ten studies) was 4.9% (95% CI 2.6 to 7.3%) In a pooled analysis of data from 14 studies, the rate of insulin dependence at last follow-up was 4.6 per 100-person years (95% CI 1.53 to 7.62). The pooled rate of insulin independence at one year (five studies) was 27% (95% CI 21 to 33%) and at two years (three studies) was 21% (95% CI 16 to 27%).

ALLOGENEIC ISLET CELL TRANSPLANT FOR TYPE 1 DIABETES

Islet cell transplantation has also been investigated as a treatment for type 1 diabetes, particularly in patients with poor glucose control despite insulin therapy.

The principal outcomes associated with treatment of type 1 diabetes are improvement in overall mortality rate, and reductions in rates of diabetic retinopathy, nephropathy, neuropathy, and cardiovascular disease normally associated with type 1 diabetes. In order to understand the impact of islet cell transplantation for treatment of type 1 diabetes on these outcomes, well-designed randomized controlled trials (RCTs) that compare this therapy to standard medical treatment, such as insulin treatment, are needed. Further, an understanding of any adverse treatment effects, particularly those associated with life-long immunosuppressant therapy, must be carefully weighed against any benefits associated with islet transplantation to understand the net treatment effect of this therapy.

Systematic Reviews

In 2020, the Canadian Agency for Drugs and Technologies in Health (CADTH) published a systematic review islet transplantation for type 1 diabetes.[8] Search dates were limited to January 1, 2014 to February 25, 2020. One systematic review, one RCT, and five non-randomized study met inclusion criteria. The one RCT (Lablanche 2018) is described in detail below. The reviewers concluded that the literature suggests that islet cell transplantation may lead to improved glycemic control and quality of life and additionally may reduce secondary complications of diabetes. There were many limitations noted, including the minimal availability of randomized studies, poor descriptions of the comparators, and lack of long-term follow-up and the authors noted that the results of these studies should be interpreted with caution given these numerous methodological limitations. Additionally, there was a trend of decreased insulin independence over time in three nonrandomized studies with long term follow-ups of 2, 5, and 10 years, which may indicate that the effectiveness of islet cell transplantation decreases over time.

In 2015 Health Quality Ontario published a systematic review on islet transplantation for type 1

diabetes, and included one health technology assessment, 11 observational, nonrandomized clinical studies, one registry report, and four guidelines.[9] There was a large degree of heterogeneity in patient populations, study design, and outcome measurement in the included studies. The reviewers reported that islet transplantation can improve blood sugar control and quality of life, and may reduce diabetic complications; however, the results were inconsistent between studies. Compared with insulin therapy, there were more adverse events with islet transplantation. The studies that were included that assessed health-related quality of life, secondary complications of diabetes, glycemic control, and adverse events were all ranked as low to very low quality, with two studies having high risk of bias. Therefore, uncertainty of the effectiveness of islet transplantation in type 1 diabetics still remains.

Randomized Controlled Trials

An open-label randomized controlled trial (RCT) was published by Lablanche in 2018 evaluating patients who had type 1 diabetes with severe hypoglycemia or in kidney transplant patients following transplantation.[10] A total of 50 patients with severe hypoglycemia, hypoglycemia unawareness, or kidney grafts with poor glycemic control received immediate islet transplantation (n=25) or intensive insulin therapy followed by delayed islet transplantation (n=22). Median follow-up was six months for both groups. The primary end point was a composite score (β score) which has not been validated and which reflected fasting glucose, HbA1c level, C-peptide, and insulin independence. The proportion of patients with a modified β-score of 6 or higher at six months was 64% of patients in the immediate transplantation group and 0% in the control group ($p<0.001$). Of note, few patients in the insulin group used continuous glucose monitoring or other technologies to monitor for hypoglycemia. At six months, insulin independence was achieved in 44% of patients in the immediate transplantation group (n= 25; $p=0.0004$). After the entire cohort received islet transplantation, the one-year insulin independence rate was 59% (n=46; $p<0.0001$). Negative effects reported at 12 months included bleeding complications in 7% of patients and a decrease in median glomerular filtration rate from 90.5 mL/min to 71.8 mL/min in islet transplant patients who had not previously received a kidney graft and from 63.0 mL/min to 57.0 mL/min in islet transplant patients who had previously received a kidney graft. Trial limitations included possible bias from open-label design as well as an inadequate follow-up period to demonstrate transplant durability.

Froud randomized 16 type 1 diabetes mellitus patients to evaluate cultured islet transplantation with or without tumor necrosis factor (TNF-alpha) blockade using Infliximab just prior to islet infusion.[11] Insulin independence was achieved in 14 patients after one to two infusions, and was maintained in 11 patients after one year, and in six patients at 33 +/- 6-months without additional infusions. The authors reported no identifiable clinical benefit with the use of Infliximab, but concluded cultured human islet allografts produced results comparable to freshly transplanted islets including normalization of HBA1c. Further research in larger studies is needed to explore different immunosuppressive regimens.

Nonrandomized Studies

Two prospective, Phase 3, single-arm, open-label, multicenter trials of purified human pancreatic islet cell transplant have been conducted in North America under the guidance of the National Institutes of Health-sponsored Clinical Islet Transplantation (CIT) Consortium.[12, 13] Hering (2016) studied 48 patients with type 1 diabetes, hypoglycemic unawareness, and a history of experiencing severe hypoglycemic events (Protocol CIT07).[13] The primary outcome

(HbA1c level ≤7% and freedom from severe hypoglycemia after one year) was achieved in 87.5% and 71% of patients at one and two years. Median HbA1c level decreased from 7.2% at baseline to 5.6% at one and two years (both p<0.001). Only two patients experienced severe hypoglycemia in the first year posttransplant. Insulin independence was achieved in 52.1% of patients at one year, and median insulin use decreased from 0.49 units/kg/day at baseline to 0 units/kg/day at one year (p<0.0003). Glomerular filtration rate decreased posttransplant (p<0.0008 vs. baseline) due to adverse effects of immunosuppression. Twenty-two serious adverse events during the first year were attributed to the procedure or subsequent immunosuppression.

Markmann (2021) reported results of a Phase 3 trial of human islet-after-kidney transplantation for type 1 diabetes. A total of 24 patients received purified human pancreatic islets. The primary endpoint of freedom from severe hypoglycemic events and HbA1c ≤ 6.5% or reduced by ≥ 1 percentage point at one-year posttransplant was achieved in 62.5% of patients. Median HbA_{1c} was significantly reduced versus baseline at one, two, and three years post-transplant (8.1%, 6.0%, 6.3%, and 6.3%, respectively; p<0.001). Severe hypoglycemia was eliminated in 79.2% of patients at one year, 75% at two years, and 62.5% at three years. Median insulin requirements decreased from 0.5 units/kg/day at baseline to 0 units/kg/day at one, two, and three years (p<0.001, p<0.001, and p=0.002, respectively). Kidney function remained stable throughout follow-up. Thirteen serious adverse events were considered related or possibly related to islet transplant or immunosuppression.

Lemos (2021) reported 20-year results for a retrospective series of 49 patients with type 1 diabetes, hypoglycemic unawareness, and severe hypoglycemia who underwent islet allotransplant.[14] Median follow-up time after transplant was 13.8 years. Median duration of graft function while on immunosuppression was 4.4 years (interquartile range, 1.3 to 12.2 years). Kaplan-Meier survival analysis showed cumulative survival of >80% at 20 years; two patients died during follow-up, one from myocardial infarction and one from suspected hypoglycemia.

In 2015 Caiazzo assessed procedure-related complications on long-term outcome of islet transplantation in 26 patients with type 1 diabetes.[15] Each patient had two to three intraportal islet infusions, performed surgically or under ultrasound guidance, within a three-month time frame. Complications included: bowel obstruction, biliary peritonitis and a major hepatic hematoma. The investigators reported no deaths or patient dropouts. Early complications occurred in nine of 68 procedures. Procedure-related complications negatively impacted graft function (p = 0.009) and was an independent negative predictor of long-term graft survival (p=0.033) in multivariate analysis. The investigators concluded that even nonsevere complications occurring during islet transplantation, despite islet preparation method or transplantation method, significantly impair primary graft function and graft survival.

Moassesfar (2016) compared safety and efficacy of islet cell transplantation to pancreas transplantation at a center in the U.S.[16] Sequential patients with type 1 diabetes had either an islet cell transplant (n=10) or a pancreas transplant (n=15). After one year, 90% of patients in the islet group and 93% of patients in the pancreas group were insulin independent. At three years, the proportion with insulin independence dropped to 70 % and 64%, respectively. The authors concluded that islet cell transplantation can produce similar outcome to pancreatic transplantation.

In 2013, Rickels reported on 12 patients with type 1 diabetes and severe hypoglycemia who had islet transplantation.[17] Mean glycosylated hemoglobin decreased from 7.0%±0.3% before the procedure to 5.6%±0.1% after six to seven months ($p<0.01$). All of the insulin sensitivity measures were significantly less than normal before islet transplantation and not significantly different from normal after transplantation. Adverse events were not discussed.

In 2013, O'Connell reported on 17 patients who underwent islet transplantation for type 1 diabetes and severe hypoglycemia.[18] The primary end point was the proportion of patients who had had an HbA1c less than 7% and no severe hypoglycemic events two months after the initial transplant. (Patients could have one or two infusions.) Fourteen of the 17 (82%) patients achieved the primary end point. Nine (53%) patients attained insulin independence for a median of 26 months. At the time of data analysis for this publication, six patients remained insulin independent. Most adverse events were related to immunosuppression. Seven of the 17 (41%) patients developed mild lymphopenia and one developed Clostridium difficile colitis; these all responded to treatment. Eight patients developed anemia shortly after transplant and one required a blood transfusion. Procedure-related complications included one partial portal vein thrombosis and three postoperative bleeds; two of the bleeds required transfusion. Patients were followed for different amounts of time; long-term follow-up data were not available for a consistent length of time.

In 2012, Vantyghem reported on 23 patients with type 1 diabetes who underwent islet transplantation; 14 had islet-only transplants and nine had islet after kidney transplants.[19] Median HbA1c was 8.3% at baseline and 6.7% at three years. Ten of the 23 patients (43%) were insulin independent three years after islet transplantation. Findings were not reported separately for the islet-only transplant recipients.

In 2011 Thompson reported on a prospective cross-over study of intensive medical therapy (pre-transplant) versus islet cell transplantation among 32 patients with type 1 diabetes.[20] Following enrollment in the study, median follow-up was 47 months pre-transplant and 66 months post-transplant. Although improvements in HbA1c, retinopathy progression, and renal function were seen in the transplant group, small sample size and lack of treatment randomization limit interpretation of these findings. The authors also noted that their finding of reduced microvascular complications after islet transplantation may be due, in part, to their choice of maintenance immunosuppression. The study used a combination of tacrolimus and mycophenolate mofetil (MMF).

In 2006, Shapiro reported on 36 patients with type 1 diabetes mellitus that had undergone islet transplantation.[21] While short-term results were promising, insulin independence was generally not sustainable; only five patients were insulin-independent at two years. In a landmark study known as the Edmonton Protocol, seven consecutive patients achieved insulin independence following islet cell transplants from two to four donors on a glucocorticoid-free immunosuppressive regimen.[22] However, five-year outcomes from the first patients transplanted under the Edmonton protocol reported less than a 10% rate of insulin independence at five years, despite persistent graft survival as measured by C-peptide positivity (~80%).[23] The authors noted that problems with glycemic lability and hypoglycemia, the primary indications for transplant, were corrected; however, no clear advantages for chronic complications of diabetes (e.g., peripheral neuropathy) were evident. Chronic complications related to standard immunosuppressive therapy led to the need to alter the protocol in 23% of patients, thus leading the authors to conclude that "safer immunosuppression associated with fewer side effects is needed." Complications and side

effects related to both immunosuppression and the procedure itself are also reported to be more common than originally thought.[24] The experience of the transplant center itself has a demonstrated effect on patient outcomes, with the more experienced centers reporting higher success rates.

Long-term results from the Edmonton Protocol were published by Brennan (2016), who reported that all seven of the original subjects continued to have some islet function more than ten years after the transplantation.[25] One of the patients achieved insulin independence for eight years, but had graft failure 10.9 years after the first transplant. Of the other six subjects, three received an additional islet transplant, five were receiving insulin, and two were insulin-independent (with one taking liraglutide). None of the subjects had lymphoma, severe hypoglycemia, or opportunistic infections during follow-up.

Several other small case series have focused on identifying alternatives to current transplant techniques, studying encapsulated islet transplantation without immunosuppression,[26] optimizing single versus multiple-donor transplantations,[27] and comparing whole pancreas transplant to islet cell transplantation.[28, 29] Recent research also addresses islet-after-kidney transplantation.[30] However, results from these studies should be interpreted with caution as the small sample sizes (n≤ 66), lack of randomized treatment allocation and/or appropriate comparison groups do not allow for ruling out chance as an explanation of findings.

Current non-randomized studies of allogeneic islet cell transplantation appear to suggest an initial benefit (such as a decline in HbA1c levels, for example) associated with the transplant. However, as a 2010 review of this therapy notes:[31]

> "[O]ne cannot be certain of the claim that partially failed islet transplantation leads to the use of less insulin and less hypoglycemia on a cause-effect basis. It could just as easily be that patients who enter transplant programs come under close clinical scrutiny by interested diabetologists who begin managing them more skillfully."

Additional randomized controlled trials are needed to determine the strength and magnitude of potential benefits associated with this therapy and to isolate such the impact of such benefits from standard medical care.

REGISTRY DATA

LaBlanche (2021) reported 10-year outcomes from the Swiss-French GRAIL Network of 44 patients who received islet transplant for type 1 diabetes between 2003 and 2010.[32] Thirty one patients were still being followed at 10 years; six patients died between years 1 and 10 posttransplant. Median HbA1c levels were 7.2% (range, 6.2% to 8.0%) after 10 years compared to 8.0% pretransplant ($p<0.001$). One patient was insulin independent at 10 years and 73.9% were free of severe hypoglycemia. Insulin requirements were significantly lower posttransplant (0.3 units/kg/day vs. 0.5 units/kg/day; $p<.001$). Islet graft survival was 51.9% at 10 years.

