The treatment of PAD aims at increasing blood flow to alleviate symptoms and prevent arterial leg ulcers, critical leg ischemia, and major complications. Management options for claudication include a structured program of regular exercise, smoking cessation, control of risk factors or associated medical diseases, percutaneous transluminal angioplasty, and surgical revascularization. Drug therapy, even with the most effective agents, was found to result in only a modest improvement. Surgical bypass reconstruction is indicated for severe cases and after failure of other forms of conservative therapy. Patients with non-healing ulcers may not be suitable for revascularization for technical reasons, frail condition, or rejection of surgical intervention. Due to the limited non-operative treatment options, long-term graft failure, perioperative deaths, and imitations or contraindications to intervention, researchers have focused their attention on mechanical methods as potential means for augmenting arterial volume flow in lower limbs (Delis 2000, Montori 2002, 2005).

The concept of using mechanical means to increase blood flow to an ischemic limb dates back to 1930s when a group of investigators applied alternating external pressure to ischemic legs with advanced atherosclerotic peripheral vascular disease. They were however unable to measure blood flow or optimize pneumatic compression. The interest in using intermittent pneumatic compression was renewed in the late 1970s when researchers observed that intermittent pneumatic compression can temporarily increase the arterial blood flow to the limbs. The devices developed apply high pressures by compression cuffs placed on the thigh, calf, and/or foot, intermittently inflate and deflate with cycle times and pressures that vary between devices.

The ArtAssist® Device (ACI Medical Inc., San Marcos, California), is a mechanical pneumatic pump consisting of an impulse generator and two plastic inflatable cuffs. It applies high pressure in a synchronized manner to the foot and calf. This outpatient treatment usually performed for three 1-hour sessions per day while the patient is sitting upright. According to the manufacturer, when the device compresses tissue below the knee, venous blood is emptied and the venous pressure drops to near zero. The resultant increase in the arteriovenous pressure gradient increases arterial blood inflow. Another potential mechanism also described by the manufacturer involves the release of vasodilating substances as endothelial nitric oxide due to the decreased local vascular resistance. Stimulation of collateral blood vessel formation may also occur (ACI medical Inc. Web site).

The ArtAssist device as well as the Flow Medic™ system, and ArterialFlow™ system are all FDA approved for use to improve blood circulation in the lower extremities to help prevent and reduce complications of poor circulation.

## Medical Technology Assessment Committee (MTAC)

### *Intermittent Pneumatic Compression*

#### **02/04/2008: MTAC Review**

**Evidence Conclusion:** The trials on intermittent pneumatic compression (IPC) studied the efficacy of the therapy, mainly using the ArtAssist device, for patients with stable intermittent claudication. There were no RCTs with clinical outcomes that evaluated the IPC for use among patients with more severe condition or those who failed revascularization. All published trials were small, single centered, conducted among highly selected groups of patients, were not blinded, short-term, and none compared IPC to a sham therapy. Kakkos and colleagues (2005), randomized 34 highly selected patients with stable intermittent claudication to receive IPC (n=13), supervised exercise (n=12), or unsupervised exercise (n=9). The study was too small, was unblinded, and had a high drop out rate. Its results show that compared to the unsupervised exercise, both IPC and supervised exercise increased the initial claudication distance (ICD) and the absolute claudication distance (ACD). The difference in improvement observed was statistically significant at the end of the six month treatment and after six additional months of follow-up. There was no significant difference however between the IPC and supervised exercise groups. In their pilot study, Ramaswami and colleagues (2005) evaluated the efficacy of IPC among 34 patients with stable intermittent claudication who were randomized to receive IPC with daily unsupervised exercise or to just perform daily unsupervised exercise. IPC was not compared to sham treatment or to a supervised exercise program. The results showed an increase in the initial and absolute claudication distances with IPC at 4 and 6 months of treatment and the improvement was sustained at 1 year. Delis and Nicolaidis (2005) also evaluated the effectiveness of IPC in 41 highly selected patients with stable intermittent claudications. These were randomly assigned to receive IPC and salicylic acid (75 mg/dL), or salicylic acid (75 mg/dL) alone. All participants in the two groups were encouraged to exercise daily and were followed up for 12 months after the treatment period. The results of the trial show that the ICD, ACD, increased significantly in the IPC group starting at the first month of treatment and was sustained for one year after completing the therapy. Only a small insignificant change was observed in the control group, and the difference between the two study groups was significant. The quality of life also improved significantly in the IPC group, but not in the control group. **Conclusion:** The available evidence from these trials as well as other earlier studies and case series suggest that intermittent pneumatic compression therapy of the foot and calf with ArtAssist device might be associated with improvement in the arterial blood flow and in the walking distance over a short term among patients with stable intermittent claudication. However, the studies included highly selected groups patients with stable claudications who had superficial femoral artery occlusion, and patent iliac arteries (also patent popliteal artery as indicated by some studies). Those with a history of a lower extremity revascularization history were excluded, as well as those with several other comorbidities. Moreover, the studies had control groups not placebo groups undergoing a sham IPC treatment. There were no long-term outcomes beyond one year of follow-up, and the studies did not determine the effectiveness of treatment in improving rest pain, ulcer healing, or reducing amputation rate, all of which may limit generalization of the results. In conclusion there is insufficient evidence to determine the efficacy of pneumatic compression devices for the treatment intermittent claudication, or more severe symptoms among patients with peripheral artery occlusive disease.

**Articles:** There were five small RCTs, one nonrandomized controlled study, and several prospective and retrospective small case series with no control or comparison groups. The majority of trials were conducted

among patients with stable claudication. There was a small trial, with intermediate outcomes that compared three modes of IPC in healthy limbs as well as those with successful grafts. The literature search did not reveal RCT that evaluated the IPC use for patients with more severe condition or those who failed revascularization. *Studies with an appropriate comparison group and/or longer follow-up duration were selected for critical appraisal:* Kakkos SK, Geroulakos G, Nicolaides AN. Improvement of the walking ability in intermittent claudication due to superficial femoral artery occlusion with supervised exercise and pneumatic foot and calf compression: A randomized controlled trial. Eur J Vasc Endovasc Surg. 2005;30:164-175. See [Evidence Table](#)

Ramaswami G, D'ayala M, Hollier LH, et al., rapid foot and calf compression increases walking distance in patients with intermittent claudication: Results of a randomized study. J Vasc Surg. 2005;41:794-801. See [Evidence Table](#)

Delis KT, Nicolaides AN. Effect of intermittent pneumatic compression on foot and calf on walking distance, hemodynamics, and quality of life in patients with arterial claudication. A prospective randomized controlled study with 1-year follow-up. Ann Surg 2005;241:431-441 See [Evidence Table](#)

The use of Intermittent pneumatic compression in the treatment of peripheral arterial occlusive disease does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Intestinal and Multi-Visceral Transplantation

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Intestinal and Multi-Visceral Transplantation (260.5)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

Intestinal and multi-visceral (stomach, duodenum, pancreas, liver, intestine, and colon) transplantation are a covered service for patients who meet **ALL of the following**:

1. Irreversible intestinal failure as defined by loss of absorptive capacity of the small bowel secondary to severe primary gastrointestinal disease or surgically induced short bowel syndrome.
2. Failed total parenteral nutrition (TPN). Defined as:
  - a. Impending or overt liver failure due to TPN induced liver injury as defined by one of the following:
    - elevated bilirubin and/or liver enzymes
    - splenomegaly
    - thrombocytopenia
    - gastroesophageal varices
    - coagulopathy
    - stomal bleeding
    - hepatic fibrosis/cirrhosis
  - b. Thrombosis of the major central venous channels; jugular, subclavian, and femoral veins as defined by one of the following:
    - Thrombosis of two or more of these vessels is considered a life threatening complication and failure of TPN therapy
    - The sequelae of central venous thrombosis is a lack of access for TPN, fatal sepsis due to infected thrombi, pulmonary thrombosis, superior vena cava syndrome, or chronic venous insufficiency
  - c. Frequent line infections and sepsis as defined as:
    - Two or more episodes of systemic sepsis secondary to line infection per year that requires hospitalization
    - A single episode of line related fungemia, septic shock and/or acute respiratory distress syndrome
  - d. Frequent episodes of severe dehydration despite intravenous fluid supplement in addition to TPN
    - Is performed in approved centers that have a volume of 10 intestinal transplants per year with a one-year actuarial survival rate of 65% using the Kaplan-Meier technique.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Intestinal transplantation is an evolving procedure that was experimentally developed more than 30 years ago. It involves transplantation of a cadaveric intestinal allograft for the purpose of restoring bowel function for patients with irreversible failure. The intestine's massive lymphocyte content and heavy bacterial load provided barriers for nearly three decades. Intestines are more susceptible to rejection, and carry higher risk of graft versus host disease (GVHD). The procedure proved to be clinically feasible for humans in the late 1980s, but had considerable morbidity and mortality. The initial recipients of the intestinal grafts did poorly because of technical complications,

graft rejection and sepsis. Recently better results were reported due to improved surgical techniques, more potent immunosuppressive drugs, and standard prophylaxis for infections and lymphoproliferative disease. Although the purpose of intestinal transplantation is to restore bowel function, patient survival should be considered the primary outcome of interest.

The first long-term success was reported in 1988 when cyclosporin-based immunosuppression was used, yet there were many failures due to rejection. The introduction of FK 506 or Tacrolimus, have led to an explosion of the intestinal transplantation activity in the 1990s. It is 100 times more potent than cyclosporin and is somewhat less toxic. Steroids are administered during the early postoperative period, and discontinued completely within a month. Since 1990 surgeons at the University of Pittsburgh Medical Center (UPMC) and Children's Hospital of Pittsburgh have performed more than 115 transplants involving the small intestine. This is close to half the total number performed worldwide.

There are three types for intestinal transplantation: small bowel transplantation (SBT), Small bowel/liver transplantation (SB/LT), and multivisceral transplantation (MVT) which is defined as en-bloc transplantation of 3 or more abdominal organs that include liver, stomach, pancreatic-duodenal complexes as well as the intestine with or without the right hemi-colon. Intestinal transplantation is not an alternative to total parenteral nutrition (TPN), but is only intended for selected patients who are predicted to have poor survival on TPN. It should be considered as a life-saving procedure. Patients who can be maintained on long term TPN are not considered for transplantation at the present time.

An isolated intestinal graft is recommended for patients who have fluid and electrolyte loss that cannot be managed by TPN, those with severely limited venous access and/or moderate liver dysfunction secondary to TPN. Combined SB/LT is offered to patients with irreversible liver failure due to TPN, or intestinal/liver failure associated with a hyper-coagulable state that is corrected by a simultaneous liver graft. Multivisceral transplantation is offered to patients with locally aggressive tumors that can only be removed by a massive evisceration of the abdominal organs. Intestinal transplantation is contraindicated in old age, cardiopulmonary deficiency, AIDS, systemic malignancy and life threatening infections.

The FDA does not regulate surgical procedures such as intestinal and multivisceral transplantation. However, immunosuppressive drugs are FDA regulated. Tacrolimus, the primary immuno-suppressant used with these transplants was approved by the FDA in April 1994 for rejection prophylaxis in allogenic liver transplantation.

## Medical Technology Assessment Committee (MTAC)

### Intestinal Transplantation

#### 04/10/2002: MTAC REVIEW

**Evidence Conclusion:** The literature reviewed did not reveal any study that compared intestinal transplantation to the long term TPN therapy, and the evidence available does not allow for definitive conclusions. The studies reviewed show that the one- year survival rate of intestinal transplantation varied among studies from 54% to 75%. This dropped to around 42-50% at 5 years. Infection was responsible for more than 40% of the deaths.

All studies were case series with limitations including potential selection bias, and lack of control or comparison group. However, it is unlikely that controlled trials, in which outcomes from intestinal/multivisceral transplantation are compared to TPN and medical management, would be conducted. The current use of intestinal transplantation as a rescue therapy for TPN-dependant patients invalidates any comparison with TPN.

**Articles:** Articles were selected based on study type. The search yielded 175 articles most of which were reviews, opinion pieces, editorials, and letters. The literature did not reveal any randomized controlled trials, or meta-analyses, only clinical reports and case series. The articles with the largest size, longest follow-up duration, and with patient survival as the primary outcome of interest were selected for critical appraisal. *Evidence tables were created for the following case series:* Abu-Elmagd K, et al. Clinical intestinal transplantation. *Annals of Surgery* 2001;234(3):404-17. See [Evidence Table](#) Jamieson NV. Adult small intestine transplantation in Europe. *Acta Gastro- Enterologica Belgica* 1999;62(2):239-43. See [Evidence Table](#) Madariaga JR, et al. The long-term efficacy of multivisceral transplantation. *Transplantation proceedings* 2000;32:1219-20. See [Evidence Table](#).

The use of Intestinal Transplantation in the treatment of irreversible intestinal failure does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Intraocular Lens Following Cataract Extraction

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Intraocular Lens (80.12)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

###### Accommodative Intraocular Lens

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

###### Multifocal Intraocular Lens

Multifocal intraocular lenses will not be covered. Standard monofocal intraocular lenses are covered following cataract surgery. The patient may elect to pay for the multifocal lens.

###### Toric Intraocular Lens

Toric intraocular lenses to correct astigmatism are not covered. The purposes of these lenses are to reduce dependence on glasses. Improved vision with glasses is the purpose of standard cataract surgery, the additional benefit of improved vision without glasses is not a covered service.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

It is estimated that over 20 million Americans older than 40 years have cataract in at least one eye. It is predicted that this number will increase to 30 million by 2020. The current approach of treating cataracts is to replace the natural crystalline lens of the eye with an artificial intraocular lens (IOL). Traditionally intraocular lenses are monofocal lenses, which can provide excellent distance vision and optical quality, but they do not deliver functional vision at other ranges of distance. After their implantation most patients need spectacles at least for near vision. Bifocal and multifocal IOLs were developed to overcome the lack of accommodation in these pseudophakic patients (i.e. patients with an artificial IOL). They provide good functional distance, near, and intermediate vision without the use of corrective lenses. However, multifocal and bifocal IOLs may have optical side effects such as decreased contrast sensitivity, glare disability, and halos, which can reduce the retinal image quality and affect the patient's visual performance (Harman 2008, Alio 2010, Alio 2011, Cochener 2011).