Bretzel reported in 2007 data collected from the International Islet Transplant Registry from 1999-2004.[33] Data were available for 458 human islet cell transplantations. At 1-year post transplant, patient survival was 97%, islet grafts were functioning in 82% of the cases, and insulin independence was achieved in 43% of the cases.

Founded in 2001 by the National Institute of Diabetes, Digestive and Kidney Diseases, the Collaborative Islet Transplant Registry (CITR) has been collecting information on allogeneic

islet transplantation in North America, Europe, and Australia. The most recent peer-reviewed publication of CITR data was published in 2012.[34] The update focused on changes in outcomes over time in 677 patients, all of whom received a transplant as of December 31, 2010 (n=575 islet-only; n=102 kidney+islet). Unfortunately, outcomes presented in this report were limited by considerable levels of missing data which increased with longer follow-up. The missing data were reported to be a mixture of unavailable medical records and data still pending entry into the registry.

The authors reported improved insulin independence at three years post-transplant, from 27% in the early era (1999 to 2002, n=214) to 37% in the mid era (2003–2006, n = 255) and 44% in the most recent era (2007 to 2010, n=208; p=0.006 for years-by-era; p=0.01 for era alone). However, not all recipients in the latter era had reached the three-year milestone at the time of this updated report. The need for islet reinfusion for loss of function of first graft by one-year decreased significantly from 60 to 65% in 1999 to 2006 to 48% in 2007 to 2010 (p<0.01). There was also a modest decrease in clinically reportable adverse events in the 2007 to 2010 era, from 50 to 53% in 1999 to 2006 to 38% in 2007 to 2010. The rates of peritoneal hemorrhage or gallbladder infusion were 5.4% in 1999-2003 and 3.1% in 2007 to 2010. The authors did not report findings separately from the subset of patients who underwent islet-only transplants.

The Institute for Clinical and Experimental Medicine (IKEM), based in the Czech Republic, published results from a retrospective analysis of a registry of all patients receiving one or more allogeneic or autologous islet transplants from 2005 to 2010 (n=15 and n=5, respectively).[35] Although islet function was documented in 11 of 15 and three of five patients, respectively, after 12 months (as indicated by C-peptide levels), only one patient receiving an allogeneic transplant was able to achieve independence from insulin beyond 12 months. The authors conclude that islet transplant may be best suited for high-risk recipients, as “routine clinical application is still hampered by the limited availability of usable organ transplants and viability of transplanted islets.”

Results from the above registry reports should be interpreted with caution as these registries are not reflective of the complete North American experience with islet transplants; not all transplant centers participated in each regional endeavor, nor is data complete for all those who do participate. Therefore, there may be inherent bias in the data. The focus on intermediate outcomes instead of long-term health outcomes, also limits interpretation of these findings.

XENOTRANSPLANTATION

Although there is research interest in porcine islets as an alternative and potentially unlimited source of islet cells, current data from human clinical trials is limited to three case series.

Matsumoto (2016) transplanted two doses of encapsulated neonatal porcine islets (approximately 5000IEQ/kg and 10,000IEQ/kg) twice in two groups of four patients each with type 1 diabetes.[36] The two transplants were performed three months apart. One patient had a serious adverse event potentially related to the treatment, paralytic ileus, which was resolved with medication. While both groups had decreases in HbA1c, for the high dose group this difference remained significant at 600 days after the first transplant.

In 2011, Wang published results from a small clinical trial on the safety and feasibility of neonatal porcine islets (NPIs) in 22 patients in China.[37] However, only six of the 22 patients

were subsequently followed for more than two months, limiting conclusions about the long-term use of NPIs.

Also in 2011, Esquivel-Pérez published a report on 23 patients not on immunosuppression, transplanted with a porcine cell-filled device.[38] Following an average of 5.7 years post-transplantation, the researchers reported that the patients with the lowest levels of antibodies were significantly more likely to report higher insulin dose reductions. However, not all patients were able to attain low levels of antibodies, for reasons not clearly known. Therefore, this report provides evidence for transplantation protocols but does not address the clinical utility of xenotransplantation.

Current literature has not directly addressed problems related to xenograft rejection and xeno-zoonosis (transmission of animal disease to humans).

PRACTICE GUIDELINE SUMMARY

In 2021, the American Diabetes Association (ADA) updated their position statement on comprehensive care for patients with type 1 diabetes. The statement includes a recommendation with a C rating stating that “Islet autotransplantation should be considered for patients requiring total pancreatectomy for medically refractory chronic pancreatitis to prevent postsurgical diabetes.” In addition, it states:

> “Successful pancreas and islet transplantation can normalize glucose levels and mitigate microvascular complications of type 1 diabetes. However, patients receiving these treatments require lifelong immunosuppression to prevent graft rejection and/or recurrence of autoimmune islet destruction. Given the potential adverse effects of immunosuppressive therapy, pancreas transplantation should be reserved for patients with type 1 diabetes undergoing simultaneous renal transplantation, following renal transplantation, or for those with recurrent ketoacidosis or severe hypoglycemia despite intensive glycemic management.”

SUMMARY

There is enough research to show that autologous islet cell transplantation is relatively safe and can reduce the chance of developing diabetes after total or near total pancreatectomy in patients with chronic pancreatitis. Therefore, autologous islet cell transplantation may be considered medically necessary as an adjunct to a total or near total pancreatectomy in patients with chronic pancreatitis.

There is not enough research to show that autologous islet cell transplantation can improve health outcomes for people with any other conditions. Therefore, autologous pancreatic islet cell transplantation for all other indications is considered investigational.

Although there is research interest in porcine islets (xeno islet cells) as a source of islet cells and allogeneic transplantation, there is not enough research to show that xenotransplantation or allogeneic transplantation is safe and effective, and there are no clinical guidelines based on research that recommend xenotransplantation or allogeneic transplantation. Therefore, xeno islet cell transplantation and allogeneic islet transplantation for any diagnosis are considered investigational.

Air Ambulance Transport

Effective: April 1, 2024

Next Review: February 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Air ambulance transportation is provided by helicopters (rotary wing) or fixed wing aircraft that are specially designed, equipped, and staffed for transporting sick and injured patients.

MEDICAL POLICY CRITERIA

Note: This policy only applies to member contracts that are subject to review for air ambulance services, as specified by their group plan. Please check the preauthorization website for the member contract to confirm requirements.

I. Air ambulance transport may be considered **medically necessary** when all of the following criteria (A. – C.) are met:

   A. Urgent and rapid ambulance transport is essential to stabilize or preserve the patient's life.

   B. One of the following criteria is met:

      1. Transport cannot be safely provided by ground ambulance due to great distances, prolonged transport time, or other obstacles that would endanger the patient's health or threaten survival; or

      2. The point of pick up is inaccessible by ground ambulance.

C. Transport is to the nearest acute care facility equipped to provide the appropriate treatment for the patient's condition.

II. Air ambulance transport is considered **not medically necessary** for circumstances not meeting the Criteria in I.A. – C. and above, including but not limited to the following:

A. Transport from a facility providing a higher level of care to a facility providing an equivalent or lower level of care, including to an inpatient rehabilitation facility, long term acute care facility, or skilled nursing facility;

B. Transport for personal or convenience purposes, such as return to home;

C. Transport beyond the nearest facility equipped to provide the most appropriate care for the patient's condition.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- Documentation that the member's medical condition required immediate and rapid ambulance transportation that could not have been provided by ground ambulance.
- Location of transport pick-up.
- Location of transport drop-off.
- Level of care of facility which the member is being transferred to.
- Level of care of facility which the member is being transferred from.
- All additional documentation supporting the need for air ambulance services (i.e., accessibility of the point of pick-up, distances, obstacles, etc.).

DESCRIPTION

An ambulatory surgery center (ASC) is a health care facility which offers same-day surgery services outside the hospital setting. An ASC is a surgical facility that does not have inpatient beds, and the entity may or may not be sponsored by a hospital. An individual's health status is considered when determining the appropriateness for the site of service among other factors including facility and geographic availability, specialty requirements, and physician privileges.

MEDICAL POLICY CRITERIA

Notes:

- This policy does not address procedures performed in an ambulatory surgery center (ASC), physician office, or emergency facility for urgent services.
- This policy addresses prior authorization for site of service only. The procedure may require prior authorization separately (see applicable Medical Policy).
- For coverage of a procedure in a hospital outpatient department, in addition to meeting the criteria in this medical policy, the type of service being performed must be considered medically necessary per prior authorization review requirements

and the applicable medical policy OR the health plan does not require prior authorization for the service being performed.

I. The use of a hospital outpatient department instead of an ambulatory surgery center (ASC) or physician office for surgical services may be considered **medically necessary** when one or more of the following Criteria is met:

A. There is no qualifying ASC within 25 miles that can provide the necessary care for the patient due to one of the following:

1. There is no geographically accessible ASC that has the necessary equipment for the procedure; or
2. There is no geographically accessible ASC available at which the individual's physician has privileges; or
3. An ASC's specific guideline regarding the individual's weight or health conditions prevents the use of an ASC;

B. The procedure requires discontinuing medications (e.g. antiarrhythmics, antiseizure medication), which necessitate preoperative or postoperative inpatient monitoring or treatment;

C. The individual is using substances or medications (e.g. cocaine, amphetamines, monoamine oxidase inhibitor, alcohol) that may interact with the anticipated anesthetic regimen or lead to withdrawal syndrome;

D. History of a significant hemodynamic instability during a prior surgical procedure and is considered a risk for future procedures;

E. Age 17 years and younger;

F. The service being performed is in conjunction with an additional service that requires the use of a hospital outpatient department and they are being performed in the same operative session;

G. American Society of Anesthesiologists (ASA) Physical Status (PS) Classification III or higher (see Policy Guidelines);

H. Body mass index (BMI) is over 40;

I. Bleeding disorder requiring replacement factor or special infusion products to correct a coagulation defect;

J. Complex anticoagulation management anticipated;

K. Transfusion anticipated;

L. Sickle cell disease;

M. Clinical documentation that cardiovascular risk is increased by any of the following factors:

1. Symptomatic cardiac arrhythmia despite medication
2. Coronary artery disease (CAD)
3. Drug eluting stents (DES) placed within one year or bare metal stents (BMS) or plain angioplasty within 90 days

4. History of cerebrovascular accident (CVA) or transient ischemic attack (TIA) within past three months
5. History of myocardial infarction (MI) within past three months
6. Implantable cardioverter-defibrillator (ICD)
7. Implanted pacemaker
8. Mechanical cardiovascular support (e.g., left ventricular assist device [LVAD] or total artificial heart)
9. Peripheral vascular disease (PVD)
10. Ongoing evidence of myocardial ischemia
11. Hypertension, severe (>180/110) or resistant (not responsive to three antihypertensive medications)
12. Uncompensated chronic heart failure (CHF) (NYHA class III or IV)
13. Valvular heart disease and/or cardiomyopathy, moderate or severe;

N. Prolonged surgery (> 3 hours);

O. Advanced liver disease (Model for End-Stage Liver Disease [MELD] Score > 8);

P. Diabetes, when uncontrolled (HgbA1c >8%) or with recurrent diabetic ketoacidosis (DKA) or severe hypoglycemia;

Q. End stage renal disease (ESRD), Stage 4 or 5 chronic kidney disease;

R. Incompletely treated skin or wound infection;

S. Pregnancy;

T. Pulmonary risk is increased by any of the following factors:
1. Abnormal airway
2. Prior difficult intubation
3. Active respiratory infection
4. Chronic obstructive pulmonary disease (COPD) (FEV1 < 50%)
5. Medical conditions that are commonly connected with difficult airway (e.g., Pierre-Robin, Treacher-Collins, Goldenhar's Syndrome, and Epidermolysis Bullosa)
6. Poorly controlled asthma (FEV1 < 80% despite medical management)
7. Moderate to severe obstructive sleep apnea:
   a. Moderate = Apnea hypopnea index (AHI) or respiratory disturbance index (RDI) $\geq$15 and $\leq$30;
   b. Severe = AHI or RDI >30/hr;
8. Dependent on a ventilator or continuous supplemental oxygen;

U. Personal history or family history of complication of anesthesia such as malignant hyperthermia;

V. History of any of the following gastrointestinal conditions that would increase risk for aspiration:

1. Documented history of achalasia

2. Documented history of delayed gastric emptying disorder or gastroparesis;

W. History of any of the following neurological diagnoses that would increase risk:

1. Active multiple sclerosis

2. Myasthenia gravis

3. Severe motor disorder (e.g. severe Parkinson's, or other severe neurological dysfunction)

4. A condition is present that will require the use of restraints;

X. History of total joint infection;

Y. Individual is awaiting major organ transplant;

Z. Risk of procedure-specific complication;

AA. Provider documents a requirement for overnight recovery based on a unique circumstance for the individual.

II. The use of a hospital outpatient department for surgical services instead of an ambulatory surgery center or physician office is considered **not medically necessary** when Criteria I. is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Site of service medical necessity reviews will be conducted for surgical procedures on the Codes list provided in this policy only when performed in an outpatient hospital setting.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS (ASA) PHYSICAL STATUS CLASSIFICATION SYSTEM[1]

ASA PS Classification	Definition	Adult Examples, including but not limited to:
ASA I	A normal healthy patient	Healthy, non-smoking, no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Current smoker, social alcohol drinker, pregnancy, obesity (30 < BMI < 40), well-controlled DM/HTN, mild lung disease
ASA III	A patient with severe systemic disease	Substantive functional limitations; One or more moderate to severe diseases. Poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis,

ASA PS Classification	Definition	Adult Examples, including but not limited to:
		premature infant PCA < 60 weeks, history (>3 months) of MI, CVA, TIA, or CAD/stents.
ASA IV	A patient with severe systemic disease that is a constant threat to life	Recent (< 3 months) MI, CVA, TIA, or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, DIC, ARD or ESRD not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	

*The addition of "E" denotes Emergency surgery: (An emergency is defined as existing when delay in treatment of the patient would lead to a significant increase in the threat to life or body part)

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and physical/chart notes
- American Society of Anesthesiologists (ASA) score, as applicable
- Clinical documentation for specific policy criteria (refer to the Policy Criteria) that qualifies the individual for the site of service requested
- For specific services requiring prior authorization in addition to the site of service, submission of the applicable medical policy clinical documentation required for review.
- The best way to ensure criteria are met is to submit the Surgical Site of Service Additional Information form if faxing a pre-authorization request for these services.

BACKGROUND

An ambulatory surgery center (ASC) is a health care facility which offers same-day surgery services outside the hospital setting. An ASC is a surgical facility that does not have inpatient beds, and the entity may or may not be sponsored by a hospital.

An individual's health status is considered when determining the appropriateness for the site of service among other factors including facility and geographic availability, specialty requirements, and physician privileges. The American Society of Anesthesiologist (ASA) physical status classification system (see Appendix I), and/or significant comorbidities may be

taken into account.[1] The ASA risk scoring system is regarded by hospitals, legal firms, accrediting bodies, and other healthcare groups as a preoperative health grading system for individuals undergoing a surgical procedure. For example, individuals with ASA I-II status might be appropriate candidates for ASC care, though ASA III and above may not. Significant comorbidities may include but are not limited to significant cardiorespiratory condition (e.g., recent myocardial infarction, cardiac arrhythmia, and myocardial ischemia), moderate-to-severe obstructive sleep apnea, pregnancy, and poorly controlled asthma.

PRACTICE GUIDELINE SUMMARY

AMERICAN SOCIETY OF ANESTHESIOLOGISTS

The American Society of Anesthesiologists (ASA) maintains a Physical Status Classification System with definitions and ASA-approved examples (reproduced in Appendix I).[1] This system is intended to be used in conjunction with other factors to aid in predicting perioperative risks. The system was originally proposed in 1942, and the current version was published in 2014 with the inclusion of examples, and was most recently updated in 2020.

SUMMARY

The use of a hospital outpatient department instead of an ambulatory surgical center (ASC) for surgical services may be considered medically necessary when the procedure is of a level of complexity such that it may not be performed in a less intensive setting, the service being performed is medically necessary, and the surgical site of service policy criteria are met.

The use of a hospital outpatient department instead of an ambulatory surgical center (ASC) for surgical services is not medically necessary when the policy criteria are not met including when the procedure can be safely performed in a less intensive setting, the specific service requires prior authorization and does not meet applicable policy criteria, or the surgical site of service policy criteria are not met.

	11000	Debridement of extensive eczematous or infected skin; up to 10% of body surface
	11010	Debridement including removal of foreign material at the site of an open fracture and/or an open dislocation (eg, excisional debridement); skin and subcutaneous tissues
	11012	Debridement including removal of foreign material at the site of an open fracture and/or an open dislocation (eg, excisional debridement); skin, subcutaneous tissue, muscle fascia, muscle, and bone
	11042	Debridement, subcutaneous tissue (includes epidermis and dermis, if performed); first 20 sq cm or less
	11044	Debridement, Debridement, bone (includes epidermis, dermis, subcutaneous tissue, muscle and/or fascia, if performed); first 20 sq cm or less
	11200	Removal of skin tags, multiple fibrocutaneous tags, any area; up to and including 15 lesions
	11310	Shaving of epidermal or dermal lesion, single lesion, face, ears, eyelids, nose, lips, mucous membrane; lesion diameter 0.5 cm or less
	11402	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), trunk, arms or legs; excised diameter 1.1 to 2.0 cm
	11403	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), trunk, arms or legs; excised diameter 2.1 to 3.0 cm
	11404	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), trunk, arms or legs; excised diameter 3.1 to 4.0 cm
	11406	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), trunk, arms or legs; excised diameter over 4.0 cm
	11420	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter 0.5 cm or less
	11421	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter 0.6 to 1.0 cm
	11422	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter 1.1 to 2.0 cm
	11423	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter 2.1 to 3.0 cm
	11424	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter 3.1 to 4.0 cm
	11426	Excision, benign lesion including margins, except skin tag (unless listed elsewhere), scalp, neck, hands, feet, genitalia; excised diameter over 4.0 cm
	11440	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter 0.5 cm or less
	11441	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter 0.6 to 1.0 cm

Codes	Number	Description
	11442	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter 1.1 to 2.0 cm
	11443	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter 2.1 to 3.0 cm
	11444	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter 3.1 to 4.0 cm
	11446	Excision, other benign lesion including margins, except skin tag (unless listed elsewhere), face, ears, eyelids, nose, lips, mucous membrane; excised diameter over 4.0 cm
	11450	Excision of skin and subcutaneous tissue for hidradenitis, axillary; with simple or intermediate repair
	11451	Excision of skin and subcutaneous tissue for hidradenitis, axillary; with complex repair
	11462	Excision of skin and subcutaneous tissue for hidradenitis, inguinal; with simple or intermediate repair
	11463	Excision of skin and subcutaneous tissue for hidradenitis, inguinal; with complex repair
	11470	Excision of skin and subcutaneous tissue for hidradenitis, perianal, perineal, or umbilical; with simple or intermediate repair
	11471	Excision of skin and subcutaneous tissue for hidradenitis, perianal, perineal, or umbilical; with complex repair
	11601	Excision, malignant lesion including margins, trunk, arms, or legs; excised diameter 0.6 to 1.0 cm
	11602	Excision, malignant lesion including margins, trunk, arms, or legs; excised diameter 1.1 to 2.0 cm
	11603	Excision, malignant lesion including margins, trunk, arms, or legs; excised diameter 2.1 to 3.0 cm
	11604	Excision, malignant lesion including margins, trunk, arms, or legs; excised diameter 3.1 to 4.0 cm
	11606	Excision, malignant lesion including margins, trunk, arms, or legs; excised diameter over 4.0 cm
	11620	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter 0.5 cm or less
	11621	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter 0.6 to 1.0 cm
	11622	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter 1.1 to 2.0 cm
	11623	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter 2.1 to 3.0 cm
	11624	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter 3.1 to 4.0 cm
	11626	Excision, malignant lesion including margins, scalp, neck, hands, feet, genitalia; excised diameter over 4.0 cm
	11640	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter 0.5 cm or less
	11641	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter 0.6 to 1.0 cm
	11642	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter 1.1 to 2.0 cm

Codes	Number	Description
	11643	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter 2.1 to 3.0 cm
	11644	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter 3.1 to 4.0 cm
	11646	Excision, malignant lesion including margins, face, ears, eyelids, nose, lips; excised diameter over 4.0 cm
	11730	Avulsion of nail plate, partial or complete, simple; single
	11750	Excision of nail and nail matrix, partial or complete (eg, ingrown or deformed nail), for permanent removal;
	11755	Biopsy of nail unit (eg, plate, bed, matrix, hyponychium, proximal and lateral nail folds) (separate procedure)
	11760	Repair of nail bed
	11765	Wedge excision of skin of nail fold (eg, for ingrown toenail)
	11770	Excision of pilonidal cyst or sinus; simple
	11772	Excision of pilonidal cyst or sinus; complicated
	11900	Injection, intralesional; up to and including 7 lesions
	12001	Simple repair of superficial wounds of scalp, neck, axillae, external genitalia, trunk and/or extremities (including hands and feet); 2.5 cm or less
	12002	Simple repair of superficial wounds of scalp, neck, axillae, external genitalia, trunk and/or extremities (including hands and feet); 2.6 cm to 7.5 cm
	12011	Simple repair of superficial wounds of face, ears, eyelids, nose, lips and/or mucous membranes; 2.5 cm or less
	12020	Treatment of superficial wound dehiscence; simple closure
	12031	Repair, intermediate, wounds of scalp, axillae, trunk and/or extremities (excluding hands and feet); 2.5 cm or less
	12032	Repair, intermediate, wounds of scalp, axillae, trunk and/or extremities (excluding hands and feet); 2.6 cm to 7.5 cm
	12034	Repair, intermediate, wounds of scalp, axillae, trunk and/or extremities (excluding hands and feet); 7.6 cm to 12.5 cm
	12035	Repair, intermediate, wounds of scalp, axillae, trunk and/or extremities (excluding hands and feet); 12.6 cm to 20.0 cm
	12037	Repair, intermediate, wounds of scalp, axillae, trunk and/or extremities (excluding hands and feet); over 30.0 cm
	12041	Repair, intermediate, wounds of neck, hands, feet and/or external genitalia; 2.5 cm or less
	12042	Repair, intermediate, wounds of neck, hands, feet and/or external genitalia; 2.6 cm to 7.5 cm
	12051	Repair, intermediate, wounds of face, ears, eyelids, nose, lips and/or mucous membranes; 2.5 cm or less
	13120	Repair, complex, scalp, arms, and/or legs; 1.1 cm to 2.5 cm
	13121	Repair, complex, scalp, arms, and/or legs; 2.6 cm to 7.5 cm
	13131	Repair, complex, forehead, cheeks, chin, mouth, neck, axillae, genitalia, hands and/or feet; 1.1 cm to 2.5 cm
	13132	Repair, complex, forehead, cheeks, chin, mouth, neck, axillae, genitalia, hands and/or feet; 2.6 cm to 7.5 cm
	13151	Repair, complex, eyelids, nose, ears and/or lips; 1.1 cm to 2.5 cm
	13152	Repair, complex, eyelids, nose, ears and/or lips; 2.6 cm to 7.5 cm
	13160	Secondary closure of surgical wound or dehiscence, extensive or complicated
	14020	Adjacent tissue transfer or rearrangement, scalp, arms and/or legs; defect 10 sq cm or less
	14040	Adjacent tissue transfer or rearrangement, forehead, cheeks, chin, mouth, neck, axillae, genitalia, hands and/or feet; defect 10 sq cm or less

Codes	Number	Description
	14060	Adjacent tissue transfer or rearrangement, eyelids, nose, ears and/or lips; defect 10 sq cm or less
	15120	Split-thickness autograft, face, scalp, eyelids, mouth, neck, ears, orbits, genitalia, hands, feet, and/or multiple digits; first 100 sq cm or less, or 1% of body area of infants and children (except 15050)
	15220	Full thickness graft, free, including direct closure of donor site, scalp, arms, and/or legs; 20 sq cm or less
	15240	Full thickness graft, free, including direct closure of donor site, forehead, cheeks, chin, mouth, neck, axillae, genitalia, hands, and/or feet; 20 sq cm or less
	15760	Graft; composite (eg, full thickness of external ear or nasal ala), including primary closure, donor area
	~~15850~~	~~Removal of sutures under anesthesia (other than local), same surgeon~~ (Deleted 1/1/2023)
	15851	Removal of sutures or staples requiring anesthesia (ie, general anesthesia, moderate sedation)
	17000	Destruction (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery, surgical curettement), premalignant lesions (eg, actinic keratoses); first lesion
	17110	Destruction (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery, surgical curettement), of benign lesions other than skin tags or cutaneous vascular proliferative lesions; up to 14 lesions
	17111	Destruction (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery, surgical curettement), of benign lesions other than skin tags or cutaneous vascular proliferative lesions; 15 or more lesions
	17311	Mohs micrographic technique, including removal of all gross tumor, surgical excision of tissue specimens, mapping, color coding of specimens, microscopic examination of specimens by the surgeon, and histopathologic preparation including routine stain(s) (eg, hematoxylin and eosin, toluidine blue), head, neck, hands, feet, genitalia, or any location with surgery directly involving muscle, cartilage, bone, tendon, major nerves, or vessels; first stage, up to 5 tissue blocks
	17313	Mohs micrographic technique, including removal of all gross tumor, surgical excision of tissue specimens, mapping, color coding of specimens, microscopic examination of specimens by the surgeon, and histopathologic preparation including routine stain(s) (eg, hematoxylin and eosin, toluidine blue), of the trunk, arms, or legs; first stage, up to 5 tissue blocks
	19020	Mastotomy with exploration or drainage of abscess, deep
	19101	Biopsy of breast; open, incisional
	19110	Nipple exploration, with or without excision of a solitary lactiferous duct or a papilloma lactiferous duct
	19112	Excision of lactiferous duct fistula
	19120	Excision of cyst, fibroadenoma, or other benign or malignant tumor, aberrant breast tissue, duct lesion, nipple or areolar lesion (except 19300), open, male or female, 1 or more lesions
	19125	Excision of breast lesion identified by preoperative placement of radiological marker, open; single lesion
	20200	Biopsy, muscle; superficial
	20205	Biopsy, muscle; deep
	20220	Biopsy, bone, trocar, or needle; superficial (eg, ilium, sternum, spinous process, ribs)
	20225	Biopsy, bone, trocar, or needle; deep (eg, vertebral body, femur)