##### Accommodative Intraocular Lens

Positional accommodating IOLs were developed to avoid the optical side effects of the multifocal IOLs and provide some accommodative capability and functional near vision. The basic mechanism of these lenses is the transmission, by haptics (plastic plates or struts), of the contracting forces of the ciliary body to the flexible lens. The design of these IOLs is based on the optic-shift concept i.e. on the axial (backward and forward) movement of the optic resulting from the contraction and relaxation of the ciliary muscle. A hinge between the optic and haptics allows the lens to move forward as the eye focuses on near objects and backward as the eye focuses on distant objects, thereby increasing the dioptric power of the pseudophakic eye. The first developed accommodative IOLs were positional single optic lenses used for both cataract and surgical correction of presbyopia. Among these are the Crystalens™ (Eyeonics, Inc., 1CU [Human Optics Erlangen, Germany], and Tetraflex [KH3500, Lenstec, St Petersburg Florida]) (Marchini 2007).

The Crystalens™ AT-45 IOL is the seventh design of the Crystalens™. It consists of a single biconvex lens with a 4.5 mm optic with two plate haptics each terminating in two polyamide loops that anchor it to the capsular bag. Adjacent to the optic are grooved flexible hinges in the plates that allow forward movement of the optic during accommodative effort to provide near and intermediate vision in pseudophakic patients. The optic is square-edged and is made of silicone to maximize biocompatibility and flexibility and allow easy insertion of the lens through a 3 mm corneal incision. A newer Crystalens™ model (Crystalens HD) has a mechanism of action based on the transitional movement of the lens in anterior and posterior direction due to ciliary muscle contraction and vitreous mass displacement (Macasai 2006, Cumming 2006).

The Tetraflex (Lenstec) lens is an anteriorly vaulted, single-piece, foldable, accommodating IOL that is implanted using a custom-designed injector system through an incision as small as 3 mm. The lens' optic is 5.75 mm and is made of a highly biocompatible and extremely flexible hydrophilic acrylic material (HEMA). The IOL's two haptics, each with two footplates, sit posteriorly in the peripheral capsular bag (Sheppard 2010).

The 1CU is a foldable single-piece lens with an optic diameter of 5.5 mm and an overall length of 9.8 mm. It is made of a hydrophilic acrylic material and has a biconvex square-edged optic and 4 modified flexible haptics that are designed to bend when constricted by the capsular bag after ciliary muscle contraction. This allows anterior displacement of the optic resulting in an increase in the refractory power (Pallikaris 2011).

The single-optic passive shift IOLs are considered pseudoaccommodative and have limited accommodative ability as their anterior movement is insufficient to provide functionally significant amplitudes of accommodation. The limited optic power of the single optic lenses led to the development of dual-optic devices as the Synchrony (Visiogen, Irvine, California, USA), and the Sarfarazi IOL (developed by FM Sarfarazi of Shenasa Medical LLC, Carlsbad, CA, USA). The configuration of these devices with a high positively-powered mobile anterior optic, connected to a stationary negatively-powered posterior optic, is designed to increase the potential accommodative amplitude (Alio 2009, Sheppard 2010).

Investigators indicate that the way of measuring the range of accommodation in pseudophakic eyes is still unclear. In a recent review article, Pallikaris and colleagues state "Objective measurement of the accommodative capability offered by the accommodative IOLs is extremely difficult to obtain, and different methods such as autorefractometers, retinoscopy, and ultrasound imaging during accommodative effort, ray tracing, or pharmacological stimulation have been developed but the results are sometimes inconsistent... Pseudophakic accommodation, that is, the dynamic component of ocular refractive variation during near vision, and pseudophakic pseudoaccommodation, that is, the depth of focus and the subjective adaptation to defocus during near vision, are the two core parts of pseudoaccommodation. Currently there is no consensus in the literature on the percentage of the participation of each part in the phenomenon of pseudoaccommodation. Several different methods are utilized by investigators for the study of the phenomenon thus resulting in different results." (Pallikaris 2011).

### **Multifocal Intraocular Lens**

Bifocal and multifocal intraocular lenses have optical side effects such as glare, halos, and decreased contrast sensitivity, which can reduce the retinal image quality and affect the patient's visual performance. The Array IOL (Advanced Medical Optics [AMO], Santa Ana, CA), one of the first IOLs approved by the FDA (1997) is a typical refractive multifocal IOL. Earlier trials demonstrated that Array IOL improved distance and near visual acuity and reduced spectacle dependency after cataract extraction, but it was also associated with problems as decreased contrast sensitivity, glare, and halos. Newer generations of multifocal IOLs have been developed with the aim of providing better visual acuities at various distances with less glare and halos and without need for any spectacles. Currently in the United States, multifocal lens options include the ReZoom™ lens (Abbott Medical Optics [AMO] Inc, Santa Ana, CA), ReSTOR® lens (Alcon Laboratories Inc, Fort Worth, TX), and the Tecnis® lens (Abbott Medical Optics Inc, Santa Ana, CA) (Kawamorita 2009).

The ReZoom™ (AMO) is a second generation multifocal refractive lens that improved on the design of the Array with the aim of decreasing the symptoms of glare and halos. It is a three-piece multifocal lens made of hydrophobic acrylic material and has five refractive optical zones; each zone designed for different light and focal distances: zones 1, 3, and 5 are adjusted for far vision, while zones 2 and 4 are adjusted for near vision. The design of ReZoom is different from the Array in that the second and third zones have been enlarged, and the fourth and fifth zones have been reduced in size. An aspheric transition between zones provides balanced intermediate vision. These changes potentially reduce in night-time glare and improves uncorrected near visual acuity (Forte 2009, Kawamorita 2009, Alio 2011, Kubal 2011, Lichtinger 2012).

The ReSTOR® (Alcon Laboratories Inc) is a diffractive one-piece posterior chamber IOL. It is the first diffractive IOL to be approved by the FDA. ReSTOR® is a biconvex lens made of a soft plastic that can be folded prior to insertion, allowing placement through an incision smaller than the optic diameter of the lens. After surgical insertion into the eye, the lens gently unfolds to restore vision. The supporting arms (haptics) provide for proper positioning of the IOL within the eye. ReSTOR® lens has 12 concentric diffractive rings that cover the central 3.6 mm of the lens. The diffractive portion of the lens is apodized i.e. the height of each diffractive step decreases with increasing distance from the lens center in order to create a smoother transition between focal points. The ReSTOR® is considered a hybrid of diffractive and refractive IOLs with the lens periphery functioning as a refractive zone focusing for distance vision. In 2007, the FDA approved the aspheric version of the ReSTOR® (AcrySof IO, ReSTOR), which has a 10 µm of negative asphericity, while maintaining its apodization and diffractive and refractive components. Recently, a new +3.0 diopter (D) was introduced to improve intermediate vision, which was suboptimal with the +4 D models (Alio 2011, Sood 2011, Zhang 2011, Kubal 2011, Lichtinger 2012).

The Tecnis® Multifocal Intraocular Lens (AMO) is an ultraviolet light-absorbing posterior chamber lens. It was first available as a 3-piece silicone lens (ZM900), then later it became available as a 3-piece acrylic (ZMA00), or a single piece acrylic (ZMB00) lens. The lens is foldable so that it can be inserted into the eye through a very small incision that is actually smaller than the diameter of the lens itself. It has an optical design based on a principle of diffraction similar to the AcrySof ReSTOR® IOL, but with the diffractive rings covering the entire posterior surface of the lens. The rings start very close to the center of the lens and then continue out toward the periphery, usually with an increasing distance between the rings. As a result, the lens achieves its multifocal effects with minimal dependence on the size of the pupil (Sood 2011, Lichtinger 2012).

The ReZoom™, AcrySof ReSTOR 3.0 and 4.0 D, and Tecnis® multifocal intraocular lenses have all received FDA clearance for the visual correction after cataract extraction in adult patients with and without presbyopia.

## Medical Technology Assessment Committee (MTAC)

### Multifocal Intraocular Lens

#### 04/11/2001: MTAC REVIEW

**Evidence Conclusion:** A single well-done RCT provides evidence that multifocal IOL are as effective as monofocal IOL for distance acuity. Patients with multifocal IOL had better uncorrected near VA and distance-corrected near VA than monofocal IOL patients, but similar best-corrected near VA add power. A case series with long-term follow-up showed a high-rate of efficacy on visual acuity with multifocal IOL. All studies reviewed indicated that a limitation of multifocal IOL is decreased contrast sensitivity. The cohort study, which had compromised validity, found less contract sensitivity with multifocal compared to monofocal IOL in daylight and twilight with no glare and twilight with central glare. The benefits of multifocal IOL should be weighed against possible decreases in contrast sensitivity and the efficacy of monofocal IOLs with glasses for near focus.

**Articles:** The search yielded 30 articles. There were 2 RCT articles; these were based on data from the same study. The majority of the articles were case series with small numbers of patients. Evidence tables were created for three studies: The most recent report of RCT data: Javitt JC, Steinert RF. Cataract extraction with multifocal intraocular lens implantation: A multinational clinical trial evaluating clinical, functional and quality-of-life outcomes. *Am Acad Ophthalmol* 2000; 107: 2040-2048. See [Evidence Table](#). A cohort study examining possible adverse effects of multifocal IOL: Winther-Nielsen A, Corydon L, Olsen T. Contrast sensitivity and glare in patients with a diffractive multifocal intraocular lens. *J Cataract Refract Surg* 1993; 19: 254-257. See [Evidence Table](#). A case series with long-term follow-up data: Slagsvold JE. 3M diffractive multifocal intraocular lens: Eight year follow-up. *J Cataract Refract Surg* 2000; 26: 402-407. See [Evidence Table](#).

The use of multifocal Intraocular Lens in the treatment of visual correction following cataract surgery does meet the *Group Health Medical Technology Assessment Criteria*.

#### 07/2005: MTAC REVIEW

##### Intraocular Lens

**Evidence Conclusion:** *Accommodative Intraocular Lens* The evidence on Crystals™ is insufficient to draw conclusions about its efficacy and safety compared to standard intraocular lenses. The single published comparative study (Alio et al., 2004) had threats to validity. It was a non-randomized comparison of three case series, one on Crystals, one on the Array multifocal lens and one on the Twinset bifocal IOL. The study is subject to selection bias because patients were not randomized and the authors did not control statistically for confounding factors. The study was also non-blinded and thus subject to observation bias. The study had four primary outcomes. Between-group differences were statistically significant for one out of the four outcomes, mean best corrected near acuity, but not for mean uncorrected distance acuity, mean best corrected distance acuity or mean uncorrected near acuity. There were two studies on the 1CU IOL by HumanOptics, a non-FDA approved

accommodative IOL. This evidence is also weak. One of the studies (Kuchle et al., 2004) was non-randomized and did not control for confounding factors, and is therefore subject to selection bias. The other study (Dogru et al., 2005) was randomized, but the study methodology was not well described, making it impossible to assess validity. There were also validity issues with the statistical analysis in the Dogru study.

**Articles:** *Accommodative Intraocular Lens* There was one study comparing the FDA approved accommodative IOL, Crystalens, to other types of IOLs. There were two studies comparing the non-FDA approved 1CU accommodative IOL (HumanOptics: Erlangen, Germany) to other IOLs. Like Crystalens, the 1CU IOL has a hinge-like design which allows for forward and backward movement. These three empirical studies were critically appraised. In addition, there was a small case series (n=14) reporting on the initial phase of the Crystalens FDA clinical trial. This study was excluded from further review. Evidence tables were created for the following studies: Crystalens™ Alio JL, Tavalato M, De la Hoz F et al. Near vision restoration with refractive lens exchange and pseudoaccommodating and multifocal refractive and diffractive intraocular lens. *J cataract Refract Surg* 2004; 30: 2494-2503. See [Evidence Table](#). Human Optics 1CU. Dogru M, Honda R, Omoto M. Early visual results with the 1CU accommodating intraocular lens. *J Cataract Refract Surg* 2005; 31: 895-902. See [Evidence Table](#). Kuchle M, Seitz B, Langenbucher A et al. Comparison of 6-month results of implantation of the 1CU accommodative intraocular lens with conventional intraocular lens. *Ophthalmology* 2004; 111: 318-324. See [Evidence Table](#).

The use of Accommodative Intraocular Lens in the treatment of visual correction following cataract surgery does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **04/16/2012: MTAC REVIEW**

##### **Intraocular Lens**

**Evidence Conclusion:** *Accommodative Intraocular Lens* Crystalens™ : AT-45 The literature search did not reveal any published large good quality RCTs that compared the implantation of the accommodative Crystalens™ with multifocal or monofocal intraocular lenses after cataract extraction. The best published evidence on Crystalens™ comes from the FDA multicenter clinical trial with 12 months follow-up (Evidence table 1). The initial study was a phase II trial that evaluated the efficacy and safety of the Crystalens™ AT-45. It was a prospective cohort study with no control or comparison group. The results of 12 months follow-up of 263 patients receiving the implant in the primary eye showed that the accommodating Crystalens™ AT-45 provided good uncorrected near and distance visual acuity with minimal adverse effects. In a substudy the authors compared contrast sensitivity under mesopic conditions with and without glare in a subgroup of patients who received the Crystalens versus a matched population of 64 patients who received standard IOL. The results of this substudy showed that the difference in contrast sensitivity between the two groups of patients was clinically irrelevant.