Codes	Number	Description
	20240	Biopsy, bone, open; superficial (eg, sternum, spinous process, rib, patella,
	20526	Injection, therapeutic (eg, local anesthetic, corticosteroid), carpal tunnel
		Arthrocentesis, aspiration and/or injection, small joint or bursa (eg, fingers, toes); without ultrasound guidance
	20604	Arthrocentesis, aspiration and/or injection, small joint or bursa (eg, fingers, toes); with ultrasound guidance, with permanent recording and reporting
	20605	Arthrocentesis, aspiration and/or injection, intermediate joint or bursa (eg, temporomandibular, acromioclavicular, wrist, elbow or ankle, olecranon bursa); without ultrasound guidance
	20606	Arthrocentesis, aspiration and/or injection, intermediate joint or bursa (eg, temporomandibular, acromioclavicular, wrist, elbow or ankle, olecranon bursa); with ultrasound guidance, with permanent recording and reporting
	20610	Arthrocentesis, aspiration and/or injection, major joint or bursa (eg, shoulder, hip, knee, subacromial bursa); without ultrasound guidance
	20611	Arthrocentesis, aspiration and/or injection, major joint or bursa (eg, shoulder, hip, knee, subacromial bursa); with ultrasound guidance, with permanent recording and reporting
	20912	Cartilage graft; nasal septum
	21011	Excision, tumor, soft tissue of face or scalp, subcutaneous; less than 2 cm
	21012	Excision, tumor, soft tissue of face or scalp, subcutaneous; 2 cm or greater
	21013	Excision, tumor, soft tissue of face and scalp, subfascial (eg, subgaleal, intramuscular); less than 2 cm
	21014	Excision, tumor, soft tissue of face and scalp, subfascial (eg, subgaleal, intramuscular); 2 cm or greater
	21029	Removal by contouring of benign tumor of facial bone (eg, fibrous dysplasia)
	21030	Excision of benign tumor or cyst of maxilla or zygoma by enucleation and curettage
	21031	Excision of torus mandibularis
	21040	Excision of benign tumor or cyst of mandible, by enucleation and/or curettage
	21046	Excision of benign tumor or cyst of mandible; requiring intra-oral osteotomy (eg, locally aggressive or destructive lesion[s])
	21048	Excision of benign tumor or cyst of maxilla; requiring intra-oral osteotomy (eg, locally aggressive or destructive lesion[s])
	21315	Closed treatment of nasal bone fracture with manipulation; without stabilization
	21320	Closed treatment of nasal bone fracture with manipulation; with stabilization
	21325	Open treatment of nasal fracture; uncomplicated
	21330	Open treatment of nasal fracture; complicated, with internal and/or external skeletal fixation
	21335	Open treatment of nasal fracture; with concomitant open treatment of fractured septum
	21336	Open treatment of nasal septal fracture, with or without stabilization
	21337	Closed treatment of nasal septal fracture, with or without stabilization
	21356	Open treatment of depressed zygomatic arch fracture (eg, Gillies approach)
	21550	Biopsy, soft tissue of neck or thorax
	21552	Excision, tumor, soft tissue of neck or anterior thorax, subcutaneous; 3 cm or greater
	21554	Excision, tumor, soft tissue of neck or anterior thorax, subfascial (eg, intramuscular); 5 cm or greater
	21555	Excision, tumor, soft tissue of neck or anterior thorax, subcutaneous; less than 3 cm

Codes	Number	Description
	21556	Excision, tumor, soft tissue of neck or anterior thorax, subfascial (eg, intramuscular); less than 5 cm
	21557	Radical resection of tumor (eg, sarcoma), soft tissue of neck or anterior thorax; less than 5 cm
	21920	Biopsy, soft tissue of back or flank; superficial
	21930	Excision, tumor, soft tissue of back or flank, subcutaneous; less than 3 cm
	21931	Excision, tumor, soft tissue of back or flank, subcutaneous; 3 cm or greater
	21932	Excision, tumor, soft tissue of back or flank, subfascial (eg, intramuscular); less than 5 cm
	22900	Excision, tumor, soft tissue of abdominal wall, subfascial (eg, intramuscular); less than 5 cm
	22901	Excision, tumor, soft tissue of abdominal wall, subfascial (eg, intramuscular); 5 cm or greater
	22902	Excision, tumor, soft tissue of abdominal wall, subcutaneous; less than 3 cm
	22903	Excision, tumor, soft tissue of abdominal wall, subcutaneous; 3 cm or greater
	23030	Incision and drainage, shoulder area; deep abscess or hematoma
	23071	Excision, tumor, soft tissue of shoulder area, subcutaneous; 3 cm or greater
	23075	Excision, tumor, soft tissue of shoulder area, subcutaneous; less than 3 cm
	23140	Excision or curettage of bone cyst or benign tumor of clavicle or scapula;
	23150	Excision or curettage of bone cyst or benign tumor of proximal humerus;
	24000	Arthrotomy, elbow, including exploration, drainage, or removal of foreign body
	24006	Arthrotomy of the elbow, with capsular excision for capsular release (separate procedure)
	24065	Biopsy, soft tissue of upper arm or elbow area; superficial
	24066	Biopsy, soft tissue of upper arm or elbow area; deep (subfascial or intramuscular)
	24071	Excision, tumor, soft tissue of upper arm or elbow area, subcutaneous; 3 cm or greater
	24073	Excision, tumor, soft tissue of upper arm or elbow area, subfascial (eg, intramuscular); 5 cm or greater
	24075	Excision, tumor, soft tissue of upper arm or elbow area, subcutaneous; less than 3 cm
	24076	Excision, tumor, soft tissue of upper arm or elbow area, subfascial (eg, intramuscular); less than 5 cm
	24101	Arthrotomy, elbow; with joint exploration, with or without biopsy, with or without removal of loose or foreign body
	24110	Excision or curettage of bone cyst or benign tumor, humerus;
	24120	Excision or curettage of bone cyst or benign tumor of head or neck of radius or olecranon process;
	24130	Excision, radial head
	24147	Partial excision (craterization, saucerization, or diaphysectomy) bone (eg, osteomyelitis), olecranon process
	24200	Removal of foreign body, upper arm or elbow area; subcutaneous
	24201	Removal of foreign body, upper arm or elbow area; deep (subfascial or intramuscular)
	24366	Arthroplasty, radial head; with implant
	25071	Excision, tumor, soft tissue of forearm and/or wrist area, subcutaneous; 3 cm or greater
	25073	Excision, tumor, soft tissue of forearm and/or wrist area, subfascial (eg, intramuscular); 3 cm or greater
	25075	Excision, tumor, soft tissue of forearm and/or wrist area, subcutaneous; less than 3 cm

Codes	Number	Description
	25076	Excision, tumor, soft tissue of forearm and/or wrist area, subfascial (eg, intramuscular); less than 3 cm
	25085	Capsulotomy, wrist (eg, contracture)
	25109	Excision of tendon, forearm and/or wrist, flexor or extensor, each
	25120	Excision or curettage of bone cyst or benign tumor of radius or ulna (excluding head or neck of radius and olecranon process);
	25130	Excision or curettage of bone cyst or benign tumor of carpal bones;
	25350	Osteotomy, radius; distal third
	26070	Arthrotomy, with exploration, drainage, or removal of loose or foreign body; carpometacarpal joint
	26105	Arthrotomy with biopsy; metacarpophalangeal joint, each
	26110	Arthrotomy with biopsy; interphalangeal joint, each
	26111	Excision, tumor or vascular malformation, soft tissue of hand or finger, subcutaneous; 1.5 cm or greater
	26113	Excision, tumor, soft tissue, or vascular malformation, of hand or finger, subfascial (eg, intramuscular); 1.5 cm or greater
	26115	Excision, tumor or vascular malformation, soft tissue of hand or finger, subcutaneous; less than 1.5 cm
	26180	Excision of tendon, finger, flexor or extensor, each tendon
	26200	Excision or curettage of bone cyst or benign tumor of metacarpal;
	26210	Excision or curettage of bone cyst or benign tumor of proximal, middle, or distal phalanx of finger;
	26357	Repair or advancement, flexor tendon, in zone 2 digital flexor tendon sheath (eg, no man's land); secondary, without free graft, each tendon
	26432	Closed treatment of distal extensor tendon insertion, with or without percutaneous pinning (eg, mallet finger)
	26433	Repair of extensor tendon, distal insertion, primary or secondary; without graft (eg, mallet finger)
	26500	Reconstruction of tendon pulley, each tendon; with local tissues (separate procedure)
	26530	Arthroplasty, metacarpophalangeal joint; each joint
	26542	Reconstruction, collateral ligament, metacarpophalangeal joint, single; with local tissue (eg, adductor advancement)
	26841	Arthrodesis, carpometacarpal joint, thumb, with or without internal fixation;
	26862	Arthrodesis, interphalangeal joint, with or without internal fixation; with autograft (includes obtaining graft)
	27006	Tenotomy, abductors and/or extensor(s) of hip, open (separate procedure)
	27043	Excision, tumor, soft tissue of pelvis and hip area, subcutaneous; 3 cm or greater
	27045	Excision, tumor, soft tissue of pelvis and hip area, subfascial (eg, intramuscular); 5 cm or greater
	27047	Excision, tumor, soft tissue of pelvis and hip area, subcutaneous; less than 3 cm
	27048	Excision, tumor, soft tissue of pelvis and hip area, subfascial (eg, intramuscular); less than 5 cm
	27062	Excision; trochanteric bursa or calcification
	27093	Injection procedure for hip arthrography; without anesthesia
	27095	Injection procedure for hip arthrography; with anesthesia
	27310	Arthrotomy, knee, with exploration, drainage, or removal of foreign body (eg, infection)
	27323	Biopsy, soft tissue of thigh or knee area; superficial
	27324	Biopsy, soft tissue of thigh or knee area; deep (subfascial or intramuscular)

Codes	Number	Description
	27327	Excision, tumor, soft tissue of thigh or knee area, subcutaneous; less than 3 cm
	27328	Excision, tumor, soft tissue of thigh or knee area, subfascial (eg, intramuscular); less than 5 cm
	27329	Radical resection of tumor (eg, sarcoma), soft tissue of thigh or knee area; less than 5 cm
	27337	Excision, tumor, soft tissue of thigh or knee area, subcutaneous; 3 cm or greater
	27339	Excision, tumor, soft tissue of thigh or knee area, subfascial (eg, intramuscular); 5 cm or greater
	27340	Excision, prepatellar bursa
	27345	Excision of synovial cyst of popliteal space (eg, Baker's cyst)
	27347	Excision of lesion of meniscus or capsule (eg, cyst, ganglion), knee
	27613	Biopsy, soft tissue of leg or ankle area; superficial
	27614	Biopsy, soft tissue of leg or ankle area; deep (subfascial or intramuscular)
	27618	Excision, tumor, soft tissue of leg or ankle area, subcutaneous; less than 3 cm
	27632	Excision, tumor, soft tissue of leg or ankle area, subcutaneous; 3 cm or greater
	27634	Excision, tumor, soft tissue of leg or ankle area, subfascial (eg, intramuscular); 5 cm or greater
	27638	Excision or curettage of bone cyst or benign tumor, tibia or fibula; with allograft
	27640	Partial excision (craterization, saucerization, or diaphysectomy), bone (eg, osteomyelitis); tibia
	27720	Repair of nonunion or malunion, tibia; without graft, (eg, compression technique)
	28011	Tenotomy, percutaneous, toe; multiple tendons
	28039	Excision, tumor, soft tissue of foot or toe, subcutaneous; 1.5 cm or greater
	28041	Excision, tumor, soft tissue of foot or toe, subfascial (eg, intramuscular); 1.5 cm or greater
	28043	Excision, tumor, soft tissue of foot or toe, subcutaneous; less than 1.5 cm
	28045	Excision, tumor, soft tissue of foot or toe, subfascial (eg, intramuscular); less than 1.5 cm
	28047	Radical resection of tumor (eg, sarcoma), soft tissue of foot or toe; 3 cm or greater
	28100	Excision or curettage of bone cyst or benign tumor, talus or calcaneus;
	28103	Excision or curettage of bone cyst or benign tumor, talus or calcaneus; with allograft
	28104	Excision or curettage of bone cyst or benign tumor, tarsal or metatarsal, except talus or calcaneus;
	28126	Resection, partial or complete, phalangeal base, each toe
	28666	Percutaneous skeletal fixation of interphalangeal joint dislocation, with manipulation
	29835	Arthroscopy, elbow, surgical; synovectomy, partial
	29900	Arthroscopy, metacarpophalangeal joint, diagnostic, includes synovial biopsy
	29901	Arthroscopy, metacarpophalangeal joint, surgical; with debridement
	30000	Drainage abscess or hematoma, nasal, internal approach
	30020	Drainage abscess or hematoma, nasal septum
	30100	Biopsy, intranasal
	30110	Excision, nasal polyp(s), simple
	30115	Excision, nasal polyp(s), extensive
	30117	Excision or destruction (eg, laser), intranasal lesion; internal approach
	30118	Excision or destruction (eg, laser), intranasal lesion; external approach (lateral rhinotomy)
	30130	Excision inferior turbinate, partial or complete, any method

Codes	Number	Description
	30140	Submucous resection inferior turbinate, partial or complete, any method
	30220	Insertion, nasal septal prosthesis (button)
	30310	Removal foreign body, intranasal; office type procedure
	30520	Septoplasty or submucous resection, with or without cartilage scoring, contouring or replacement with graft
	30580	Removal foreign body, intranasal; requiring general anesthesia
	30630	Repair fistula; oromaxillary (combine with 31030 if antrotomy is included)
	30801	Repair nasal septal perforations
	30802	Ablation, soft tissue of inferior turbinates, unilateral or bilateral, any method (eg, electrocautery, radiofrequency ablation, or tissue volume reduction); intramural (ie, submucosal)
	30901	Ablation, soft tissue of inferior turbinates, unilateral or bilateral, any method (eg, electrocautery, radiofrequency ablation, or tissue volume reduction); superficial
	30903	Control nasal hemorrhage, anterior, simple (limited cautery and/or packing) any method
	30930	Control nasal hemorrhage, anterior, complex (extensive cautery and/or packing) any method
	31020	Fracture nasal inferior turbinate(s), therapeutic
	31030	Sinusotomy, maxillary (antrotomy); intranasal
	31032	Sinusotomy, maxillary (antrotomy); radical (Caldwell-Luc) without removal of antrochoanal polyps
	31200	Ethmoidectomy; intranasal, anterior
	31205	Ethmoidectomy; extranasal, total
	31238	Sinusotomy, maxillary (antrotomy); radical (Caldwell-Luc) with removal of antrochoanal polyps
	31525	Laryngoscopy direct, with or without tracheoscopy; diagnostic, except newborn
	31526	Nasal/sinus endoscopy, surgical; with control of nasal hemorrhage
	31528	Laryngoscopy direct, with or without tracheoscopy; diagnostic, with operating microscope or telescope
	31529	Laryngoscopy direct, with or without tracheoscopy; with dilation, initial
	31530	Laryngoscopy direct, with or without tracheoscopy; with dilation, subsequent
	31535	Laryngoscopy, direct, operative, with foreign body removal;
	31536	Laryngoscopy, direct, operative, with biopsy;
	31540	Laryngoscopy, direct, operative, with biopsy; with operating microscope or telescope
	31541	Laryngoscopy, direct, operative, with excision of tumor and/or stripping of vocal cords or epiglottis;
	31545	Laryngoscopy, direct, operative, with excision of tumor and/or stripping of vocal cords or epiglottis; with operating microscope or telescope
	31570	Laryngoscopy, direct, operative, with operating microscope or telescope, with submucosal removal of non-neoplastic lesion(s) of vocal cord; reconstruction with local tissue flap(s)
	31571	Laryngoscopy, direct, with injection into vocal cord(s), therapeutic;
	31574	Laryngoscopy, flexible; with injection(s) for augmentation (eg, percutaneous, transoral), unilateral
	31575	Laryngoscopy, direct, with injection into vocal cord(s), therapeutic; with operating microscope or telescope
	31576	Laryngoscopy, flexible; diagnostic
	31578	Laryngoscopy, flexible; with biopsy(ies)
	31591	Laryngoplasty, medialization, unilateral
	31611	Laryngoscopy, flexible; with removal of lesion(s), non-laser