ICU (Human Optics) Several randomized and nonrandomized trials compared the performance of 1CU with monofocal and multifocal intraocular lenses (IOLs) (Evidence tables 2-4). The results of the studies showed that distance corrected near vision was significantly better in the 1CU group versus other groups receiving non-accommodating IOLs. Two small studies showed that the accommodative ability of the lens may decrease by time (8 months in Sauder and colleagues' trial and 12 months in Dogru and colleagues' study) leading to a reduction in the near vision acuity. The studies had some limitations and long-term follow-up is needed to determine the long-term safety and efficacy of the lens. In a large prospective, controlled, but non-randomized trial with potential biases (Evidence table 3), Uthoff and colleagues found that 1CU had a minor statistical advantage of half a reading step towards monofocal IOLs measured with subjective methods in near point, defocusing curve, and near visual acuity with BSCVA. They explained that this could be due to the pseudophakic accommodation by the optic shift or as a result of the additional pseudophakic pseudoaccommodation. The accommodative effect differed between patients and was unpredictable.

*Tetraflex:* The prospective nonrandomized US Food and Drug Administration trial (Sanders 2010) on Tetraflex accommodative IOL is ongoing. In this study 255 patients received Tetraflex IOLs and 101 received monofocal IOLs. Interim results of 12 months follow-up of 239 patients in the Tetraflex arm and 96 controls show that the Tetraflex patients read better than the controls at print sizes of 20/80 (P=.04), 20/63 (P=.01), 20/50 (P<.001), 20/40 (P=.001), 20/32 (P<.001), and 20/25 (P=.001). The proportion of patients reading at a speed of ≥80 words per minute was significantly higher with the Tetraflex IOL (P=.003). Ninety-six percent of Tetraflex patients reported never wearing glasses for distance compared with 80% of control patients (P<.001). Seventy-five percent of the Tetraflex patients reported that they did not or occasionally needed to wear glasses for near reading small print and/or dim light compared with 46% of control patients (P<.001). The trial had its limitations and the study groups were not randomly assigned to type the IOL implanted which is a source of selection bias. They were also not blinded to the IOL received, which is another source of bias especially with subjective outcomes as self reporting of use of spectacles. Moreover, the reading ability and speed is dependent on many factors in addition to visual acuity. In conclusion, large randomized, controlled, and blinded trials with long-term follow-up are needed to determine the long-term efficacy, durability of benefit, and safety of the accommodative intraocular lenses.

**Multifocal Intraocular Lens:** A Cochrane meta-analysis with valid methodology (Leyland et al, 2008, evidence table 1) pooled the results of ten randomized controlled trials that compared visual outcomes of multifocal IOLs versus monofocal IOL implantation after cataract surgery. There were variations between the studies in population sizes, measures and outcomes reported, as well as follow-up durations. The main pooled results of the analysis showed no significant differences between multifocal and monofocal IOLs in uncorrected distance visual acuity or the proportion of patients achieving distance 6/6 best-corrected distance visual acuity. The uncorrected near vision was improved with the multifocal IOLs, and the rate of freedom from use of glasses was also higher with the multifocal IOLs. Contrast sensitivity was lower among participants receiving multifocal IOL implants who also experienced significantly higher rates of glare and halos. The results of another meta-analysis (Cochener et al 2011, Evidence table 2) that had the limitation of pooling results of observational studies together with randomized controlled trials, also showed that multifocal IOLs provided better uncorrected near visual acuity and less need for spectacles compared to monofocal IOLs. The results of the analysis also showed that diffractive multifocal lenses led to better results than the refractive IOLs, and that ReSTOR® had better uncorrected near visual acuity, uncorrected distance visual acuity, and higher spectacle independence rates compared with other multifocal IOLs. The incidence of halos was higher with multifocal lenses versus monofocal IOLs, but there was no significant difference between the different multifocal IOLs. No sensitivity analysis including only RCTs was made, and the results of the meta-analysis should be interpreted with caution. A more recent randomized controlled trial by Alió and colleagues (2011, Evidence table 3) compared the visual performance of 4 different IOLs: monofocal Acri.Smart, multifocal Acrysof ReSTOR® SN6AD3, multifocal Acri.Lisa 366D, and multifocal ReZoom refractive IOL. The same type of lens was implanted bilaterally in each of the 152 participants (304 eyes). After six months of follow up, the results showed that all patients had postoperative significant improvement in uncorrected and corrected visual acuities. Patients with the ReSTOR® and Acri.Lisa multifocal lens implants had significantly better uncorrected reading acuity than those in the monofocal or the refractive ReZoom™ groups. The monofocal group had the greatest uncorrected reading distance at 1 and 6 months postoperatively. The authors did not evaluate patient satisfaction with the different types of IOLs, nor did they assess the contrast sensitivity, or presence of glare and halos. Studies comparing ReSTOR® +3.0 D versus ReSTOR® +4.0 D were not critically appraised in this report, but their overall results showed better intermediate visual acuity, but more glares with the +3.0 D vs.+4.0 D IOLs. Conclusion: There is good evidence from the published literature that multifocal intraocular lenses improve near visual acuity when compared to monofocal lenses, without compromising distance visual acuity. There is good evidence that patients undergoing multifocal IOLs implantation have higher rates of spectacle independence compared to those with monofocal lens implants. There is evidence that patients with multifocal IOL implants experience more halos and glare and have lower contrast sensitivity than those with monofocal implants. There is fair evidence that optical outcomes are better with diffractive versus refractive multifocal IOLs, and that improvement in near vision without use of glasses and patient satisfaction are more evident with ReSTOR® compared to other multifocal IOLs. There is insufficient evidence to determine any significant difference in contrast sensitivity, glare, or halos between multifocal IOLs.

**Articles:** *Accommodative Intraocular Lens* Single optic IOLs - The majority of studies published on the accommodative intraocular lenses evaluated single optic accommodative IOL, mainly the ICU (Humans Optics), and to a lesser extent the Crystalens™ AT-45. The search identified one meta-analysis of RCTs, a small number of controlled randomized and nonrandomized trials, and case series. The larger trials with more valid methodology and longer term follow-up were selected for critical appraisal. The meta-analysis was not critically appraised as it had a low methodological quality and only included only 5 RCTs with very small sample sizes, along with other nonrandomized, and non-controlled studies published from 1996-2006. Dual optic IOLs - The literature search revealed a small pilot prospective case series with a retrospective control on the Synchrony dual-optic IOL. Phase III FDA clinical trials are still ongoing. The following studies were critically appraised: Harman FE, Maling S, Kampougeris G, et al. Comparing the 1CU accommodative, multifocal, and monofocal intraocular lenses: a randomized trial. *Ophthalmology*. 2008;115:993-1001. See [Evidence Table](#). Cumming JS, Colvard DM, Dell SJ, et al. Clinical evaluation of the Crystalens AT-45 accommodating intraocular lens: results of the U.S. Food and Drug Administration clinical trial. *J Cataract Refract Surg*. 2006;32:812-825 See [Evidence Table](#). Mesci C, Erbil HH, Olgun A, et al. Visual performances with monofocal, accommodating, and multifocal intraocular lenses in patients with unilateral cataract. *Am J Ophthalmol*. 2010;150:609-618. See [Evidence Table](#). Uthoff D, Gulati A, Hepper D, Potentially accommodating 1CU intraocular lens: 1-year results in 553 eyes and literature review. *J Refract Surg*. 2007;23:159-171. See [Evidence Table](#).

**Multifocal Intraocular Lens** The literature search revealed a large number of studies on multifocal intraocular lenses. The majority were prospective or retrospective observational studies and case series with different population sizes and follow-up durations and no comparison or control groups. There were also a number of published randomized or nonrandomized controlled trials that evaluated the visual function, and /or quality of life after the implantation of monofocal versus multifocal lenses. The search also identified three meta-analyses that pooled the results of trials comparing multifocal versus monofocal intraocular lenses, one meta-analysis of studies compared different IOLs, as well as a pooled analysis of two non-randomized trials that compared outcomes of ReSTOR vs. monofocal IOLs lenses. The most recent meta-analysis comparing outcomes of monofocal versus

multifocal lenses, and the meta-analysis that compared different multifocal lenses were selected for critical appraisal. A recent RCT that compared outcomes of one monofocal and three different multifocal IOLs was also critically appraised. Alió JL, Grabner G, Plaza-Puche AB., et al. Postoperative bilateral reading performance with 4 intraocular lens models: six-month results. *Cataract Refract Surg.* 2011;37:842-852. See [Evidence Table](#). Cochener B, Lafuma A, Khoshnood B, et al. Comparison of outcomes with multifocal intraocular lenses: a meta-analysis. *Clin Ophthalmol.* 2011; 7:45-56. See [Evidence Table](#). Leyland M, Pringle E. Multifocal versus monofocal intraocular lenses after cataract extraction. *Cochrane Database of Systematic Reviews* 2008, issue 4. See [Evidence Table](#).

The use of Accommodative Intraocular Lens in the treatment of visual correction following cataract surgery does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Intraoperative Neurophysiological Monitoring

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

##### Local Coverage Determination (LCD)

[Sensory Evoked Potentials & Intraoperative Neurophysiology Monitoring \(L34072\)](#)

##### For Non-Medicare Members

Intraoperative neurophysiological monitoring is indicated for all of the following:

- Spinal deformity
- Intradural spinal lesions
- Anterior thoracic lesions/discs
- Anterior lumbar interbody fusions
- Extreme lateral interbody fusions
- Acoustics neuromas
- Intraparenchymal tumors in or near eloquent cortex
- Anterior cervical discectomy and fusion
- Microvascular decompression
- Cerebral aneurysms
- Chiari malformation

The following may be appropriate on a case by case basis and will require Medical Director Review:

- Cervical decompressive laminectomies with myelopathy
- Minimally invasive lumbar fusions
- Re-operative lumbar fusions

Intraoperative neurophysiological monitoring is not indicated for all of the following:

- Cervical foraminotomies
- Thoracic laminectomies for decompression/edh/infection
- Lumbar laminectomies/discectomies
- Open lumbar fusions (PLIF/TLIF)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Intraoperative neurophysiologic monitoring (IONM) describes a variety of procedures that are used to monitor the integrity of neural pathways during high-risk surgery. Involving the detection of electrical signals produced by the nervous system, the overall goal of IONM is to promptly identify and correct nervous system impairment prior to causing irreversible damage (Fehlings, Brodke et al. 2010). More specifically, IONM might employ a variety of different techniques of monitoring including electroencephalogram (EEG), somatosensory evoked potentials (SSEP), electromyography (EMG), and motor-evoked potentials (MEP). Signals are continuously monitored and interpreted by a neurophysiologist to detect adverse changes, thus enabling corrective action.

Conventionally, IONM has been practiced locally, or on-site, with the physician neurophysiologist present in the operating room. Advances in technology, however, have allowed for remote monitoring. Remote IONM is substantially different from the traditional on-site monitoring with communications between the neurophysiologist and physicians in the operating room (OR) limited to text message or telephone.

Currently in the United States (US), almost half of all IONM performed is remote (Greiner, Mess et al. 2012; Emerson and Husain 2013; Nuwer, Cohen et al. 2013). In any case, there is substantial controversy regarding the current evidence base leaving the choice to utilize IONM up to the discretion of the surgical team.

The IONM field is not regulated by the US Food and Drug Administration (FDA). Instead, standards of practice and education are provided by a number of professional societies (AAN 1990; Nuwer, Emerson et al. 2012; ACNS 2013). IONM has not previously been reviewed by the Medical Technology and Assessment Committee (MTAC) and is currently under consideration due to support a coverage decision.

## Medical Technology Assessment Committee (MTAC)

### Intraoperative Neurophysiologic Monitoring (IONM)

#### 08/17/2015: MTAC REVIEW

**Evidence Conclusion:** The selected studies offer a small sample of the extensive literature currently available relating to IONM. For the most part, the available evidence is descriptive and details the experience of IONM in various surgical settings. In the selected studies, IONM is used to support surgeries in various specialties including neurosurgery (brain and spine), cardiac, and vascular. Population sizes range from 62 to 119 and assessed pre- and post- surgical outcomes such as neurophysiologic alerts during surgery and post-operative neurological deficits. Conclusions from the selected studies conflict with some asserting the utility of IONM technology and others finding minimal utility due to the inability to predict post-operative complications (Schramm, Koht et al. 1990; Linstedt, Maier et al. 1998; Ghariani, Liard et al. 1999; Bose, Sestokas et al. 2004). Surgical procedures and interventions are not always based on scientific evidence and instead, tend to evolve over time. Today, IONM is considered to be a standard of care limiting the ability to carry out methodologically sound comparative studies due to equipoise. Beyond that, the existing literature base is extremely heterogeneous addressing various surgical procedures in different populations with varying and conflicting conclusions. As a result, the evidence is insufficient to be able to determine if IONM is truly effective at detecting and preventing neurologic complications.

**Conclusions:** There is insufficient evidence to establish that IONM, either on-site or remote, reduces the risk of neurologic injuries during surgical procedures. There is insufficient evidence to support the safety of IONM.

**Articles:** The literature search revealed a large number of publications relating to IONM. There were no randomized controlled trials (RCTs) comparing the outcomes of surgeries that employed the use of IONM (either remote or on-site) with those not utilizing the monitoring technique nor were there any studies making a comparison between remote and onsite monitoring. The search yielded a wide variety of observational studies the majority of which had no comparison group. Due to the extensive amount of literature identified, the following studies are a small sample of the available evidence: Bose B, Sestokas AK, Schwartz DM. Neurophysiological monitoring of spinal cord function during instrumented anterior cervical fusion. *The Spine Journal*. 2004;4(2):202-207. [See Evidence Table 1](#). Schramm J, Koht A, Schmidt G, et al. Surgical and electrophysiological observations during clipping of 134 aneurysms with evoked potential monitoring. *Neurosurgery*. 1990;26(1):61-70. [See Evidence Table 1](#). Ghariani S, Liard L, Spaey J, et al. Retrospective study of somatosensory evoked potential monitoring in deep hypothermic circulatory arrest. *The Society of Thoracic Surgeons*. 1999;67:1915-1918. [See Evidence Table 1](#). Linstedt U, Maier C, Petry A. Intraoperative monitoring with somatosensory evoked potentials in carotid artery surgery – less reliable in patients with preoperative neurologic deficiency? *Acta Anaesthesiol Scand*. 1998;42(1):13-16. [See Evidence Table 1](#).

The use of Intraoperative Neurophysiologic Monitoring (IONM) does not meet *Group Health Medical Technology Assessment Criteria*.

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	<a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	None

#### For Non-Medicare Members

Group Health has elected to use the Iontophoresis (GHC-0617) MCG\* for medical necessity determinations.

**\*The MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Last 6 months of clinical notes from requesting provider &/or specialist

#### For Medication Delivery with Iontophoresis for Temporomandibular Joint (TMJ) Dysfunction and Joint Pain or Devices for use in the member's home.

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Evidence and Source Documents

[Iontophoresis for Hyperhidrosis using Drionic or Idrostar Devices](#)

[Iontophoresis for Joint Pain](#)

[Medication Delivery with Iontophoresis for Temporomandibular Joint \(TMJ\) Dysfunction](#)

### Background

Iontophoresis is the use of electricity to enhance the percutaneous absorption of a drug or chemical ions. Ions in solution are transferred through the skin by passing DC electrical current between two electrodes. Iontophoresis uses a low current and patients' have little or no sensation during the procedure. Drugs used in iontophoresis should be those that ionize. Drugs used for iontophoresis may include lidocaine hydrochloride (a positive ion forming drug) and dexamethasone sodium phosphate (a negative ion forming drug). Possible advantages include greater convenience and less discomfort compared to injection, less variation in absorption, and fewer side effects compared to oral administration of medication.

### Medical Technology Assessment Committee (MTAC)

#### *Iontophoresis for Hyperhidrosis using Drionic or Idrostar Devices*

##### BACKGROUND

Hyperhidrosis or excessive sweating may be classified into primary or essential hyperhidrosis with an unknown cause, and secondary hyperhidrosis which is due to an underlying condition as hyperthyroidism, menopause,

obesity, psychiatric disorder, and others. It may be localized in one or several locations of the body, most often in the hands (palmer hyperhidrosis) but may also be plantar, axillary, facial, or general. Several methods are used to treat patients with primary hyperhidrosis, or secondary cases with heavy sweating or untreatable conditions. These include the use of antiperspirants, drugs, psychotherapy, surgery, iontophoresis, use of botulinum toxin, alternative medicine, and others. Iontophoresis can be defined as a means of delivering medication to a localized tissue area by applying electrical current to a solution of the medication. It consists of applying low intensity current (15-18 mA) supplied by a D/C generator to the palms and/or soles immersed in an electrolyte solution. The procedure has to be repeated regularly, and the results may vary among patients. The Drionic and Idrostar devices are battery- operated methods of inducing tap water iontophoresis.

#### **06/12/2002: MTAC REVIEW**

##### **Iontophoresis for Hyperhidrosis using Drionic or Idrostar Devices**

**Evidence Conclusion:** There is not enough evidence to permit conclusions on the use of either the Drionic or Idrostar device for treating hyperhidrosis.

**Articles:** The search yielded three articles, two of which were reviews, and the third was a small case series with 22 patients with hyperhidrosis treated with the Drionic unit.

The use of idrostar in the treatment of hyperhidrosis via iontophoresis does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **08/03/2009: MTAC REVIEW**

##### **Iontophoresis in the Treatment of Hyperhidrosis**

**Evidence Conclusion:** There is insufficient evidence to draw conclusions on the safety and efficacy of iontophoresis for treating hyperhidrosis. No published comparative studies were identified. The literature base consists of case series, mostly with fewer than 25 patients and one case series with 112 patients. The larger series reported that about 81% of participants responded to treatment. The criteria provided for response was not clearly defined and there was no long-term follow-up.

**Articles:** Four empirical studies specifically evaluating iontophoresis for hyperhidrosis were identified. There were no randomized or non-randomized controlled studies. All of the empirical studies were case series. Three had fewer than 25 patients and were excluded from further review. The fourth (Karakoc et al., 2002) included 112 patients and was critically appraised. See [Evidence Table](#).

The use of iontophoresis in the treatment of hyperhidrosis does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **Iontophoresis for Joint Pain**

##### **BACKGROUND**

Iontophoresis is proposed as a treatment for joint pain. It has been used for various types of tendonitis including epicondylitis, patellar tendonitis, biceps tendonitis, rotator cuff tendonitis and Achilles tendonitis (Winn, unpublished manuscript). Iontophoresis is the use of electricity to enhance the percutaneous absorption of a drug or chemical ions. Ions in solution are transferred through the skin by passing DC electrical current between two electrodes. Iontophoresis uses a low current and patients have little or no sensation during the procedure. Drugs used in iontophoresis should be those that ionize. Dexamethasone sodium phosphate, a negative ion, is a commonly used drug used for iontophoresis treatment of joint pain. Possible advantages include greater convenience and less discomfort compared to injection, less variation in absorption, and fewer side effects compared to oral administration of medication. Common treatments for joint pain include rest, ice after exercise, stretching, bracing and immobilization; medications such as analgesics and non-steroidal anti-inflammatory drugs (NSAIDs) and injection of corticosteroids. A well-done randomized controlled trial (Hay et al., 1999) found that local injection of corticosteroid was more effective for treating lateral epicondylitis than NSAID treatment, but that more than 80% of patients were improved at 12 months regardless of treatment.

#### **10/08/2003: MTAC REVIEW**

##### **Iontophoresis for Joint Pain**

**Evidence Conclusion:** There is insufficient evidence to conclude that iontophoresis for joint pain is effective compared to the accepted alternatives, corticosteroid injection and NSAID treatment. No studies compared iontophoresis with one of these established treatments. There is some evidence that iontophoresis is not more effective than placebo treatment, although the data are limited. The highest quality study identified was an RCT comparing active iontophoresis with placebo iontophoresis in patients with epicondylitis (Nirschl). This study found a greater effect with active iontophoresis two-days after treatment, but no difference in efficacy after one-month.

The study was powered to detect a 20% difference between groups. Another RCT conducted with patients with epicondylitis (Runeson) found no difference in the efficacy of active or placebo iontophoresis 3- and 6-months after treatment. Neither RCT had an intention to treat analysis, but follow-up was much higher in the Nirschl study (90% compared to 64% in the Runeson study). Statistical power was not discussed in the Runeson study. The quality of evidence for conditions other than epicondylitis was low.

**Articles:** The search yielded 12 articles. None of the studies compared iontophoresis to corticosteroid injection or oral medication treatment. There were four RCTs conducted with patients who had epicondylitis. Two studies compared active iontophoresis treatment to placebo treatment and were critically appraised. The two other studies had irrelevant comparison groups and were not reviewed: one compared iontophoresis with two types of active substances and one compared iontophoresis to an experimental treatment, phonophoresis. In addition, there were three controlled studies conducted among patients with other types of tendonitis. All three had weaker methodology than the placebo-controlled epicondylitis studies and were not reviewed. Two did not compare the different treatment groups in analysis and one had a sample size of only 22 patients. *The following studies were critically appraised:*

Nirschl RP, Rodin DM, Ochiai et al. Iontophoretic administration of dexamethasone sodium phosphate for acute epicondylitis. *Am J Sports Med* 2003; 31: 189-195. See [Evidence Table](#). Runeson L, Haker E. Iontophoresis with cortisone in the treatment of lateral epicondylalgia (tennis elbow)- a double blind study. *Scand J Med Sci Sports* 2002; 12: 136-142. See [Evidence Table](#).

The use of iontophoresis in the treatment of joint pain does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Medication Delivery with Iontophoresis for Temporomandibular Joint (TMJ) Dysfunction**

#### **BACKGROUND**

Temporomandibular joint (TMJ) dysfunction is a common condition and involves pain, particularly in the chewing muscles and jaw joint, radiating pain in the face, neck or shoulders, painful clicking sounds in the jaw joint, and restricted jaw movement. Drug therapies for TMJ dysfunction include analgesics, minor tranquilizers or muscle relaxants at bedtime, antidepressants, injections of a local anesthetic and cortisone injections.

Iontophoresis is the use of electricity to enhance the percutaneous absorption of a drug or chemical ions. Ions in solution are transferred through the skin by passing DC electrical current between two electrodes. Iontophoresis uses a low current and patients' have little or no sensation during the procedure. Drugs used in iontophoresis should be those that ionize. Drugs used for iontophoresis to treat TMJ include lidocaine hydrochloride (a positive ion forming drug) and dexamethasone sodium phosphate (a negative ion forming drug) (Lark & Gangarosa). Iontophoresis is proposed as an alternative to local anesthetic injections for the treatment of TMJ dysfunction. Possible advantages are less discomfort than interarterial injection and fewer side effects than systemic medications.

#### **02/13/2002: MTAC REVIEW**

#### **Iontophoresis in the Treatment of Temporomandibular Joint Syndrome**

**Evidence Conclusion:** There is insufficient published scientific evidence on which to base conclusions about the effect of medication delivery with iontophoresis on health outcomes in patients with temporomandibular joint syndrome. Two small RCTs were reviewed, both of which may have had insufficient statistical power to detect clinically important differences between groups; neither of the study discussed statistical power calculations. Shiffman did not compare the randomized groups in analysis. Reid did not find that iontophoresis was more effective than placebo.

**Articles:** The search yielded eight articles. The majority were review articles/opinion pieces. There were two small randomized controlled trials (RCTs) with clinical outcomes. These two articles were critically appraised: Shiffman EL, Braun BL, Lindgren BR. Temporomandibular joint iontophoresis: A double-blind randomized clinical trial. *J Orofacial Pain* 1996; 10: 157-65. See [Evidence Table](#). Reid KJ, Dionne RA, Sicard-Rosenbaum L, Lord D, Dubner RA. Evaluation of iontophoretically applied dexamethasone for painful pathologic temporomandibular joints. *Oral Surg Oral Med Oral Pathol* 1994; 77: 605-9. See [Evidence Table](#).

The use of iontophoresis in the treatment of temporomandibular joint syndrome does not meet the *Group Health Medical Technology Assessment Criteria*.

Criteria

For Medicare Members

Table with 2 columns: Source and Policy. Rows include CMS Coverage Manuals, National Coverage Determinations (NCD), Local Coverage Determinations (LCD), and Local Coverage Article.

For Non-Medicare Members

Intraoperative radiation therapy (IORT) may be considered medically necessary in the following situation:

- Rectal cancer with positive or close margins with T4 lesions or recurrent disease.

IORT is considered investigational when used for all other oncologic applications, including but not limited to:

- Breast cancer
Fibromatosis
Gastric cancer
Glioma
Gynecologic cancers
Head and neck cancers
Neuroblastoma
Pancreatic cancer
Renal cell cancer
Soft tissue sarcoma

Some requests may be approved on a case by case basis by the Medical Director

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

Background

The usual method for delivering radiation is external beam with high-energy photons. However, the external beam doses required to achieve local tumor control can exceed the radiation tolerance of some normal organs and other structures of the body.

Intra-operative radiation therapy (IORT) is being investigated as a technique to deliver a high dose of radiation to a locally advanced tumor while attempting to protect adjacent normal tissues at the time of surgery. It is delivered with applicators and cones attached to the treatment head of high-energy medical linear accelerators. After all or most of the cancer is surgically removed, a large, single-dose of high-energy radiation is aimed directly at the tumor site. Nearby healthy tissue is protected with special shields.

The goal of IORT is to enhance local tumor control. Most patients receiving IORT are concurrently treated with high-dose external beam photon irradiation. The term “intraoperative radiation therapy” may also refer to intraoperative brachytherapy, the temporary or permanent implantation of radioactive seeds. Intra-operative radiation therapy is usually a component of a multi-disciplinary treatment approach for localized cancers that cannot be completely removed or that have a high risk of recurring in nearby tissues.