Codes	Number	Description
	31622	Construction of tracheoesophageal fistula and subsequent insertion of an alaryngeal speech prosthesis (eg, voice button, Blom-Singer prosthesis)
	31623	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; diagnostic, with cell washing, when performed (separate procedure)
	31624	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with brushing or protected brushings
	31625	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with bronchial alveolar lavage
	31628	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with bronchial or endobronchial biopsy(s), single or multiple sites
	31652	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with transbronchial lung biopsy(s), single lobe
	31820	Bronchoscopy, rigid or flexible, including fluoroscopic guidance, when performed; with endobronchial ultrasound (EBUS) guided transtracheal and/or transbronchial sampling (eg, aspiration[s]/biopsy[ies]), one or two mediastinal and/or hilar lymph node stations or structures
	32408	Core needle biopsy, lung or mediastinum, percutaneous, including imaging guidance, when performed
	32555	Thoracentesis, needle or catheter, aspiration of the pleural space; with imaging guidance
	32557	Pleural drainage, percutaneous, with insertion of indwelling catheter; with imaging guidance
	36010	Surgical closure tracheostomy or fistula; without plastic repair
	36215	Selective catheter placement, arterial system; each first order thoracic or brachiocephalic branch, within a vascular family
	36246	Selective catheter placement, arterial system; initial second order abdominal, pelvic, or lower extremity artery branch, within a vascular family
	36556	Insertion of non-tunneled centrally inserted central venous catheter; age 5 years or older
	36569	Insertion of peripherally inserted central venous catheter (PICC), without subcutaneous port or pump, without imaging guidance; age 5 years or older
	36571	Insertion of peripherally inserted central venous access device, with subcutaneous port; age 5 years or older
	36581	Replacement, complete, of a tunneled centrally inserted central venous catheter, without subcutaneous port or pump, through same venous access
	36582	Replacement, complete, of a tunneled centrally inserted central venous access device, with subcutaneous port, through same venous access
	36589	Removal of tunneled central venous catheter, without subcutaneous port or pump
	36590	Removal of tunneled central venous access device, with subcutaneous port or pump, central or peripheral insertion
	37607	Ligation or banding of angioaccess arteriovenous fistula
	38221	Diagnostic bone marrow; biopsy(ies)
	38222	Diagnostic bone marrow; biopsy(ies) and aspiration(s)
	38500	Biopsy or excision of lymph node(s); open, superficial
	38505	Biopsy or excision of lymph node(s); by needle, superficial (eg, cervical, inguinal, axillary)
	38510	Biopsy or excision of lymph node(s); open, deep cervical node(s)
	38520	Biopsy or excision of lymph node(s); open, deep cervical node(s) with excision scalene fat pad
	38525	Biopsy or excision of lymph node(s); open, deep axillary node(s)
	38740	Axillary lymphadenectomy; superficial

Codes	Number	Description
	38760	Inguinofemoral lymphadenectomy, superficial, including Cloquet's node (separate procedure)
	40490	Biopsy of lip
	40510	Excision of lip; transverse wedge excision with primary closure
	40520	Excision of lip; V-excision with primary direct linear closure
	40525	Excision of lip; full thickness, reconstruction with local flap (eg, Estlander or fan)
	40530	Resection of lip, more than one-fourth, without reconstruction
	40808	Biopsy, vestibule of mouth
	40810	Excision of lesion of mucosa and submucosa, vestibule of mouth; without repair
	40812	Excision of lesion of mucosa and submucosa, vestibule of mouth; with simple repair
	40814	Excision of lesion of mucosa and submucosa, vestibule of mouth; with complex repair
	40816	Excision of lesion of mucosa and submucosa, vestibule of mouth; complex, with excision of underlying muscle
	41010	Incision of lingual frenum (frenotomy)
	41100	Biopsy of tongue; anterior two-thirds
	41105	Biopsy of tongue; posterior one-third
	41108	Biopsy of floor of mouth
	41110	Excision of lesion of tongue without closure
	41112	Excision of lesion of tongue with closure; anterior two-thirds
	41113	Excision of lesion of tongue with closure; posterior one-third
	41116	Excision, lesion of floor of mouth
	42100	Biopsy of palate, uvula
	42104	Excision, lesion of palate, uvula; without closure
	42106	Excision, lesion of palate, uvula; with simple primary closure
	42330	Sialolithotomy; submandibular (submaxillary), sublingual or parotid, uncomplicated, intraoral
	42335	Sialolithotomy; submandibular (submaxillary), complicated, intraoral
	42405	Biopsy of salivary gland; incisional
	42408	Excision of sublingual salivary cyst (ranula)
	42410	Excision of parotid tumor or parotid gland; lateral lobe, without nerve dissection
	42415	Excision of parotid tumor or parotid gland; lateral lobe, with dissection and preservation of facial nerve
	42420	Excision of parotid tumor or parotid gland; total, with dissection and preservation of facial nerve
	42425	Excision of parotid tumor or parotid gland; total, en bloc removal with sacrifice of facial nerve
	42440	Excision of submandibular (submaxillary) gland
	42450	Excision of sublingual gland
	42500	Plastic repair of salivary duct, sialodochoplasty; primary or simple
	42650	Dilation salivary duct
	42800	Biopsy; oropharynx
	42804	Biopsy; nasopharynx, visible lesion, simple
	42808	Excision or destruction of lesion of pharynx, any method
	42810	Excision branchial cleft cyst or vestige, confined to skin and subcutaneous tissues
	42821	Tonsillectomy and adenoidectomy; age 12 or over
	42826	Tonsillectomy, primary or secondary; age 12 or over
	42831	Adenoidectomy, primary; age 12 or over
	42870	Excision or destruction lingual tonsil, any method (separate procedure)

Codes	Number	Description
	43191	Esophagoscopy, rigid, transoral; diagnostic, including collection of specimen(s) by brushing or washing when performed (separate procedure)
	43195	Esophagoscopy, rigid, transoral; with balloon dilation (less than 30 mm diameter)
	43197	Esophagoscopy, flexible, transnasal; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	43200	Esophagoscopy, flexible, transoral; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	43211	Esophagoscopy, flexible, transoral; with endoscopic mucosal resection
	43212	Esophagoscopy, flexible, transoral; with placement of endoscopic stent (includes pre- and post-dilation and guide wire passage, when performed)
	43213	Esophagoscopy, flexible, transoral; with dilation of esophagus, by balloon or dilator, retrograde (includes fluoroscopic guidance, when performed)
	43214	Esophagoscopy, flexible, transoral; with dilation of esophagus with balloon (30 mm diameter or larger) (includes fluoroscopic guidance, when performed)
	43215	Esophagoscopy, flexible, transoral; with removal of foreign body(s)
	43216	Esophagoscopy, flexible, transoral; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps
	43217	Esophagoscopy, flexible, transoral; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	43220	Esophagoscopy, flexible, transoral; with transendoscopic balloon dilation (less than 30 mm diameter)
	43226	Esophagoscopy, flexible, transoral; with insertion of guide wire followed by passage of dilator(s) over guide wire
	43227	Esophagoscopy, flexible, transoral; with control of bleeding, any method
	43229	Esophagoscopy, flexible, transoral; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)
	43231	Esophagoscopy, flexible, transoral; with endoscopic ultrasound examination
	43232	Esophagoscopy, flexible, transoral; with transendoscopic ultrasound-guided intramural or transmural fine needle aspiration/biopsy(s)
	43233	Esophagogastroduodenoscopy, flexible, transoral; with dilation of esophagus with balloon (30 mm diameter or larger) (includes fluoroscopic guidance, when performed)
	43235	Esophagogastroduodenoscopy, flexible, transoral; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	43237	Esophagogastroduodenoscopy, flexible, transoral; with endoscopic ultrasound examination limited to the esophagus, stomach or duodenum, and adjacent structures
	43238	Esophagogastroduodenoscopy, flexible, transoral; with transendoscopic ultrasound-guided intramural or transmural fine needle aspiration/biopsy(s), (includes endoscopic ultrasound examination limited to the esophagus, stomach or duodenum, and adjacent structures
	43239	Esophagogastroduodenoscopy, flexible, transoral; with biopsy, single or multiple
	43240	Esophagogastroduodenoscopy, flexible, transoral; with transmural drainage of pseudocyst (includes placement of transmural drainage catheter[s]/stent[s], when performed, and endoscopic ultrasound, when performed)
	43241	Esophagogastroduodenoscopy, flexible, transoral; with insertion of intraluminal tube or catheter

Codes	Number	Description
	43242	Esophagogastroduodenoscopy, flexible, transoral; with transendoscopic ultrasound-guided intramural or transmural fine needle aspiration/biopsy(s) (includes endoscopic ultrasound examination of the esophagus, stomach, and either the duodenum or a surgically altered stomach where the jejunum is examined distal to the anastomosis)
	43243	Esophagogastroduodenoscopy, flexible, transoral; with injection sclerosis of esophageal/gastric varices
	43244	Esophagogastroduodenoscopy, flexible, transoral; with band ligation of esophageal/gastric varices
	43245	Esophagogastroduodenoscopy, flexible, transoral; with dilation of gastric/duodenal stricture(s) (e.g., balloon, bougie)
	43246	Esophagogastroduodenoscopy, flexible, transoral; with directed placement of percutaneous gastrostomy tube
	43247	Esophagogastroduodenoscopy, flexible, transoral; with removal of foreign body(s)
	43248	Esophagogastroduodenoscopy, flexible, transoral; with insertion of guide wire followed by passage of dilator(s) through esophagus over guide wire
	43249	Esophagogastroduodenoscopy, flexible, transoral; with transendoscopic balloon dilation of esophagus (less than 30 mm diameter)
	43250	Esophagogastroduodenoscopy, flexible, transoral; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps
	43251	Esophagogastroduodenoscopy, flexible, transoral; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	43253	Esophagogastroduodenoscopy, flexible, transoral; with transendoscopic ultrasound-guided transmural injection of diagnostic or therapeutic substance(s) (eg, anesthetic, neurolytic agent) or fiducial marker(s) (includes endoscopic ultrasound examination of the esophagus, stomach, and either the duodenum or a surgically altered stomach where the jejunum is examined distal to the anastomosis)
	43254	Esophagogastroduodenoscopy, flexible, transoral; with endoscopic mucosal resection
	43259	Esophagogastroduodenoscopy, flexible, transoral; with endoscopic ultrasound examination, including the esophagus, stomach, and either the duodenum or a surgically altered stomach where the jejunum is examined distal to the anastomosis
	43260	Endoscopic retrograde cholangiopancreatography (ERCP); diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	43261	Endoscopic retrograde cholangiopancreatography (ERCP); with biopsy, single or multiple
	43266	Esophagogastroduodenoscopy, flexible, transoral; with placement of endoscopic stent (includes pre- and post-dilation and guide wire passage, when performed)
	43270	Esophagogastroduodenoscopy, flexible, transoral; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)
	43450	Dilation of esophagus, by unguided sound or bougie, single or multiple passes
	43453	Dilation of esophagus, over guide wire
	44340	Revision of colostomy; simple (release of superficial scar) (separate procedure)
	44360	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, not including ileum; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)

Codes	Number	Description
	44361	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, not including ileum; with biopsy, single or multiple
	44364	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, not including ileum; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	44369	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, not including ileum; with ablation of tumor(s), polyp(s), or other lesion(s) not amenable to removal by hot biopsy forceps, bipolar cautery or snare technique
	44376	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, including ileum; diagnostic, with or without collection of specimen(s) by brushing or washing (separate procedure)
	44377	Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, including ileum; with biopsy, single or multiple
	44380	Ileoscopy, through stoma; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	44381	Ileoscopy, through stoma; with transendoscopic balloon dilation
	44382	Ileoscopy, through stoma; with biopsy, single or multiple
	44385	Endoscopic evaluation of small intestinal pouch (eg, Kock pouch, ileal reservoir [S or J]); diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	44386	Endoscopic evaluation of small intestinal pouch (eg, Kock pouch, ileal reservoir [S or J]); with biopsy, single or multiple
	44388	Colonoscopy through stoma; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	44389	Colonoscopy through stoma; with biopsy, single or multiple
	44391	Colonoscopy through stoma; with control of bleeding, any method
	44392	Colonoscopy through stoma; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps
	44394	Colonoscopy through stoma; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	44408	Colonoscopy through stoma; with decompression (for pathologic distention) (eg, volvulus, megacolon), including placement of decompression tube, when performed
	44705	Preparation of fecal microbiota for instillation, including assessment of donor specimen
	45100	Biopsy of anorectal wall, anal approach (eg, congenital megacolon)
	45171	Excision of rectal tumor, transanal approach; not including muscularis propria (ie, partial thickness)
	45172	Excision of rectal tumor, transanal approach; including muscularis propria (ie, full thickness)
	45190	Destruction of rectal tumor (eg, electrodesiccation, electrosurgery, laser ablation, laser resection, cryosurgery) transanal approach
	45305	Proctosigmoidoscopy, rigid; with biopsy, single or multiple
	45330	Sigmoidoscopy, flexible; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	45331	Sigmoidoscopy, flexible; with biopsy, single or multiple
	45332	Sigmoidoscopy, flexible; with removal of foreign body(s)
	45333	Sigmoidoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps
	45334	Sigmoidoscopy, flexible; with control of bleeding, any method
	45335	Sigmoidoscopy, flexible; with directed submucosal injection(s), any substance