## Medical Technology Assessment Committee (MTAC)

### *Intraoperative Radiation Therapy (IORT) for Breast Cancer*

#### BACKGROUND

Breast cancer is the most common cancer in women of all races and ethnicities (not counting skin cancer), and the second most common cause of death from cancer among white, black, Asian/Pacific Islander, and American Indian/Alaska Native women. The American Cancer Society (ACS) estimated that in 2015, 231,840 new cases of invasive breast cancer and 62,570 breast carcinoma in-situ, will be diagnosed among women in the U.S. and that 40,290 will die from breast cancer. The reported five-year relative survival rate is 98.5% for women diagnosed with localized breast cancer. This drops to 84% among women with cancer that has spread to nearby lymph nodes (regional stage) and to 24% in those with metastases in distant lymph nodes and/or other organs (CDC and ACS web pages accessed October 27, 2015). The widespread screening programs and new developments in early detection of cancer have led to an increase in the incidence of early stage breast cancer. Surgical treatment has thus shifted from radical mastectomy to personalized local treatment that preserves the breast and axillary lymph nodes, together with adjuvant therapy. Breast conserving surgery (BCS) followed by postoperative whole breast external beam radiotherapy (EBRT or WBRT) is currently considered the standard treatment for patients with early-stage breast cancer. This approach has been shown to reduce local recurrence (LR) and improve the overall survival. Traditional whole breast EBRT is administered in the postoperative setting as 45-50 Gy in daily fractions for 5 consecutive weeks. An additional external beam boost of 10-16 Gy is often delivered to the tumor bed to improve local control and reduce local recurrence. It is reported that almost one third of the patients undergoing BCS in North America do not receive post-BCS breast radiation therapy and many others choose mastectomy instead, for several reasons including the long course of treatment, comorbidities, advanced age, distance from the radiation therapy facility, inconvenience, and cost (Vaidya, 2010, Esposito 2014, Abbott 2015, Zhang 2015). Accelerated partial breast irradiation (APBI), is a radiation technique that targets partial breast tissue around the tumor cavity with fewer fractions. APBI has emerged in the last 2 decades, and is increasingly being accepted as an alternative to whole breast EBRT. It is based on the observation that more than 90% of local recurrences occur at /or near the tumor bed after BCS. There are several techniques for delivering APBI, including multi-catheter interstitial brachytherapy, balloon catheter brachytherapy, 3D- conformal radiation therapy, and intraoperative radiation therapy (IORT). These techniques differ widely in regards to the degree of invasiveness, radiation delivery, operator proficiency, acceptance between radiation oncologists, and length of treatment (Njeh 2010, Vaidya 2010, Abbott 2015, Esposito 2015, Zhang 2015). IORT is an APBI approach that delivers a single dose of irradiation directly to the tumor bed at the time of surgery. Unlike other APBI techniques that target the index quadrant, IORT specifically targets the tumor cavity. The index quadrant is not demarcated anatomically, whereas the tumor cavity is easily located by the operating surgeon. IORT can be delivered by using low-energy X-rays, electron beam radiation therapy, brachytherapy, high-dose-rate (HDR) after loaders, and other hybrid devices (Esposito 2015). The intrabeam<sup>®</sup> device (Carl Zeiss, Oberkochen, Germany) is a device used to deliver IORT during surgery after removal of the tumor. It comprises a miniature low-energy X -ray source (50 kVp) that delivers a dose of 20 Gy at the surface of the applicator and 5-5 Gy at 1 cm deep, in 20-40 minutes treatment time. Tungsten-impregnated sheets are used to shield the wound before treatment. Access to the operating room should be controlled and the medical personnel shielded during treatment. The intraoperative electron radiation therapy (IOERT) is another method for delivering IORT that involves the application of electron radiation directly to the tumor bed at the time of surgery. Compared to the X-ray beams, the electron beams have limited penetration into the tissue and faster delivery of the required radiation dose. The IOERT systems are designed to deliver radiation in non-shielded operating theaters. Currently there are three mobile linear accelerators that can be moved easily into an operating room and deliver IOERT (Novac 7<sup>®</sup>, Liac<sup>®</sup>, and the Mobetron<sup>®</sup>). The radiation procedure is completed in 2 minutes delivering a dose of 21 Gy with the depth of 90% isodose ranging from 13-24 mm (Esposito 2015). The advantages of IORT include the reduced treatment visits by delivering a single radiotherapy fraction during surgery, immediate visualization of the operative bed before delivering the radiotherapy, minimizing the possibility of missing the target, shielding the surrounding organs, avoiding treatment

delay for patients who may also need to undergo chemotherapy, and reducing healthcare costs. Disadvantages of IORT on the other hand, include longer operating time, reported increased local recurrence compared to EBRT, and lack of final pathological results before delivering the IORT. In patients with positive margins that require re-excision, an IORT boost may be ineffective and may cause complications in re-excision of the margins and difficulty in interpreting the pathology. In addition, IORT requires training of staff, operating room equipment efforts, and expensive devices (Hanna 2014, Esposito 2015).

## 12/21/2015: MTAC REVIEW

### IROT for breast cancer

**Evidence Conclusion:** There are two large published intraoperative radiation therapy (IORT) trials that investigated whether IORT is equivalent (ELIOT) or noninferior (TARGIT-A) to standard EBRT for the treatment of women with early stage breast cancer undergoing breast conservative surgery. The ELIOT trial used electron IORT (using 2 linear accelerators; NOVAC 7 and Liac) and the TARGIT-A trial used a point source low-energy x-rays (50kV maximum) using the Intrabeam device. TARGIT-A trial (Vaidya et al, 2010, 2014), Evidence Table 1 This was a large multicenter trial that examined the noninferiority of IORT to EBRT (within a specified margin of 2.5%) after breast conserving surgery (BCS). 2,232 women 48-75 years of age, with invasive ductal breast cancer undergoing BCS were randomly assigned to receive either a standard regimen of 25-25 fractions (40-56 Gy) EBRT or a single fraction low energy IORT. Randomization was performed either before surgery (pre-pathology entry) or after surgery (post-pathology entry). In the latter group IORT was given after surgery by reopening the wound. 15% of the patients in the IORT group received additional EBRT (the trial protocol allowed recipients of IORT to receive additional EBRT based on unfavorable features found in the pathology [risk adapted policy]). The primary outcome of the trial was pathologically confirmed ipsilateral breast tumor recurrence (IBTR). The initial results of the trial were published in 2010 when only less than one fifth of the participants were followed-up for at least 4 years (median 25 months for all subjects). These results showed that the IBTR rate was 1.2% in the IORT arm and 0.95% the EBRT arm ( $p=0.41$ ). More recent results were published in 2014 after the addition of 1,219 participants, and longer follow-up for the initial cohort. The estimated 5-year risk of local recurrence was 3.3% in the IORT group and 1.3% in the EBRT group ( $p=0.042$ ) (median follow-up was 29 months due to the short follow-up of the additional patients; only 18% of the patients had 5 years of follow-up). The results published in the first report indicate that rate of ipsilateral local recurrence in the IORT group IORT met the noninferiority margin of 2.5% (prespecified by the investigators) for the overall patient population, and for the pre-pathology subgroup, but not for the post-pathology group. However, the incidence of the local recurrence was significantly higher with IORT vs. EBRT. This higher rate was observed at a median follow-up of 29 months which is below the median time when local recurrences are expected, especially when 90% of the women had estrogen receptor positive tumors that tend to recur later. In addition, almost two thirds of the women received adjuvant hormonal therapy which delays recurrence in estrogen receptor positive cases (Silverstein 2014). The results also show that the women who received IORT alone had 3 times the recurrence rate vs. those who received IORT+EBRT (2.7 vs. 0.9%). The authors indicated that the difference was not statistically significant, but no p value was provided. The trial was multicenter, randomized, and controlled. However, it had several methodological limitations, mainly the inadequacy of follow-up duration needed to provide conclusive evidence on the noninferiority of IORT to EBRT. The prespecified non-inferiority margin of 2.5% required a 5-year follow-up for all patients, which was only fulfilled by 20% of the study cohort. Other limitations of the trial include the open-label design (due to the nature of the intervention), and the multiple amendments made to the protocol along the course of the study such as the addition of more participating countries, increasing the population size, changing the start and ending date of the trial, and changing the funding source. In addition, each center participating in the trial managed the EBRT group according to its institutional guidelines, and determined its own criteria for treating patients with IORT given alone or as a boost therapy. ELIOT trial (Veronesi, et al 2013), Evidence Table 2 This was a prospective single-center trial that randomized 1,305 women 48-75 year of age with clinically invasive T1-T2,  $\leq 2.5$  cm breast cancer suitable for breast conservative surgery (BCS), to undergo whole breast EBRT delivered over 6 weeks, or receive a single dose of electron beam IORT. The primary outcome of the trial was ipsilateral breast tumor recurrence (IBTR). The results of the analysis show that after a median follow-up of 5.8 years the IBTR fell within the pre-defined equivalence margin of 4.5%, but the rate was significantly higher in the IORT group (4.4% vs. 0.4% in the EBRT group,  $p<0.0001$ , NNH of 25). The significantly higher rates of IBTR in the IORT group were observed for both the true local recurrence in the index quadrant, and for new ipsilateral breast tumors in other quadrants. The author indicated that the difference may be attributable to the very low recurrence rates in the EBRT group because of the high experience and quality of management. Some investigators raised the question on whether the 4-cm applicator size used in the trial might have been too small to adequately treat microscopic disease that extended beyond the existed tumor. Axillary or other regional lymph node metastasis and locoregional tumor recurrence were also significantly higher in the IORT group (NNH=143 and 22 and respectively). There were no significant differences between the two study arms in the development of contralateral breast metastasis, distant metastasis, or in the 5-year overall survival rate. Subgroup analysis according to patients' risk based on tumor size, grade,

receptor status, and nodal positivity, showed that low risk women (69.4% of the study participants) had a 5-year IBTR rate of only 1.5% compared to 11.3% of those with one or more high-risk factors. A multivariate analysis showed that tumors size >2 cm, ≥4 positive lymph nodes, poorly differentiated tumors, and tumors with triple negative subtypes doubled the risk of IBTR. The rate of adverse skin effects (erythema, dryness and hyperpigmentation) was significantly higher in the EBRT group, and the rate of fat necrosis was significantly higher in the IORT group. There were no significant differences between the groups in mammary retraction, pain, or burning. Conclusion: The results of the two large published RCTs show that the rate of local recurrence with IORT was non-inferior (TARGIT-A trial) or equivalent (ELIOT trial) to EBRT. However, these results were based on margins prespecified by the investigators of the trials. The results of both TARGIT-A and ELIOT trials show that the risk of ipsilateral tumor recurrence was significantly higher with the IORT compared to EBRT. The published trials had relatively short follow-up duration and do not provide sufficient evidence to determine the long-term risk of delayed cancer recurrence inside or outside the index quadrant, as well as the long-term efficacy and safety of the therapy. There was significant heterogeneity between the published studies as regards to the study design, patients' ages, tumor size, threshold values, radiation sources and techniques used for delivering the IORT, as well as the follow-up duration. Multivariate analysis of the ELIOT trial results showed that the risk of ipsilateral local recurrence in women receiving IORT was almost double in patients with tumors size >2 cm, ≥4 positive lymph nodes, poorly differentiated tumors, or with triple negative subtypes.

**Articles:** The literature search revealed two large RCTs on IORT (TARGIT-A trial and ELIOT trial) as well as a systematic review and meta-analysis of published studies, and a large number of single institution cohort studies. The two large RCTs and the meta-analysis were selected for critical appraisal. Vaidya JS, Joseph DJ, Tobias JS, et al. Targeted intraoperative radiotherapy versus whole breast radiotherapy for breast cancer (TARGIT-A trial): an international, prospective, randomised, non-inferiority phase 3 trial. *Lancet*. 2010 Jul 10; 376 (9735):91-102. See [Evidence Table 1](#). Vaidya JS, Wenz F, Bulsara M, et al. Risk-adapted targeted intraoperative radiotherapy versus whole-breast radiotherapy for breast cancer: 5-year results for local control and overall survival from the TARGIT-A randomised trial. *Lancet*. 2014 Feb 15; 383 (9917):603-613. See [Evidence Table 1](#). Veronesi U, Orecchia R, Maisonneuve P, et al. Intraoperative radiotherapy versus external radiotherapy for early breast cancer (ELIOT): A randomized controlled equivalence trial. *Lancet Oncol*. 2013 Dec; 14 (13):1269-1277. <u>Intraperitoneal Hyperthermic Chemotherapy (IPHC) for the following indications:</u> Colon Cancer Ovarian Cancer Gastric Cancer Diffuse Malignant Peritoneal Mesothelioma (DMPM)	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
Intraperitoneal chemotherapy without hyperthermic methodology	Intraperitoneal chemotherapy without hyperthermic methodology is considered standard therapy and is not subject for review and is covered.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

#### Colon Cancer

In the United States, approximately 108,070 patients are diagnosed with colon cancer (CRC) per year, and between 10-30% of these patients will develop peritoneal carcinomatosis (PC) at some point after their initial diagnosis. PC is characterized by intraperitoneal spread of tumor nodules in the peritoneum which may occur as a result of growth of the tumor and its invasion through the serosal lining of the bowel lumen, or as result of iatrogenic manipulation during surgical procedures. PC of colorectal origin has poor survival and is the second most frequent cause of death in patients with colorectal cancer (CRC), after metastatic liver disease. It has always been regarded as a terminal condition and was commonly treated only with palliative therapies (Franko 2012, Macri 2010, Ripley 2010, Chua 2012).

Over the last two decades, significant advances made in the field of cytotoxic chemotherapy and biological agents have changed the treatment of PC from a palliative to a potentially curative approach. Modern chemotherapeutic

regimens have increased the response rate and median survival of patients with PC. However, few patients experience long-term survival with chemotherapy alone. In the 1980s a multimodal technique was developed to manage PC based on cytoreduction of the primary tumor, peritonectomy, and hyperthermic antineoplastic peritoneal perfusion (HIPEC). Theoretically cytoreductive surgery (CRS) treats the macroscopic residual disease and intraperitoneal (IP) chemotherapy treats the microscopic residual disease. IP chemotherapy is based on the principle that a high concentration of chemotherapy within the abdominal cavity will kill the tumor cells on the surface with less diffusion into the tissues and thus are less toxic. Hyperthermia with IP chemotherapy optimizes the process as heat has direct cytotoxic effects on cancer cells and increases the cytotoxicity and penetration of certain cytotoxic drugs (Verwaal 2008, Macri 2010, Ripley 2010, Vaira 2010, Glehen 2010, Mizumoto 2012, Chua 2012, Miceli 2012).

HIPEC is achieved by the intraperitoneal administration of a large volume of chemotherapeutic agents in a carrier solution through an open or closed technique. It involves the placement of one inflow and three outflow catheters in the abdominal cavity after the cytoreduction surgery. The cytotoxic agent is applied through the inflow drainage using a roller pump and heat exchanger in a closed system that allows perfusion circulation. The intraperitoneal temperature should reach 41-42°C and is monitored by two sensors placed in the inflow catheter and in the Douglas pouch. At the end of the procedure the solution is drained and the abdominal wall is closed. There is no standardized procedure for HIPEC and there are variations between the centers in the combinations and/or concentrations for the cytotoxic agents used, as well as the intraabdominal temperature and duration of the treatment which ranges from 30 minutes to 2 hours depending on the protocol of the drug used. The combination therapy of cytoreductive surgery and HIPEC is complex, has a steep learning curve, and is associated with significant morbidity and mortality. Preoperative selection of patients to achieve complete cytoreduction plays a crucial role for the success of therapy regarding the clinical and oncological outcomes as well as the patient quality of life (Glockzin 2009, Mizumoto 2012).