Codes	Number	Description
	45337	Sigmoidoscopy, flexible; with decompression (for pathologic distention) (eg, volvulus, megacolon), including placement of decompression tube, when performed
	45338	Sigmoidoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	45340	Sigmoidoscopy, flexible; with transendoscopic balloon dilation
	45341	Sigmoidoscopy, flexible; with endoscopic ultrasound examination
	45342	Sigmoidoscopy, flexible; with transendoscopic ultrasound guided intramural or transmural fine needle aspiration/biopsy(s)
	45346	Sigmoidoscopy, flexible; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)
	45347	Sigmoidoscopy, flexible; with placement of endoscopic stent (includes pre- and post-dilation and guide wire passage, when performed)
	45349	Sigmoidoscopy, flexible; with endoscopic mucosal resection
	45350	Sigmoidoscopy, flexible; with band ligation(s) (eg, hemorrhoids)
	45378	Colonoscopy, flexible; diagnostic, including collection of specimen(s) by brushing or washing, when performed (separate procedure)
	45379	Colonoscopy, flexible; with removal of foreign body(s)
	45380	Colonoscopy, flexible; with biopsy, single or multiple
	45381	Colonoscopy, flexible; with directed submucosal injection(s), any substance
	45382	Colonoscopy, flexible; with control of bleeding, any method
	45384	Colonoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps
	45385	Colonoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique
	45386	Colonoscopy, flexible; with transendoscopic balloon dilation
	45388	Colonoscopy, flexible; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)
	45389	Colonoscopy, flexible; with endoscopic stent placement (includes pre- and post-dilation and guide wire passage, when performed)
	45390	Colonoscopy, flexible; with endoscopic mucosal resection
	45391	Colonoscopy, flexible; with endoscopic ultrasound examination limited to the rectum, sigmoid, descending, transverse, or ascending colon and cecum, and adjacent structures
	45392	Colonoscopy, flexible; with transendoscopic ultrasound guided intramural or transmural fine needle aspiration/biopsy(s), includes endoscopic ultrasound examination limited to the rectum, sigmoid, descending, transverse, or ascending colon and cecum, and adjacent structures
	45393	Colonoscopy, flexible; with decompression (for pathologic distention) (eg, volvulus, megacolon), including placement of decompression tube, when performed
	45398	Colonoscopy, flexible; with band ligation(s) (e.g., hemorrhoids)
	45505	Proctoplasty; for prolapse of mucous membrane
	45541	Proctopexy (eg, for prolapse); perineal approach
	45560	Repair of rectocele (separate procedure)
	45905	Dilation of anal sphincter (separate procedure) under anesthesia other than local
	45910	Dilation of rectal stricture (separate procedure) under anesthesia other than local
	45915	Removal of fecal impaction or foreign body (separate procedure) under anesthesia

Codes	Number	Description
	45990	Anorectal exam, surgical, requiring anesthesia (general, spinal, or epidural), diagnostic
	46020	Placement of seton
	46030	Removal of anal seton, other marker
	46040	Incision and drainage of ischiorectal and/or perirectal abscess (separate procedure)
	46045	Incision and drainage of intramural, intramuscular, or submucosal abscess, transanal, under anesthesia
	46050	Incision and drainage, perianal abscess, superficial
	46060	Incision and drainage of ischiorectal or intramural abscess, with fistulectomy or fistulotomy, submuscular, with or without placement of seton
	46080	Sphincterotomy, anal, division of sphincter (separate procedure)
	46083	Incision of thrombosed hemorrhoid, external
	46200	Fissurectomy, including sphincterotomy, when performed
	46220	Excision of single external papilla or tag, anus
	46221	Hemorrhoidectomy, internal, by rubber band ligation(s)
	46230	Excision of multiple external papillae or tags, anus
	46250	Hemorrhoidectomy, external, 2 or more columns/groups
	46255	Hemorrhoidectomy, internal and external, single column/group;
	46257	Hemorrhoidectomy, internal and external, single column/group; with fissurectomy
	46258	Hemorrhoidectomy, internal and external, single column/group; with fistulectomy, including fissurectomy, when performed
	46260	Hemorrhoidectomy, internal and external, 2 or more columns/groups;
	46261	Hemorrhoidectomy, internal and external, 2 or more columns/groups; with fissurectomy
	46262	Hemorrhoidectomy, internal and external, 2 or more columns/groups; with fistulectomy, including fissurectomy, when performed
	46270	Surgical treatment of anal fistula (fistulectomy/fistulotomy); subcutaneous
	46275	Surgical treatment of anal fistula (fistulectomy/fistulotomy); intersphincteric
	46280	Surgical treatment of anal fistula (fistulectomy/fistulotomy); transsphincteric, suprasphincteric, extrasphincteric or multiple, including placement of seton, when performed
	46285	Surgical treatment of anal fistula (fistulectomy/fistulotomy); second stage
	46288	Closure of anal fistula with rectal advancement flap
	46320	Excision of thrombosed hemorrhoid, external
	46505	Chemodenervation of internal anal sphincter
	46606	Anoscopy; with biopsy, single or multiple
	46607	Anoscopy; with high-resolution magnification (HRA) (eg, colposcope, operating microscope) and chemical agent enhancement, with biopsy, single or multiple
	46610	Anoscopy; with removal of single tumor, polyp, or other lesion by hot biopsy forceps or bipolar cautery
	46612	Anoscopy; with removal of multiple tumors, polyps, or other lesions by hot biopsy forceps, bipolar cautery or snare technique
	46615	Anoscopy; with ablation of tumor(s), polyp(s), or other lesion(s) not amenable to removal by hot biopsy forceps, bipolar cautery or snare technique
	46700	Anoplasty, plastic operation for stricture; adult
	46750	Sphincteroplasty, anal, for incontinence or prolapse; adult
	46910	Destruction of lesion(s), anus (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; electrodesiccation
	46917	Destruction of lesion(s), anus (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; laser surgery

Codes	Number	Description
	46922	Destruction of lesion(s), anus (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; surgical excision
	46924	Destruction of lesion(s), anus (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), extensive (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	46930	Destruction of internal hemorrhoid(s) by thermal energy (eg, infrared coagulation, cautery, radiofrequency)
	46940	Curettage or cautery of anal fissure, including dilation of anal sphincter (separate procedure); initial
	46945	Hemorrhoidectomy, internal, by ligation other than rubber band; single hemorrhoid column/group, without imaging guidance
	46946	Hemorrhoidectomy, internal, by ligation other than rubber band; 2 or more hemorrhoid columns/groups, without imaging guidance
	47000	Biopsy of liver, needle; percutaneous
	49082	Abdominal paracentesis (diagnostic or therapeutic); without imaging guidance
	49083	Abdominal paracentesis (diagnostic or therapeutic); with imaging guidance
	49422	Removal of tunneled intraperitoneal catheter
	49500	Repair initial inguinal hernia, age 6 months to younger than 5 years, with or without hydrocelectomy; reducible
	49505	Repair initial inguinal hernia, age 5 years or older; reducible
	49507	Repair initial inguinal hernia, age 5 years or older; incarcerated or strangulated
	49520	Repair recurrent inguinal hernia, any age; reducible
	49521	Repair recurrent inguinal hernia, any age; incarcerated or strangulated
	49525	Repair inguinal hernia, sliding, any age
	49550	Repair initial femoral hernia, any age; reducible
	49553	Repair initial femoral hernia, any age; incarcerated or strangulated
	49650	Laparoscopy, surgical; repair initial inguinal hernia
	49651	Laparoscopy, surgical; repair recurrent inguinal hernia
	49900	Suture, secondary, of abdominal wall for evisceration or dehiscence
	50430	Injection procedure for antegrade nephrostogram and/or ureterogram, complete diagnostic procedure including imaging guidance (eg, ultrasound and fluoroscopy) and all associated radiological supervision and interpretation; new access
	50435	Exchange nephrostomy catheter, percutaneous, including diagnostic nephrostogram and/or ureterogram when performed, imaging guidance (eg, ultrasound and/or fluoroscopy) and all associated radiological supervision and interpretation
	50575	Renal endoscopy through nephrotomy or pyelotomy, with or without irrigation, instillation, or ureteropyelography, exclusive of radiologic service; with endopyelotomy (includes cystoscopy, ureteroscopy, dilation of ureter and ureteral pelvic junction, incision of ureteral pelvic junction and insertion of endopyelotomy stent)
	50590	Lithotripsy, extracorporeal shock wave
	50688	Change of ureterostomy tube or externally accessible ureteral stent via ileal conduit
	51040	Cystostomy, cystotomy with drainage
	51102	Aspiration of bladder; with insertion of suprapubic catheter
	51600	Injection procedure for cystography or voiding urethrocystography
	51610	Injection procedure for retrograde urethrocystography
	51702	Insertion of temporary indwelling bladder catheter; simple (eg, Foley)
	51710	Change of cystostomy tube; complicated

Codes	Number	Description
	51715	Endoscopic injection of implant material into the submucosal tissues of the urethra and/or bladder neck
	51720	Bladder instillation of anticarcinogenic agent (including retention time)
	51726	Complex cystometrogram (ie, calibrated electronic equipment);
	51728	Complex cystometrogram (ie, calibrated electronic equipment); with voiding pressure studies (ie, bladder voiding pressure), any technique
	51729	Complex cystometrogram (ie, calibrated electronic equipment); with voiding pressure studies (ie, bladder voiding pressure) and urethral pressure profile studies (ie, urethral closure pressure profile), any technique
	52000	Cystourethroscopy (separate procedure)
	52001	Cystourethroscopy with irrigation and evacuation of multiple obstructing clots
	52005	Cystourethroscopy, with ureteral catheterization, with or without irrigation, instillation, or ureteropyelography, exclusive of radiologic service;
	52007	Cystourethroscopy, with ureteral catheterization, with or without irrigation, instillation, or ureteropyelography, exclusive of radiologic service; with brush biopsy of ureter and/or renal pelvis
	52204	Cystourethroscopy, with biopsy(s)
	52214	Cystourethroscopy, with fulguration (including cryosurgery or laser surgery) of trigone, bladder neck, prostatic fossa, urethra, or periurethral glands
	52224	Cystourethroscopy, with fulguration (including cryosurgery or laser surgery) or treatment of MINOR (less than 0.5 cm) lesion(s) with or without biopsy
	52234	Cystourethroscopy, with fulguration (including cryosurgery or laser surgery) and/or resection of; SMALL bladder tumor(s) (0.5 up to 2.0 cm)
	52235	Cystourethroscopy, with fulguration (including cryosurgery or laser surgery) and/or resection of; MEDIUM bladder tumor(s) (2.0 to 5.0 cm)
	52240	Cystourethroscopy, with fulguration (including cryosurgery or laser surgery) and/or resection of; LARGE bladder tumor(s)
	52260	Cystourethroscopy, with dilation of bladder for interstitial cystitis; general or conduction (spinal) anesthesia
	52265	Cystourethroscopy, with dilation of bladder for interstitial cystitis; local anesthesia
	52275	Cystourethroscopy, with internal urethrotomy; male
	52276	Cystourethroscopy with direct vision internal urethrotomy
	52281	Cystourethroscopy, with calibration and/or dilation of urethral stricture or stenosis, with or without meatotomy, with or without injection procedure for cystography, male or female
	52282	Cystourethroscopy, with insertion of permanent urethral stent
	52283	Cystourethroscopy, with steroid injection into stricture
	52285	Cystourethroscopy for treatment of the female urethral syndrome with any or all of the following: urethral meatotomy, urethral dilation, internal urethrotomy, lysis of urethrovaginal septal fibrosis, lateral incisions of the bladder neck, and fulguration of polyp(s) of urethra, bladder neck, and/or trigone
	52287	Cystourethroscopy, with injection(s) for chemodenervation of the bladder
	52300	Cystourethroscopy; with resection or fulguration of orthotopic ureterocele(s), unilateral or bilateral
	52310	Cystourethroscopy, with removal of foreign body, calculus, or ureteral stent from urethra or bladder (separate procedure); simple
	52315	Cystourethroscopy, with removal of foreign body, calculus, or ureteral stent from urethra or bladder (separate procedure); complicated
	52317	Litholapaxy: crushing or fragmentation of calculus by any means in bladder and removal of fragments; simple or small (less than 2.5 cm)

Codes	Number	Description
	52318	Litholapaxy: crushing or fragmentation of calculus by any means in bladder and removal of fragments; complicated or large (over 2.5 cm)
	52320	Cystourethroscopy (including ureteral catheterization); with removal of ureteral calculus
	52325	Cystourethroscopy (including ureteral catheterization); with fragmentation of ureteral calculus (eg, ultrasonic or electro-hydraulic technique)
	52327	Cystourethroscopy (including ureteral catheterization); with subureteric injection of implant material
	52330	Cystourethroscopy (including ureteral catheterization); with manipulation, without removal of ureteral calculus
	52332	Cystourethroscopy, with insertion of indwelling ureteral stent (eg, Gibbons or double-J type)
	52341	Cystourethroscopy; with treatment of ureteral stricture (eg, balloon dilation, laser, electrocautery, and incision)
	52344	Cystourethroscopy with ureteroscopy; with treatment of ureteral stricture (eg, balloon dilation, laser, electrocautery, and incision)
	52351	Cystourethroscopy, with ureteroscopy and/or pyeloscopy; diagnostic
	52352	Cystourethroscopy, with ureteroscopy and/or pyeloscopy; with removal or manipulation of calculus (ureteral catheterization is included)
	52353	Cystourethroscopy, with ureteroscopy and/or pyeloscopy; with lithotripsy (ureteral catheterization is included)
	52354	Cystourethroscopy, with ureteroscopy and/or pyeloscopy; with biopsy and/or fulguration of ureteral or renal pelvic lesion
	52356	Cystourethroscopy, with ureteroscopy and/or pyeloscopy; with lithotripsy including insertion of indwelling ureteral stent (eg, Gibbons or double-J type)
	52450	Transurethral incision of prostate
	52500	Transurethral resection of bladder neck (separate procedure)
	52601	Transurethral electrosurgical resection of prostate, including control of postoperative bleeding, complete (vasectomy, meatotomy, cystourethroscopy, urethral calibration and/or dilation, and internal urethrotomy are included)
	52630	Transurethral resection; residual or regrowth of obstructive prostate tissue including control of postoperative bleeding, complete (vasectomy, meatotomy, cystourethroscopy, urethral calibration and/or dilation, and internal urethrotomy are included)
	52640	Transurethral resection; of postoperative bladder neck contracture
	53020	Meatotomy, cutting of meatus (separate procedure); except infant
	53200	Biopsy of urethra
	53230	Excision of urethral diverticulum (separate procedure); female
	53260	Excision or fulguration; urethral polyp(s), distal urethra
	53265	Excision or fulguration; urethral caruncle
	53270	Excision or fulguration; Skene's glands
	53440	Sling operation for correction of male urinary incontinence (eg, fascia or synthetic)
	53445	Insertion of inflatable urethral/bladder neck sphincter, including placement of pump, reservoir, and cuff
	53450	Urethromeatoplasty, with mucosal advancement
	53500	Urethrolysis, transvaginal, secondary, open, including cystourethroscopy (eg, postsurgical obstruction, scarring)
	53605	Dilation of urethral stricture or vesical neck by passage of sound or urethral dilator, male, general or conduction (spinal) anesthesia
	53665	Dilation of female urethra, general or conduction (spinal) anesthesia
	54001	Slitting of prepuce, dorsal or lateral (separate procedure); except newborn

Codes	Number	Description
	54055	Destruction of lesion(s), penis (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; electrodesiccation
	54057	Destruction of lesion(s), penis (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; laser surgery
	54060	Destruction of lesion(s), penis (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), simple; surgical excision
	54065	Destruction of lesion(s), penis (eg, condyloma, papilloma, molluscum contagiosum, herpetic vesicle), extensive (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	54100	Biopsy of penis; (separate procedure)
	54110	Excision of penile plaque (Peyronie disease);
	54150	Circumcision, using clamp or other device with regional dorsal penile or ring block
	54161	Circumcision, surgical excision other than clamp, device, or dorsal slit; older than 28 days of age
	54162	Lysis or excision of penile post-circumcision adhesions
	54163	Repair incomplete circumcision
	54164	Frenulotomy of penis
	54300	Plastic operation of penis for straightening of chordee (eg, hypospadias), with or without mobilization of urethra
	54450	Foreskin manipulation including lysis of preputial adhesions and stretching
	54512	Excision of extraparenchymal lesion of testis
	54530	Orchiectomy, radical, for tumor; inguinal approach
	54600	Reduction of torsion of testis, surgical, with or without fixation of contralateral testis
	54620	Fixation of contralateral testis (separate procedure)
	54640	Orchiopexy, inguinal or scrotal approach
	54700	Incision and drainage of epididymis, testis and/or scrotal space (eg, abscess or hematoma)
	54830	Excision of local lesion of epididymis
	54840	Excision of spermatocele, with or without epididymectomy
	54860	Epididymectomy; unilateral
	55000	Puncture aspiration of hydrocele, tunica vaginalis, with or without injection of medication
	55040	Excision of hydrocele; unilateral
	55041	Excision of hydrocele; bilateral
	55060	Repair of tunica vaginalis hydrocele (Bottle type)
	55100	Drainage of scrotal wall abscess
	55110	Scrotal exploration
	55120	Removal of foreign body in scrotum
	55250	Vasectomy, unilateral or bilateral (separate procedure), including postoperative semen examination(s)
	55400	Vasovasostomy, vasovasorrhaphy
	55500	Excision of hydrocele of spermatic cord, unilateral (separate procedure)
	55520	Excision of lesion of spermatic cord (separate procedure)
	55540	Excision of varicocele or ligation of spermatic veins for varicocele; with hernia repair
	55700	Biopsy, prostate; needle or punch, single or multiple, any approach
	56405	Incision and drainage of vulva or perineal abscess
	56420	Incision and drainage of Bartholin's gland abscess
	56440	Marsupialization of Bartholin's gland cyst
	56441	Lysis of labial adhesions

Codes	Number	Description
	56442	Hymenotomy, simple incision
	56501	Destruction of lesion(s), vulva; simple (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	56515	Destruction of lesion(s), vulva; extensive (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	56605	Biopsy of vulva or perineum (separate procedure); 1 lesion
	56620	Vulvectomy simple; partial
	56700	Partial hymenectomy or revision of hymenal ring
	56740	Excision of Bartholin's gland or cyst
	56810	Perineoplasty, repair of perineum, nonobstetrical (separate procedure)
	56821	Colposcopy of the vulva; with biopsy(s)
	57000	Colpotomy; with exploration
	57061	Destruction of vaginal lesion(s); simple (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	57065	Destruction of vaginal lesion(s); extensive (eg, laser surgery, electrosurgery, cryosurgery, chemosurgery)
	57100	Biopsy of vaginal mucosa; simple (separate procedure)
	57130	Excision of vaginal septum
	57135	Excision of vaginal cyst or tumor
	57210	Colpoperineorrhaphy, suture of injury of vagina and/or perineum (nonobstetrical)
	57240	Anterior colporrhaphy, repair of cystocele with or without repair of urethrocele, including cystourethroscopy, when performed
	57250	Posterior colporrhaphy, repair of rectocele with or without perineorrhaphy
	57260	Combined anteroposterior colporrhaphy, including cystourethroscopy, when performed;
	57268	Repair of enterocele, vaginal approach (separate procedure)
	57282	Colpopexy, vaginal; extra-peritoneal approach (sacrospinous, iliococcygeus)
	57283	Colpopexy, vaginal; intra-peritoneal approach (uterosacral, levator myorrhaphy)
	57287	Removal or revision of sling for stress incontinence (eg, fascia or synthetic)
	57300	Closure of rectovaginal fistula; vaginal or transanal approach
	57400	Dilation of vagina under anesthesia (other than local)
	57410	Pelvic examination under anesthesia (other than local)
	57415	Removal of impacted vaginal foreign body (separate procedure) under anesthesia (other than local)
	57420	Colposcopy of the entire vagina, with cervix if present;
	57421	Colposcopy of the entire vagina, with cervix if present; with biopsy(s) of vagina/cervix
	57425	Laparoscopy, surgical, colpopexy (suspension of vaginal apex)
	57452	Colposcopy of the cervix including upper/adjacent vagina;
	57454	Colposcopy of the cervix including upper/adjacent vagina; with biopsy(s) of the cervix and endocervical curettage
	57456	Colposcopy of the cervix including upper/adjacent vagina; with endocervical curettage
	57461	Colposcopy of the cervix including upper/adjacent vagina; with loop electrode conization of the cervix
	57500	Biopsy of cervix, single or multiple, or local excision of lesion, with or without fulguration (separate procedure)
	57505	Endocervical curettage (not done as part of a dilation and curettage)
	57510	Cautery of cervix; electro or thermal
	57513	Cautery of cervix; laser ablation

Codes	Number	Description
	57520	Conization of cervix, with or without fulguration, with or without dilation and curettage, with or without repair; cold knife or laser
	57522	Conization of cervix, with or without fulguration, with or without dilation and curettage, with or without repair; loop electrode excision
	57530	Trachelectomy (cervicectomy), amputation of cervix (separate procedure)
	57700	Cerclage of uterine cervix, nonobstetrical
	57720	Trachelorrhaphy, plastic repair of uterine cervix, vaginal approach
	57800	Dilation of cervical canal, instrumental (separate procedure)
	58100	Dilation and curettage, diagnostic and/or therapeutic (nonobstetrical)
	58120	Hysteroscopy, surgical; with sampling (biopsy) of endometrium and/or polypectomy, with or without D & C
	58263	Vaginal hysterectomy, for uterus 250 g or less; with removal of tube(s), and/or ovary(s), with repair of enterocele
	58558	Hysteroscopy, surgical; with division or resection of intrauterine septum (any method)
	58560	Hysteroscopy, surgical; with removal of leiomyomata
	58561	Hysteroscopy, surgical; with bilateral fallopian tube cannulation to induce occlusion by placement of permanent implants
	58565	Laparoscopy, surgical; with fulguration or excision of lesions of the ovary, pelvic viscera, or peritoneal surface by any method
	58662	Laparoscopy, surgical; with fulguration of oviducts (with or without transection)
	58670	Laparoscopy, surgical; with occlusion of oviducts by device (eg, band, clip, or Falope ring)
	58671	Salpingectomy, complete or partial, unilateral or bilateral (separate procedure)
	58700	Ovarian cystectomy, unilateral or bilateral
	58925	Insertion of cervical dilator (eg, laminaria, prostaglandin) (separate procedure)
	59200	Destruction by neurolytic agent, trigeminal nerve; supraorbital, infraorbital, mental, or inferior alveolar branch
	62270	Spinal puncture, lumbar, diagnostic;
	63661	Removal of spinal neurostimulator electrode percutaneous array(s), including fluoroscopy, when performed
	63663	Revision including replacement, when performed, of spinal neurostimulator electrode percutaneous array(s), including fluoroscopy, when performed
	64418	Injection(s), anesthetic agent(s) and/or steroid; suprascapular nerve
	64425	Injection(s), anesthetic agent(s) and/or steroid; ilioinguinal, iliohypogastric nerves
	64530	Injection, anesthetic agent; celiac plexus, with or without radiologic monitoring
	64600	Chemodenervation of trunk muscle(s); 6 or more muscles
	64610	Destruction by neurolytic agent, trigeminal nerve; second and third division branches at foramen ovale under radiologic monitoring
	64642	Chemodenervation of one extremity; 1-4 muscle(s)
	64644	Chemodenervation of one extremity; 5 or more muscles
	64646	Chemodenervation of trunk muscle(s); 1-5 muscle(s)
	64647	Excision of neuroma; digital nerve, 1 or both, same digit
	64702	Neuroplasty; digital, 1 or both, same digit
	64718	Neuroplasty and/or transposition; ulnar nerve at elbow
	64719	Neuroplasty and/or transposition; ulnar nerve at wrist
	64721	Neuroplasty and/or transposition; median nerve at carpal tunnel
	64774	Excision of neuroma; cutaneous nerve, surgically identifiable
	64776	Excision of neuroma; hand or foot, except digital nerve
	64782	Excision of neuroma; major peripheral nerve, except sciatic
	64784	Excision of neurofibroma or neurolemmoma; cutaneous nerve

Codes	Number	Description
	64788	Suture of 1 nerve; median motor thenar
	64795	Biopsy of nerve
	64831	Suture of digital nerve, hand or foot; 1 nerve
	64835	Repair of laceration; cornea, nonperforating, with or without removal foreign body
	65275	Excision of lesion, cornea (keratectomy, lamellar, partial), except pterygium
	65400	Excision or transposition of pterygium; without graft
	65420	Excision or transposition of pterygium; with graft
	65426	Removal of corneal epithelium; with or without chemocauterization (abrasion, curettage)
	65435	Removal of corneal epithelium; with application of chelating agent (eg, EDTA)
	65436	Keratoplasty (corneal transplant); anterior lamellar
	65710	Keratoplasty (corneal transplant); penetrating (except in aphakia or pseudophakia)
	65730	Keratoplasty (corneal transplant); penetrating (in aphakia)
	65750	Keratoplasty (corneal transplant); penetrating (in pseudophakia)
	65755	Corneal relaxing incision for correction of surgically induced astigmatism
	65756	Keratoplasty (corneal transplant); endothelial
	65772	Corneal wedge resection for correction of surgically induced astigmatism
	65778	Placement of amniotic membrane on the ocular surface; without sutures
	65779	Placement of amniotic membrane on the ocular surface; single layer, sutured
	65780	Ocular surface reconstruction; amniotic membrane transplantation, multiple layers
	65800	Paracentesis of anterior chamber of eye (separate procedure); with removal of aqueous
	65815	Paracentesis of anterior chamber of eye (separate procedure); with removal of blood, with or without irrigation and/or air injection
	65820	Goniotomy
	65850	Trabeculotomy ab externo
	65855	Trabeculoplasty by laser surgery
	65865	Severing adhesions of anterior segment of eye, incisional technique (with or without injection of air or liquid) (separate procedure); goniosynechiae
	65875	Severing adhesions of anterior segment of eye, incisional technique (with or without injection of air or liquid) (separate procedure); posterior synechiae
	65920	Removal of implanted material, anterior segment of eye
	66020	Injection, anterior chamber of eye (separate procedure); air or liquid
	66170	Fistulization of sclera for glaucoma; trabeculectomy ab externo in absence of previous surgery
	66172	Fistulization of sclera for glaucoma; trabeculectomy ab externo with scarring from previous ocular surgery or trauma (includes injection of antifibrotic agents)
	66179	Aqueous shunt to extraocular equatorial plate reservoir, external approach; without graft
	66180	Aqueous shunt to extraocular equatorial plate reservoir, external approach; with graft
	66183	Insertion of anterior segment aqueous drainage device, without extraocular reservoir, external approach
	66184	Revision of aqueous shunt to extraocular equatorial plate reservoir; without graft
	66185	Revision of aqueous shunt to extraocular equatorial plate reservoir; with graft
	66250	Revision or repair of operative wound of anterior segment, any type, early or late, major or minor procedure