There is controversy around the use of cytoreduction therapy and HIPEC for peritoneal surface disease from CRC, and the procedure is not widely accepted despite the Consensus Statement (issued by representatives from the major Peritoneal Surface Malignancy Centers from around the world) on the role of cytoreductive surgery and HIPEC in the management of peritoneal surface malignancies of colonic origin (Esquivel 2007).

### **Ovarian Cancer**

Ovarian cancer is the fifth leading cause of death in women in the US and the most common cause of death from gynecological cancer in the Western World. It was estimated that around 22,280 women will be diagnosed with ovarian cancer and that 15,500 women will die of the disease in the US in 2012. Approximately two thirds of the women are diagnosed at an advanced stage due to the nonspecific nature of the presenting symptoms of ovarian cancer and its high tendency for early peritoneal spread. Peritoneal carcinomatosis occurs through exfoliation of malignant cells into the peritoneal fluid and their dissemination along the abdominal and pelvic peritoneum. Traditionally these patients with extensive peritoneal carcinomatosis were often labeled as having terminal disease and were only given palliative therapy with no curative intent (Chua 2009, Spiliotis 2011, Chan 2012, de Bree E 2012, Mulier 2012, Siegal 2012, Tentes 2012).

The standard therapy for patients with ovarian cancer is maximal cytoreductive surgery (CRS) followed by systemic chemotherapy with a platinum based agent and a taxane combination. Ovarian cancer is one of the most chemosensitive tumors, and its response to this initial therapy is high, but the disease often recurs, mostly locoregionally, involving the peritoneum and adjacent intra-abdominal organs. The sensitivity of epithelial ovarian cancer to chemotherapy and its tendency to remain confined to the peritoneal cavity through much of its natural history, have led the researchers to investigate regional treatment such as intraperitoneal (IP) administration of chemotherapy (IPC). The theoretical benefits include the achievement of a high drug concentration in the peritoneal cavity without the toxic effects of the systemic chemotherapy. IP chemotherapy has been investigated in clinical trials including the Gynecologic Oncology Group (GOG-172) phase III trial that showed approximately 16 months improvement in the median survival of women treated with a combination intravenous (IV) and IP chemotherapy compared to those treated with IV chemotherapy alone, but on the expense of the increased risk of toxicity and catheter-related complications. Based on the results of this as well as other trials, the National Cancer Institute (NCI) issued a clinical announcement in 2006 recommending that women with optimally debulked stage III ovarian cancer and their physicians consider a combination of intravenous (IV) and intraperitoneal chemotherapy (IPC). IPC has limited tissue penetration and may be indicated only following optimal resection of peritoneal disease when there is either no or very small macroscopic disease remaining (<1.0 cm). The use of IPC however, is controversial and is not widely accepted by the medical community as a standard treatment in the management of advanced epithelial ovarian cancer, due to its high toxicity, catheter-related complications, and negative impact on the patients' quality of life (Almadrones 2007, Trimble 2008, Runowicz 2008, Lim 2009, Spiliotis 2011, Tentes 2012, Chan 2012, de Bree 2012).

In the last two decades researchers investigated the synergistic effect of combining regional hyperthermia and intraperitoneal chemotherapy (hyperthermic IPC, or HIPEC) together with the CRS. Theoretically, in addition its tumoricidal effect, hyperthermia increases the permeability of the drug to the tumor cells (up to 5-6 mm compared to 2-3 mm of the conventional IPC). Hyperthermia may also alter the cellular metabolism, and cellular drug pharmacogenetics. A potential advantage of administering HIPEC intraoperatively is providing superior and homogenous exposure of the seroperitoneal surface to the drug and heat before the development of adhesions. The disadvantage of HIPEC compared to IPC is the shorter tumor exposure time and its administration only once during the surgery or at the most twice when a secondary surgery is performed (de Bree 2012).

### **Other primary peritoneal malignancies or secondary dissemination from gastrointestinal tract or other pelvic organs.**

Primary peritoneal malignancies such as peritoneal mesothelioma or papillary serous carcinoma are rare, but peritoneal dissemination from gastrointestinal tract and ovarian carcinomas are common. In the past these carcinomas were regarded as terminal and the patients were only treated with palliative measures. Over the last 30 years however, novel more aggressive treatment strategies that combine cytoreductive surgery with intraperitoneal (IP) chemotherapy were explored. Hyperthermic intraperitoneal chemotherapy (HIPEC) and early postoperative IP chemotherapy emerged as the most commonly used IP adjuvant therapies. Theoretically cytoreductive therapy treats the macroscopic disease, and intraperitoneal chemotherapy (IP) treats the microscopic disease and the residual or free tumor cells left in the peritoneal cavity after surgery, in order to prevent and control peritoneal dissemination. IP chemotherapy is based on the principle that a high concentration of chemotherapy within the abdominal cavity will kill the tumor cells on the surface with less diffusion into the tissues and less toxicity. Hyperthermia with IP chemotherapy optimizes the process as heat has direct cytotoxic effects on cancer cells and increases the cytotoxicity and penetration of certain cytotoxic drugs. Hyperthermia is also believed to modulate the cells of the innate and adaptive immune system, thereby improving effectiveness (Shen 2009, Glehen 2010, Mizumoto 2012, Sun 2012, MI 2013).

### ***Intraperitoneal Hyperthermic Chemotherapy (IPHC)***

#### **04/02/2007: MTAC REVIEW**

**Evidence Conclusion:** *Prevention of peritoneal carcinomatosis* Two randomized controlled trials from Japan, conducted among patients who underwent surgery for T2-T4 gastric carcinoma with serosal involvement, found a significant benefit from including HIPEC treatment. The study with the stronger methodology (Yonemura et al., 2001) found a higher estimated 5-year survival in the group receiving cytoreduction and HIPEC (61%), compared to two other groups (cytoreduction and normothermic intraperitoneal chemotherapy, 44%; and surgery alone 42%). The other RCT (Fujimoto et al., 1999) had poorly described methodology, and also found a significantly higher estimated survival rate in a group receiving cytoreduction plus HIPEC compared to surgery alone. The first study had a minimum of 2.4 years of follow-up; length of follow-up was not reported in the Fujimoto study. Findings from studies on Japanese gastric cancer may not be generalizable to the United States. *Treatment of peritoneal carcinomatosis* There is evidence from one reasonably valid randomized controlled trial that HIPEC is beneficial as a treatment for peritoneal carcinomatosis (Verwaal et al., 2003). The study, which included 105 patients with histologically proven peritoneal metastases of colorectal adenocarcinoma, compared an experimental treatment (cytoreduction and HIPEC, plus adjuvant chemotherapy) to standard treatment (outpatient chemotherapy, surgery only if necessary). After a median follow-up of 22 months, the survival rate was significantly higher in the experimental treatment group (56% vs. 39%). Sub-group analyses suggest that survival was lower in patients with extensive residual disease or involvement of more than 5 regions of the abdominal cavity. A case series by the same research group found an estimated one-year survival of 75% and three-year survival of 28% with the experimental treatment. There were no long-term survival data for the standard treatment group. The evidence base would be strengthened with additional comparative studies.

**Articles:** *Prevention of peritoneal carcinomatosis* Three RCTs were identified: all were conducted by Japanese investigators. The two trials with the larger sample sizes (n=139 and n=141) were critically appraised. The third study was smaller (n=82) and had limitations including a non-significant finding with no discussion of statistical power. *Citations for the reviewed studies are as follows:* Yonemura Y, deAretxabala X, Fukimura T et al. Intraoperative chemohyperthermic peritoneal perfusion as an adjuvant to gastric cancer: Final results of a randomized controlled study. *Hepato-Gastroenterology* 2001; 48: 1776-1782. See [Evidence Table](#). Fujimoto S, Takahashi M, Mutou T et al. Successful intraperitoneal hyperthermic chemoperfusion for the prevention of postoperative peritoneal recurrence in patients with advanced gastric carcinoma. *Cancer* 1999; 85: 529-534. See [Evidence Table](#). *Treatment of peritoneal carcinomatosis:*

One RCT from the Netherlands was identified and critically appraised (Verwaal et al., 2003). There have also been a number of case series, most had sample sizes under 100. The largest case series was a multicenter study

by Glehen et al., 2004 and included 506 patients. This study was limited in that it combined data from different centers that had different protocols and patient populations. All of the centers used perioperative intraperitoneal chemotherapy, but it appears that not all used hyperthermic treatment. As a result, the Glehen article was excluded from further review. The next largest case series available in English was by Verwaal et al., 2005. This article reported long-term follow-up on 117 patients, 48 of whom were included in the 2003 RCT, and was critically appraised. *The two studies reviewed were as follows:* Verwaal VJ, van Ruth S, de Bree E et al. Randomized trial of cytoreduction and hyperthermic intraperitoneal chemotherapy versus systemic chemotherapy and palliative surgery in patients with peritoneal carcinomatosis of colorectal cancer. *J Clin Oncol* 2003; 21: 3737-3743. See [Evidence Table](#). Verwaal VJ, van Ruth S, Witkamp A et al. Long-term survival of peritoneal carcinomatosis of colorectal origin. *Ann Surg Oncol* 2005; 12: 65-71. See [Evidence Table](#)

The use of intraperitoneal hyperthermic chemotherapy (IPHC) in the treatment of peritoneal carcinomatosis does not meet the *Group Health Medical Technology Assessment Criteria*.

### ***Intraperitoneal Hyperthermic Chemotherapy (IPHC)***

#### **10/16/2012: MTAC REVIEW**

**Evidence Conclusion:** Verwaal and colleagues (2003, 2008) conducted a randomized controlled trial in one center in the Netherlands to compare the efficacy of cytoreductive surgery (CRS) and HIPEC versus systemic chemotherapy and surgery in the management of peritoneal carcinomatosis of colorectal origin. The study randomized 105 patients younger than 71 years of age, with peritoneal metastases of CRC to undergo CRS in combination with hyperthermic intraperitoneal therapy (HIPEC) or systemic chemotherapy and surgery. The authors published the results after a median of 21.6 months, and later after an extended follow-up of 91 month. The initial results of the trial showed a significantly higher median survival of the patients treated with CRS and HIPEC vs. standard therapy (22.3 months and 12.6 months respectively). After 8-years of follow-up, 9 patients were still alive. This long-term follow-up showed a median progression-free survival of 12.6 months in the CRS and HIPEC group and 7.7 months in the standard therapy group. Subgroup analyses of the results showed that patients with 6-7 regions had a very poor survival (median 5.4 months) compared to those with 0-5 regions (median >29 months), and that survival was significantly higher with success of surgical procedure i.e. complete cytoreduction. The trial had generally valid methodology; it was randomized and controlled. However, it was conducted over a decade ago and significant progress in chemotherapy has been accomplished since then. The systemic therapy with 5-FU and leucovorin used in the control group is outdated, and mitomycin-C, the HIPEC drug used in the experimental group is not the most effective drug for used for CRC. In addition, the experimental group underwent both cytoreduction and HIPEC and it is difficult to determine whether the survival benefit was due to one of the two treatment modalities or their combination, and whether heating of the chemotherapy had an additive effect to the IP therapy.

**Articles:** The search revealed one meta-analysis, one randomized controlled trial with long-term follow-up, and a number of observational studies with or without comparison groups. The randomized trial was selected for critical appraisal. The meta-analysis pooled the results of that RCT together with a retrospective study and was not critically reviewed. Verwaal VJ, van Ruth S, de Bree E, et al Randomized trial of cytoreduction and hyperthermic intraperitoneal chemotherapy versus systemic chemotherapy and palliative surgery in patients with peritoneal carcinomatosis of colorectal cancer. *J Clin Oncol* 2003;21:3737-3743 See [Evidence Table](#). Verwaal VJ, Bruin S, Boot H, et al 8-year follow-up of randomized trial: cytoreduction and hyperthermic intraperitoneal chemotherapy versus systemic chemotherapy in patients with peritoneal carcinomatosis of colorectal cancer. *Ann Surg Oncol*.2008; 15:2426-2432 See [Evidence Table](#).

The use of intraperitoneal hyperthermic chemotherapy (IPHC) in the treatment of peritoneal carcinomatosis does not meet the *Group Health Medical Technology Assessment Criteria*.