Codes	Number	Description
	66682	Suture of iris, ciliary body (separate procedure) with retrieval of suture through small incision (eg, McCannel suture)
	66710	Ciliary body destruction; cyclophotocoagulation, transscleral
	66711	Ciliary body destruction; cyclophotocoagulation, endoscopic, without concomitant removal of crystalline lens
	66761	Iridotomy/iridectomy by laser surgery (eg, for glaucoma) (per session)
	66762	Iridoplasty by photocoagulation (1 or more sessions) (eg, for improvement of vision, for widening of anterior chamber angle)
	66821	Discission of secondary membranous cataract (opacified posterior lens capsule and/or anterior hyaloid); laser surgery (eg, YAG laser) (1 or more stages)
	66825	Repositioning of intraocular lens prosthesis, requiring an incision (separate procedure)
	66840	Removal of lens material; aspiration technique, 1 or more stages
	66850	Removal of lens material; phacofragmentation technique (mechanical or ultrasonic) (eg, phacoemulsification), with aspiration
	66852	Removal of lens material; pars plana approach, with or without vitrectomy
	66982	Extracapsular cataract removal with insertion of intraocular lens prosthesis (1-stage procedure), manual or mechanical technique (eg, irrigation and aspiration or phacoemulsification), complex, requiring devices or techniques not generally used in routine cataract surgery (eg, iris expansion device, suture support for intraocular lens, or primary posterior capsulorrhexis) or performed on patients in the amblyogenic developmental stage; without endoscopic cyclophotocoagulation
	66983	Intracapsular cataract extraction with insertion of intraocular lens prosthesis (1 stage procedure)
	66984	Extracapsular cataract removal with insertion of intraocular lens prosthesis (1 stage procedure), manual or mechanical technique (eg, irrigation and aspiration or phacoemulsification); without endoscopic cyclophotocoagulation
	66985	Insertion of intraocular lens prosthesis (secondary implant), not associated with concurrent cataract removal
	66986	Exchange of intraocular lens
	66987	Extracapsular cataract removal with insertion of intraocular lens prosthesis (1-stage procedure), manual or mechanical technique (eg, irrigation and aspiration or phacoemulsification), complex, requiring devices or techniques not generally used in routine cataract surgery (eg, iris expansion device, suture support for intraocular lens, or primary posterior capsulorrhexis) or performed on patients in the amblyogenic developmental stage; with endoscopic cyclophotocoagulation
	66988	Extracapsular cataract removal with insertion of intraocular lens prosthesis (1 stage procedure), manual or mechanical technique (eg, irrigation and aspiration or phacoemulsification); with endoscopic cyclophotocoagulation
	67005	Removal of vitreous, anterior approach (open sky technique or limbal incision); partial removal
	67010	Removal of vitreous, anterior approach (open sky technique or limbal incision); subtotal removal with mechanical vitrectomy
	67015	Aspiration or release of vitreous, subretinal or choroidal fluid, pars plana approach (posterior sclerotomy)
	67025	Injection of vitreous substitute, pars plana or limbal approach (fluid-gas exchange), with or without aspiration (separate procedure)
	67028	Intravitreal injection of a pharmacologic agent (separate procedure)
	67031	Severing of vitreous strands, vitreous face adhesions, sheets, membranes or opacities, laser surgery (1 or more stages)
	67036	Vitrectomy, mechanical, pars plana approach;

Codes	Number	Description
	67039	Vitrectomy, mechanical, pars plana approach; with focal endolaser photocoagulation
	67040	Vitrectomy, mechanical, pars plana approach; with endolaser panretinal photocoagulation
	67041	Vitrectomy, mechanical, pars plana approach; with removal of preretinal cellular membrane (eg, macular pucker)
	67042	Vitrectomy, mechanical, pars plana approach; with removal of internal limiting membrane of retina (eg, for repair of macular hole, diabetic macular edema), includes, if performed, intraocular tamponade (ie, air, gas or silicone oil)
	67043	Vitrectomy, mechanical, pars plana approach; with removal of subretinal membrane (eg, choroidal neovascularization), includes, if performed, intraocular tamponade (ie, air, gas or silicone oil) and laser photocoagulation
	67101	Repair of retinal detachment, including drainage of subretinal fluid when performed; cryotherapy
	67105	Repair of retinal detachment, including drainage of subretinal fluid when performed; photocoagulation
	67107	Repair of retinal detachment; scleral buckling (such as lamellar scleral dissection, imbrication or encircling procedure), including, when performed, implant, cryotherapy, photocoagulation, and drainage of subretinal fluid
	67108	Repair of retinal detachment; with vitrectomy, any method, including, when performed, air or gas tamponade, focal endolaser photocoagulation, cryotherapy, drainage of subretinal fluid, scleral buckling, and/or removal of lens by same technique
	67110	Repair of retinal detachment; by injection of air or other gas (eg, pneumatic retinopexy)
	67113	Repair of complex retinal detachment (eg, proliferative vitreoretinopathy, stage C-1 or greater, diabetic traction retinal detachment, retinopathy of prematurity, retinal tear of greater than 90 degrees), with vitrectomy and membrane peeling, including, when performed, air, gas, or silicone oil tamponade, cryotherapy, endolaser photocoagulation, drainage of subretinal fluid, scleral buckling, and/or removal of lens
	67120	Removal of implanted material, posterior segment; extraocular
	67121	Removal of implanted material, posterior segment; intraocular
	67141	Prophylaxis of retinal detachment (eg, retinal break, lattice degeneration) without drainage; cryotherapy, diathermy
	67145	Prophylaxis of retinal detachment (eg, retinal break, lattice degeneration) without drainage; photocoagulation
	67210	Destruction of localized lesion of retina (eg, macular edema, tumors), 1 or more sessions; photocoagulation
	67218	Destruction of localized lesion of retina (eg, macular edema, tumors), 1 or more sessions; radiation by implantation of source (includes removal of source)
	67220	Destruction of localized lesion of choroid (eg, choroidal neovascularization); photocoagulation (eg, laser), 1 or more sessions
	67221	Destruction of localized lesion of choroid (eg, choroidal neovascularization); photodynamic therapy (includes intravenous infusion)
	67228	Treatment of extensive or progressive retinopathy (eg, diabetic retinopathy), photocoagulation
	67311	Strabismus surgery, recession or resection procedure; 1 horizontal muscle
	67312	Strabismus surgery, recession or resection procedure; 2 horizontal muscles
	67314	Strabismus surgery, recession or resection procedure; 1 vertical muscle (excluding superior oblique)

Codes	Number	Description
	67316	Strabismus surgery, recession or resection procedure; 2 or more vertical muscles (excluding superior oblique)
	67318	Strabismus surgery, any procedure, superior oblique muscle
	67345	Chemodenervation of extraocular muscle
	67400	Orbitotomy without bone flap (frontal or transconjunctival approach); for exploration, with or without biopsy
	67412	Orbitotomy without bone flap (frontal or transconjunctival approach); with removal of lesion
	67414	Orbitotomy without bone flap (frontal or transconjunctival approach); with removal of bone for decompression
	67420	Orbitotomy with bone flap or window, lateral approach (eg, Kroenlein); with removal of lesion
	67445	Orbitotomy with bone flap or window, lateral approach (eg, Kroenlein); with removal of bone for decompression
	67550	Orbital implant (implant outside muscle cone); insertion
	67560	Orbital implant (implant outside muscle cone); removal or revision
	67700	Blepharotomy, drainage of abscess, eyelid
	67800	Excision of chalazion; single
	67801	Excision of chalazion; multiple, same lid
	67805	Excision of chalazion; multiple, different lids
	67808	Excision of chalazion; under general anesthesia and/or requiring hospitalization, single or multiple
	67810	Incisional biopsy of eyelid skin including lid margin
	67825	Correction of trichiasis; epilation by other than forceps (eg, by electrosurgery, cryotherapy, laser surgery)
	67840	Excision of lesion of eyelid (except chalazion) without closure or with simple direct closure
	67875	Temporary closure of eyelids by suture (eg, Frost suture)
	67935	Suture of recent wound, eyelid, involving lid margin, tarsus, and/or palpebral conjunctiva direct closure; full thickness
	67961	Excision and repair of eyelid, involving lid margin, tarsus, conjunctiva, canthus, or full thickness, may include preparation for skin graft or pedicle flap with adjacent tissue transfer or rearrangement; up to one-fourth of lid margin
	67966	Excision and repair of eyelid, involving lid margin, tarsus, conjunctiva, canthus, or full thickness, may include preparation for skin graft or pedicle flap with adjacent tissue transfer or rearrangement; over one-fourth of lid margin
	67971	Reconstruction of eyelid, full thickness by transfer of tarsoconjunctival flap from opposing eyelid; up to two-thirds of eyelid, 1 stage or first stage
	67973	Reconstruction of eyelid, full thickness by transfer of tarsoconjunctival flap from opposing eyelid; total eyelid, lower, 1 stage or first stage
	67975	Reconstruction of eyelid, full thickness by transfer of tarsoconjunctival flap from opposing eyelid; second stage
	68100	Biopsy of conjunctiva
	68110	Excision of lesion, conjunctiva; up to 1 cm
	68115	Excision of lesion, conjunctiva; over 1 cm
	68135	Destruction of lesion, conjunctiva
	68320	Conjunctivoplasty; with conjunctival graft or extensive rearrangement
	68440	Snip incision of lacrimal punctum
	68530	Removal of foreign body or dacryolith, lacrimal passages
	68700	Plastic repair of canaliculi
	68720	Dacryocystorhinostomy (fistulization of lacrimal sac to nasal cavity)

Codes	Number	Description
	68750	Conjunctivorhinostomy (fistulization of conjunctiva to nasal cavity); with insertion of tube or stent
	68761	Closure of the lacrimal punctum; by plug, each
	68801	Dilation of lacrimal punctum, with or without irrigation
	68811	Probing of nasolacrimal duct, with or without irrigation; requiring general anesthesia
	68815	Probing of nasolacrimal duct, with or without irrigation; with insertion of tube or stent
	69000	Drainage external ear, abscess or hematoma; simple
	69100	Biopsy external ear
	69110	Excision external ear; partial, simple repair
	69140	Excision exostosis(es), external auditory canal
	69145	Excision soft tissue lesion, external auditory canal
	69205	Removal foreign body from external auditory canal; with general anesthesia
	69222	Debridement, mastoidectomy cavity, complex (eg, with anesthesia or more than routine cleaning)
	69310	Reconstruction of external auditory canal (meatoplasty) (eg, for stenosis due to injury, infection) (separate procedure)
	69320	Reconstruction external auditory canal for congenital atresia, single stage
	69421	Myringotomy including aspiration and/or eustachian tube inflation requiring general anesthesia
	69424	Ventilating tube removal requiring general anesthesia
	69433	Tympanostomy (requiring insertion of ventilating tube), local or topical anesthesia
	69436	Tympanostomy (requiring insertion of ventilating tube), general anesthesia
	69440	Middle ear exploration through postauricular or ear canal incision
	69450	Tympanolysis, transcanal
	69502	Mastoidectomy; complete
	69505	Mastoidectomy; modified radical
	69550	Excision aural glomus tumor; transcanal
	69602	Revision mastoidectomy; resulting in modified radical mastoidectomy
	69610	Tympanic membrane repair, with or without site preparation of perforation for closure, with or without patch
	69620	Myringoplasty (surgery confined to drumhead and donor area)
	69631	Tympanoplasty without mastoidectomy (including canalplasty, atticotomy and/or middle ear surgery), initial or revision; without ossicular chain reconstruction
	69632	Tympanoplasty without mastoidectomy (including canalplasty, atticotomy and/or middle ear surgery), initial or revision; with ossicular chain reconstruction (eg, postfenestration)
	69633	Tympanoplasty without mastoidectomy (including canalplasty, atticotomy and/or middle ear surgery), initial or revision; with ossicular chain reconstruction and synthetic prosthesis (eg, partial ossicular replacement prosthesis [PORP], total ossicular replacement prosthesis [TORP])
	69635	Tympanoplasty with antrotomy or mastoidotomy (including canalplasty, atticotomy, middle ear surgery, and/or tympanic membrane repair); without ossicular chain reconstruction
	69636	Tympanoplasty with antrotomy or mastoidotomy (including canalplasty, atticotomy, middle ear surgery, and/or tympanic membrane repair); with ossicular chain reconstruction
	69641	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); without ossicular chain reconstruction

Codes	Number	Description
	69642	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); with ossicular chain reconstruction
	69643	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); with intact or reconstructed wall, without ossicular chain reconstruction
	69644	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); with intact or reconstructed canal wall, with ossicular chain reconstruction
	69645	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); radical or complete, without ossicular chain reconstruction
	69646	Tympanoplasty with mastoidectomy (including canalplasty, middle ear surgery, tympanic membrane repair); radical or complete, with ossicular chain reconstruction
	69650	Stapes mobilization
	69660	Stapedectomy or stapedotomy with reestablishment of ossicular continuity, with or without use of foreign material;
	69661	Stapedectomy or stapedotomy with reestablishment of ossicular continuity, with or without use of foreign material; with footplate drill out
	69662	Revision of stapedectomy or stapedotomy
	69666	Repair oval window fistula
	69801	Labyrinthotomy, with perfusion of vestibuloactive drug(s), transcanal
	69805	Endolymphatic sac operation; without shunt
	69806	Endolymphatic sac operation; with shunt
HCPCS	G0104	Colorectal cancer screening; flexible sigmoidoscopy
	G0105	Colorectal cancer screening; colonoscopy on individual at high risk
	G0106	Colorectal cancer screening; alternative to G0104, screening sigmoidoscopy, barium enema
	G0120	Colorectal cancer screening; alternative to G0105, screening colonoscopy, barium enema
	G0121	Colorectal cancer screening; colonoscopy on individual not meeting criteria for high risk
	G0122	Colorectal cancer screening; barium enema