### ***Intraperitoneal Hyperthermic Chemotherapy (IPHC)***

#### **02/11/2013: MTAC REVIEW**

**Evidence Conclusion:** There is insufficient published evidence to determine the efficacy and safety of hyperthermic intraperitoneal chemotherapy for the treatment of patients with ovarian cancer whether as an initial therapy, consolidation therapy, or for the treatment of a persistent or recurrent disease. The published studies on HIPEC for ovarian cancer are all prospective or retrospective case series. The studies included heterogeneous groups of women of different ages, different disease characteristics, stages, and tumor load, previous use of systemic chemotherapy regimens, chemoresistance, and with different indications for HIPEC therapy (primary, consolidation, persistent, or recurrent disease after initial therapy). In addition, the published studies recruited patients over long periods of time, and used different HIPEC protocols and chemotherapeutic regimens some of which were outdated by the time the studies were completed and their results published. In a small observational study, Spiliotis and colleagues (2011, evidence table 1) compared survival benefit of HIPEC for ovarian cancer among two case series: one with 24 patients treated with CRS followed by HIPEC and systemic chemotherapy,

and the other with 24 were treated with CRS and systemic chemotherapy alone without HIPEC for various reasons not explained by the authors. The results of the study show that the median survival was significantly higher for those who received HIPEC vs. those who did not (19.4 months vs. 11.2 months). The 1-year and 3-year survival rates were also significantly higher among patients treated with HIPEC. Within each of the two groups survival outcomes were better among patients with less extensive peritoneal disease and more complete cytoreduction. Due to the study design, the potential selection bias and confounding, it is difficult to determine whether improved survival was due to HIPEC, successful cytoreduction, or other confounding factors. An earlier observational study (Gori et al, 2005) compared the outcomes of a second look surgery and HIPEC (4-8 weeks after standard CRS and systemic chemotherapy) in 29 patients, to the outcomes for 19 patients who refused the second look and HIPEC. All patients had stage III ovarian cancer and had undergone a primary complete or optimal cytoreductive surgery (residual lesion <2cm) and 6 cycles of systemic chemotherapy. After a median follow-up of 73 months (range 24-134 months) the results showed a higher but statistically insignificant median survival patients treated with HIPEC vs. those who refused to undergo the treatment. The results of a larger retrospective case series with a historical comparison group (Ryu et al 2004, evidence table 2) show that HIPEC may be associated with better disease response and survival in patients with ovarian cancer. However, these results must be interpreted cautiously due to the limitations of the study including but not limited to potential selection bias, confounding, and other inherent limitations of case series and the use of retrospective data.

**Conclusion:** Overall the results of the published observational studies suggest, but do not provide sufficient evidence to conclude, that HIPEC is feasible and may improve survival in women with advanced ovarian cancer. Due to the inherent limitations of the observational studies, it is hard to ascertain the extent at which the reported survival benefit resulted from selection bias, and whether it was due to the intraoperative intraperitoneal therapy, the hyperthermia, the aggressive cytoreduction therapy, the systemic chemotherapy regimes used, or other confounding factors. It is also difficult to determine whether complications occurring after major cytoreduction surgery and HIPEC were due to the surgery itself or the HIPEC. Only well conducted, adequately powered, randomized controlled trials with long-term follow-up may determine the net clinical benefit of incorporating HIPEC in the management of patients with ovarian cancer. Currently, at least three randomized controlled trials are ongoing to investigate the efficacy and safety of adding HIPEC to primary or secondary cytoreductive surgery in women with stage III or relapsing ovarian cancer. Among these trials are the OVIHIPEC trial in the Netherlands, the CHIPOR trial in France, and the HORSE trial in Italy. Their results may answer many questions about the role of HIPEC in treating ovarian cancers, its indications, efficacy, morbidity, and net clinical benefits.

**Articles:** The literature search did not reveal any randomized controlled trial that compared the efficacy of HIPEC to standard therapy for treatment of women with ovarian cancer. The published studies were mainly prospective or retrospective observational studies. The search identified one retrospective review and three case series that compared the outcomes of patients undergoing HIPEC to those who refused to undergo the procedure or did not receive the HIPEC therapy for various other reasons.

Two case series that compared the outcomes of patients who received HIPEC to those of patients who did not were selected for critical appraisal. Spiliotis J, Vaxevanidou A, Sergouniotis F et al. The role of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy in the management of recurrent advanced ovarian cancer: a prospective study. *J Buon* 2011;16:74-75. See [Evidence Table](#). Ryu KS, Kim JH, et al. Effects of intraperitoneal hyperthermic chemotherapy in ovarian cancer. *Gynecol Oncol*. 2004; 94:325-332. See [Evidence Table](#).

The use of intraperitoneal hyperthermic chemotherapy (IPHC) in the treatment of ovarian cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### ***Intraperitoneal Hyperthermic Chemotherapy (IPHC)***

#### **08/19/2013: MTAC REVIEW**

**Evidence Conclusion:** The current review focuses on the safety and efficacy of HIPEC therapy for non-ovarian, non-colorectal cancers with serosal invasion or peritoneal carcinomatosis. Perioperative HIPEC in combination with cytoreductive surgery was evaluated in small, randomized controlled trials and a number of meta-analyses for patients with gastric cancer. The search did not identify any RCTs or large prospective studies that evaluated HIPEC for the treatment of peritoneal mesothelioma, pseudomyxoma peritonei, or for peritoneal carcinomatosis secondary to urinary bladder cancer, or uterine leiomyosarcoma. *HIPEC for Gastric cancer:* Mi DH and colleagues' meta-analysis (2013) pooled the results of 16 trials that examined the effectiveness and safety of radical surgery (RS) combined with HIPEC vs. RS without HIPEC in 1,906 patients with histologically diagnosed, primary, locally advanced gastric cancer with macroscopic serosal invasion, but with no peritoneal or distant metastases. The primary outcome of the analysis was overall survival. The pooled results indicate that compared with surgery alone, the combination of surgery with HIPEC was associated with a significant improvement in survival rate at 1,2,3,5 and 9 years. It was also associated with a significant reduction in recurrence rates at 2, 3, and 5 years. There was however, a significantly higher incidence of abdominal pain with HIPEC. The rates of other adverse events were too small to show a significant difference. Sun and colleagues' meta-analysis (2012) also examined the effectiveness and safety of gastrectomy combined with HIPEC versus gastrectomy alone in patients with

advanced gastric cancer with serosal invasion but without distant metastases or peritoneal carcinomatosis. The analysis included 10 trials with a total of 1,062 patients. The primary outcome was overall survival defined as the time from treatment to the last follow-up or death. Similar to MI et al's analysis, the pooled results indicate that surgery combined with HIPEC may improve the overall survival for patients and prevent peritoneal local recurrence. These pooled results do not show a significantly higher risk of complications associated with HIPEC, but again the numbers were too small to provide sufficient statistical power. The two meta-analyses had had generally valid methodology and analysis. However, they had only 5 trials in common despite almost similar literature search dates. The trials included were small, all were conducted in Asia, and many were performed in the late 1980s and early 1990s and the procedures used may be currently outdated. In addition, there was no standardized agent or dose used for HIPEC; different chemotherapeutic agents were used among the trials and at different doses. The most commonly used agents in the trials were mitomycin C and cisplatin given alone, in combination together, or in combination with other agents. A small phase III RCT (Yang et al, 2011) conducted in Japan, evaluated the efficacy and safety of cytoreductive surgery (CRS) in combination with hyperthermic intraperitoneal therapy (HIPEC using mitomycin C and cisplatin) for the treatment peritoneal carcinomatosis (PC) from gastric cancer. The study randomised 68 participants to receive CRS combined with open HIPEC or CRS alone. The primary outcome was overall survival. After a median follow-up of 32 months (range 7.5-83.5 months), the results showed that patients in the CRS and HIPEC had significantly better overall survival compared to those who underwent CRS with no HIPEC. The numbers of serious adverse events were higher in the HIPEC group but were too small to allow any conclusion. *HIPEC for diffuse malignant peritoneal mesothelioma (DMPM)*: Baratti and colleagues (2009) analyzed data from a prospective database for 70 patients with DMPM who were treated with cytoreduction surgery and HIPEC by the same surgical team from 1996 to 2008 at a cancer institute in Italy. Disease progression was the primary outcome of the study. This occurred among 38 (54.28%) of the participants after a median follow-up of 43 months. The median time to disease progression (TTP) among these patients was 9 months and the median survival from progression was 8 months. Failure pattern was categorized as peritoneal progression, which occurred among 31(81.58%) patients, liver metastasis in one patient, abdominal lymph node involvement in 2, and pleural seeding in 4 patients. Residual tumor  $\leq 2.2$  mm was the only independent risk factor for disease progression. Progressive disease was treated with second HIPEC in 3 patients, debulking in 4, systemic chemotherapy in 16, and supportive care in 15. A multivariate analysis showed that time to progression <9 months, poor performance status, and supportive care correlated to reduced survival from progression. These results should be interpreted with caution as the study was small, observational, conducted in a single center, and had no comparison or control group. *HIPEC for Pseudomyxoma peritonei (PMP)* In a retrospective study, Chua and colleagues (2012) reported on the outcome of nearly 2,300 patients from 16 institutions worldwide that were treated with cytoreductive surgery (CRS) and HIPEC over an 18-years period for pseudomyxoma peritonei (PMP) that arose from the appendix. The study was based on data from the Peritoneal Surface Oncology Group International registry. The median survival was 16.3 years, and the median progression-free survival was 8.2 years, with 10 year survival rate of 63% and a 15 year survival rate of 59%. The postoperative mortality rate after cytoreductive surgery and HIPEC was low (2%), but 24% of patients experienced major complications and 10% of patients required surgery for their complications. Data on quality of life were not provided. A multivariate analysis indicated that prior chemotherapy treatment, peritoneal mucinous carcinomatosis (PMCA) histopathological subtype, major postoperative complications, high peritoneal cancer index, and debulking surgery were independent predictors for a poorer progression-free survival. Use of HIPEC was associated with a favorable progression-free survival. Older age, major postoperative complications, debulking surgery, prior chemotherapy treatment, and PMCA histopathological subtype were independent predictors of a poorer overall survival. Elias and colleagues (2010) also conducted a retrospective analysis of data from a registry with 301 patients with PMP treated with CRS and HIPEC between 1993 and 2007 in 18 French speaking centers in Europe and Canada. The mean follow-up was 88 months, the 5-year and 10-year overall survival rates were 73% and 54.8% respectively. The 5-year disease-free survival was 56%. 4.4 % of the patients died postoperatively, 40% had a grade 3-4 complication. 17.5% of all patients required a re-operation due to complications. These results of these retrospective analyses should be interpreted with caution due to the methodological limitations of retrospective studies, and lack of control groups. Conclusion: There is some evidence from small RCTs conducted in Asia, and meta-analyses pooling their results that cytoreductive surgery combined with intraperitoneal hyperthermic chemotherapy may improve the overall survival in patients with advanced gastric cancer without macroscopic peritoneal carcinomatosis or distant metastases. There is insufficient evidence to determine the subgroup of patients with gastric cancer who would benefit most from HIPEC as the effectiveness of HIPEC may depend on size and depth of micrometastases. There is insufficient evidence to determine the optimal regimen for HIPEC. There is insufficient evidence to determine the efficacy of HIPEC in patients with peritoneal carcinomatosis from gastric cancer. There is insufficient evidence to determine the safety of HIPEC or its effect on the quality of life in patients with gastric cancer with or without dissemination to the peritoneum. There is insufficient evidence to determine the safety and efficacy of HIPEC for the treatment of other peritoneal malignancies, whether of a primary origin or peritoneal carcinomatosis secondary to cancer in other organs within the peritoneal cavity.

**Articles:** The literature search for studies on the efficacy and safety of HIPEC in patients with pseudomyxoma peritonei, GI cancers (other than colorectal cancer) identified two recent meta-analyses of RCTs, two older ones, and a phase III RCT on HIPEC for patients with gastric cancer. The search did not reveal any RCTs that evaluated HIPEC for primary peritoneal malignancies, or other peritoneal disseminations from other cancers evaluated in this review. The published studies were mainly small prospective or retrospective case series with no comparison or control groups. The two more recent meta-analyses and the RCT that evaluated the efficacy and safety of HIPEC for gastric carcinoma were selected for critical appraisal.

CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Islet Cell Transplantation in the Context of a Clinical Trial (260.3.1)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Some patients with Type I diabetes fail to obtain adequate glucose control despite insulin treatment. Pancreas allo-transplantation can restore metabolic control, but this procedure is limited by a shortage of donor organs and a complex surgical procedure with associated morbidity and mortality. Transplantation of pancreatic islet cells is a possible alternative treatment. The islet of Langerhans cells contain insulin-secreting *b* cells and make up only about 1% of the whole pancreas.

In the early 1970s, researchers found that islet cell transplantation could be used to treat diabetes in rats. Since that time, there have been attempts to apply this treatment to humans. Most of the applications of this procedure were unsuccessful; the Islet Transplant Registry estimated in 1996 that only 6 percent of islet transplantations done between 1990-1996 were successful (success defined as not needing insulin treatment for a year after transplantation).

#### Medical Technology Assessment Committee (MTAC)

##### Islet Cell Transplantation

###### 10/11/2001: MTAC REVIEW

**Evidence Conclusion:** To date, there has been one report of some success with islet cell transplantation in 7 patients; only 3 of these were followed-up for at least a year. The effectiveness of islet cell transplantation for type 1 diabetes cannot be determined based on the current published scientific evidence. A randomized controlled trial, which will provide higher-quality data, was recently initiated by the Juvenile Diabetes Foundation and the National Institutes of Health to study the effectiveness of islet cell transplantation.

**Articles:** The searches yielded 60 articles. These were predominantly review articles and articles on technical aspects of the procedure. There were no randomized controlled trials or meta-analyses. There were 3 empirical articles with clinical outcomes; all were case series studies with sample sizes less than n=10. An evidence table was done for the case series that used the most up-to-date techniques: Shapiro AMJ, Lakey JRT, Ryan EA, Korbitt GS, Toth E, Warnock GL, Kneteman NM, Rajotte RV. Islet cell transplantation in seven patients with type 1 diabetes mellitus using a glucocorticoid-free immunosuppressive regimen. NEJM 2000; 343: 230-8. See [Evidence Table](#).

The use of Islet Cell Transplantation in the treatment of diabetes does not meet the *Group Health Medical Technology Assessment Criteria*.

CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None - Carrier discretion.

##### For Non-Medicare Members

Jaw motion rehabilitation system is medically necessary to treat mandibular hypomobility when caused by radiation therapy in persons with head and neck cancer.

It is **not medically necessary** for any other indication as there is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Trismus, defined as a tonic spasm of the muscles of mastication from diseases of the trigeminal nerve, is often used to describe mandibular hypomotility of any cause. Mandibular hypomotility is a common symptom in patients suffering from temporomandibular disorders as well as variety pathologies of the masticatory system. It may be related to intra- or extra-articular conditions such as synovitis, osteoarthritis, fibrosis, facial space infections, coronoid hyperplasia, fibrosis following radiation therapy, and tumors involving the head and neck regions. Patients with mandibular hypomotility experience limitations during eating, speaking, and with oral hygiene (Israel 1997, Cohen 2005, Melchers 2009).

The temporomandibular joint (TMJ) is a synovial joint that functions according to the same biological rules as other synovial joints and follows the same principles of joint motion and rehabilitation. Several manual, mechanical, and electromechanical approaches have been used for TMJ mobilization and increasing mouth opening. The most common methods used are isometric and range of motion exercises, tongue depressor therapy, and mechanical stretching devices (Israel 1997).

The Therabite System (Therabite Corporation, Bryn Mawr, PA) is a handheld patient controlled, mechanical device with two mouthpieces that are inserted between the teeth of the upper and lower jaw. By squeezing the handles, the mouthpieces open and assist the opening of the mouth. The horse shoe-shaped surfaces on the arms come in contact with the teeth and spread the load across 10 anterior teeth in each jaw. This generates less force on the incisors than spatulas or screws and makes the Therabite appliance more comfortable to use. The force applied by squeezing and releasing the handle stretches the fibrosis intermittently. Maximum device opening can be adjusted between 25 and 45 mm using a single screw and can be sequentially increased by the patient or clinician. Similar to other exercise regimens and physiotherapy, the patient must be motivated and must use the device correctly and regularly. Adherence to exercise regimens has a positive effect on outcome, and poor adherence may be a barrier to treatment success (Buchbinder 1993, Gibbons 2007, Melchers 2009).

#### Medical Technology Assessment Committee (MTAC)

**Jaw Motion Rehabilitation Device**

**04/16/2012: MTAC REVIEW**

**Evidence Conclusion:** In a relatively small unblinded, randomized, controlled trial, Maloney and colleagues (2002) compared the effectiveness of a passive jaw motion device (Therabite) and wooden tongue depressors (WTD) in patients with temporomandibular joint and muscle disorders that did not respond to manual manipulation and bite plane therapy. The authors did not discuss the cause of mouth opening restriction. After undergoing manual manipulation of the mandible combined with flat bite plane therapy for 4 weeks, eligible patients were randomly assigned to one of three treatment groups: Therabite group, wooden tongue depressor group, or control group. Patients in the first 2 intervention groups received treatment for 4 weeks, and the control group received a total of 8 weeks of flat bite plane therapy only. The authors did not discuss compliance with therapy or completeness of follow-up. The results of the trial show that passive jaw motion therapy using Therabite was more effective than using wooden tongue depressor in reducing pain, and increasing the maximum interincisal opening. In a smaller RCT, Buchbinder and colleagues (1993) compared the use of Therabite system plus unassisted exercise vs. tongue blade therapy plus unassisted exercise, or unassisted exercise only for 10 weeks in 21 patients with decreased interincisal opening secondary to radiation therapy after head and neck cancer resection. The initial average maximum interincisal opening (MO) was 21.6 mm. All three groups showed an initial increase in the MO in the first 4 weeks, after which there was only minimal further gain in the unassisted exercise group with or without tongue blade therapy. After 6 weeks of treatment, the net increase in MO in the Therabite group was significantly greater than either of the other 2 groups. In conclusion, evidence from two small RCTs suggest that passive jaw motion rehabilitation using Therabite device may be more effective than unassisted exercise, manual manipulation, and bite plane therapy with or without tongue blade therapy in reducing pain, and improving maximum interincisal opening in patients with mandibular hypomobility.

**Articles:** The literature on the use jaw motion rehabilitation devices for patients with mandibular hypomotility is limited. Only two small RCTs comparing TheraBite to other treatment were identified and critically appraised, Maloney GE, Mehta N, Forgiione AG, et al. Effect of a passive jaw motion device on pain and range of motion in TMD patients not responding to flat plane intraoral appliances. Cranio. 2002;20:55-66. See [Evidence Table](#). Buchbinder D, Currivan RB, Kaplan AJ, et al. Mobilization regimens for the prevention of jaw hypomobility in the radiated patient: a comparison of three techniques. J Oral Maxillofac Surg. 1993;51:863-867.

The use of jaw motion rehabilitation device for mandibular hypomobility does not meet the *Group Health Medical Technology Assessment Criteria*.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Kidney transplant is a surgical procedure to implant a healthy kidney into a patient with kidney disease or kidney failure. The kidney transplant may be taken from a living donor or from a recently deceased donor.

The transplant is conducted when the patient has non-reversible, end stage renal failure with a glomerular filtration rate 20 mL/min/1.73m<sup>2</sup> (0.33 mL/sec/1.73m<sup>2</sup>) or less. There are several causes for renal failure but the most common cause is diabetes or hypertension.

##### For Non-Medicare Members

Group Health has elected to use the Renal Transplant (S-1015) MCG\* for medical necessity determinations.

**\*MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Copy of final summary report from multidisciplinary transplant team

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

This service is covered when it is medically necessary and identified as a benefit in the consumer's coverage contract. The Group Health Nephrologists in collaboration with the GHC Transplant Committee and the Transplant Centers define the Group Health patient selection criteria.

#### Evidence and Source Documents

*Group Health Committee on Emerging Technology*

Transplant, simultaneous Pancreas/Kidney (SPK) - 7/11/1990

Simultaneous pancreas/kidney transplantation is approved for diabetic patients who otherwise would be candidates for a kidney transplant, subject to review in six months.

The University of Washington transplant criteria set are used as a source document and updated when new efficacy data becomes available by the GHC Nephrology section with approval by the GHC Transplant Committee.

## Clinical Review Criteria

### Kyphoplasty

#### [See separate criteria for vertebroplasty.](#)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

See [LCD for Percutaneous Vertebral Augmentation \(L34106\)](#).

#### For Non-Medicare Members

- I. Percutaneous balloon kyphoplasty may be considered medically necessary for the treatment of no more than 3 symptomatic vertebral fractures of the T5-L5 spine when **ALL of the following criteria are met:**
  - A. Appropriate imaging (plain film x-ray or MRI) has been performed preoperatively and the findings of such imaging correlate unequivocally with the patient's pain; **and**
  - B. There is documentation in the medical record that the member's pain is predominantly, if not solely, related to the demonstrated fracture(s); **and**
  - C. The member has failed to respond to conservative treatment (e.g., analgesics, physical therapy, rest) for at least 6 weeks; **and**
  - D. Prior to the procedure a documented assessment confirms the absence of the following contraindications:
    1. Chronic (>12 months) fracture at the same vertebral level
    2. Untreated symptomatic foraminal or canal stenosis, facet arthropathy, or other significant coexistent spinal or bony pain generators
    3. Bone fragment retropulsion
    4. Symptoms that cannot be related to a fracture
    5. Unstable fracture or requirement for stabilization procedure in same or adjacent spinal region
    6. Active osteomyelitis whether fungal, bacterial or mycobacterial, or any other active infection, including urinary tract infection (UTI)
    7. Uncorrected coagulation disorders
    8. Known allergy to any of the materials used in these procedures
- II. Percutaneous kyphoplasty with a balloon device is not covered for all other indications, including but not limited to the following:
  - A. Acute vertebral fractures due to osteoporosis or trauma (before 6 weeks of conservative therapy as noted above)
  - B. Vertebrae of the cervical spine and thoracic levels T1-5
  - C. Stabilization of insufficiency fractures or lesions of the sacrum (sacroplasty) or coccyx (coccygeoplasty)
  - D. Prophylactic treatment for osteoporosis of the spine or for chronic back pain of long-standing duration, even if associated with old compression fracture(s).
  - E. Absence of a confirmed acute or subacute fracture
  - F. Symptoms that cannot be related to a fracture;
  - G. Radicular symptoms that are explained by bone impinging on nerves or another anatomic lesion;
  - H. Unstable fracture;
  - I. Asymptomatic vertebral compression fracture;
  - J. Active osteomyelitis, whether fungal, bacterial or mycobacterial;
  - K. Burst fracture with retropulsed fragments demonstrated by imaging study;
  - L. Uncorrected coagulation disorders; and
  - M. Known allergy to any of the materials used in either procedure
  - N. Compression fractures shown by the medical record to be more than one year old.
- III. Percutaneous vertebral augmentation by any technique other than inflatable balloon is not covered which includes but not limited to the following:

- A. Vertebroplasty – [See separate criteria for vertebroplasty](#)
- B. Radiofrequency-assisted vertebral augmentation with ultrahigh viscosity cement, including but not limited to Radiofrequency-Targeted Vertebral Augmentation™ (RF-TVA™) with the StabiliT® System – [See separate criteria for Radiofrequency Ablation for Vertebral Augmentation](#)
- C. Mechanical vertebral augmentation using any device other than a balloon device, including but not limited to use of the following:
  - 1. Use of the Kiva® system

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Vertebral compression fractures (VCFs) occur when the bones of the spine become compressed and break. It is estimated that about five million new vertebral fractures occur worldwide each year. Most common in elderly populations and females, osteoporosis is responsible for more than 1.5 million fractures annually, the majority of which are vertebral. Other potential causes of VCFs include trauma, steroid use, malignancy in the vertebrae, and haemangioma. In any case, VCFs can be asymptomatic and resolve without treatment, however, they are frequently associated with pain, disability, and reduced quality of life (QoL). To add to this, VCFs are a risk factor for subsequent fractures which can lead to additional complications such as kyphosis, impairment of mobility or balance, and increased mortality to name a few (Chitale and Prasad 2013).

The majority of patients with VCFs are successfully treated with conservative management aimed to alleviate symptoms via external bracing, decreased activity and analgesics. Some patients, however, will experience persistent pain and symptoms refractory to medical therapy and may require additional intervention.

Over the last twenty years, two minimally invasive techniques to augment the vertebral bodies and reduce pain have been developed as a treatment option for refractory VCFs. The first technique, percutaneous vertebroplasty, was first introduced in France by Deramond and colleagues in 1984 and later, in 1993, was introduced into clinical practice in the United States (US). The procedure, initially performed to strengthen vertebrae weakened by angiomas, involved injection of polymethylmethacrylate (PMMA) into a collapsed vertebral body under fluoroscopic guidance (Deramond, Depriester et al. 1998). Since then, however, indications for vertebroplasty have expanded to include metastatic vertebral cancer, multiple myeloma, as well as, osteoporotic VCFs that have not responded to conservative therapy. The second procedure, kyphoplasty, was devised in 1998 after mounting concerns over flaws in the vertebroplasty technique. With the same aims and desired outcomes as vertebroplasty, kyphoplasty employs the use of inflatable balloon tamp to restore vertebral height and reduce kyphotic deformity before stabilization with PMMA. It is believed that the cavity formation and the use of more viscous cement introduced with less pressure, compared to vertebroplasty leads to lower risk of cement extravasation (Atalay, Caner et al. 2005; Wardlaw, Cummings et al. 2009).

## Medical Technology Assessment Committee (MTAC)

### 06/07/2001: MTAC REVIEW

#### Kyphoplasty

**Evidence Conclusion:** The published evidence consists of one poorly described case series that is insufficient to draw conclusions about the safety and efficacy of kyphoplasty.

**Articles:** The literature search yielded one published article. The article reported on a study using cadavers and does not have data appropriate for MTAC review. One other published article was received from Kyphon. This was largely a review article; it included one paragraph about the use of the kyphoplasty procedures. No details on study methodology were given so that this study also could not be evaluated. There is also one article documented to be in-press in Spine. An evidence table was created for this case series. Lieberman IH, Dudeney S, Reinhardt M-K, Bell G. Initial outcome and efficacy of “kyphoplasty” in the treatment of painful osteoporotic vertebral compression fractures. Spine 2001; in-press. See [Evidence Table](#).

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does not meet the *Group Health Medical Technology Assessment Criteria*.

### 07/14/2004: MTAC REVIEW

#### Kyphoplasty

**Evidence Conclusion:** The evidence is insufficient to draw conclusions about the safety and efficacy of kyphoplasty. It consists of two small (fewer than 30 patients) case series, one published in 2001 and one with the abstract published electronically in April 2004 ahead of the print version.

**Articles:** The search yielded 41 articles, most of which were discussion pieces and technical reports. The single new empirical study was an “electronic publication ahead of print” and was not yet available. An inspection of the abstract showed that this was a case series with 27 patients.

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **06/06/2005: MTAC REVIEW**

##### **Kyphoplasty**

**Evidence Conclusion:** There are no randomized controlled studies that compared the short and long-term outcomes of kyphoplasty with those of the more conservative standard therapies. The Grohs’ study compared kyphoplasty head to head with vertebroplasty however, it was small, nonrandomized and unblinded. Postoperative comparison was made versus baseline condition for each intervention with no direct comparison between the two techniques. The results of the study show that both procedures offered significant pain relief, which was maintained at a lower level with the kyphoplasty. The functional disability on the other hand was significantly improved only with kyphoplasty and not vertebroplasty. The observed improvement was statistically significant for the first year only. The results of the study also indicate that the rate of fracture of an adjacent vertebra seems to be higher with the kyphoplasty vs. vertebroplasty (21% vs. 4%). The other article reviewed was a case series with some advantages: it was relatively large, had inclusion/exclusion criteria, and had objective outcomes. However, like all case series it lacks a control or comparison group, and has potential selection and observation bias. Overall its results showed that the pain was completely relieved in 78% of the patients, and, that the vertebral height significantly improved after kyphoplasty. There were no long-term follow-up data to determine the long-lasting effects or late complications of the intervention. In conclusion, the published literature does not provide sufficient evidence to determine the effects of the procedure on the spine, or its long lasting effect on pain relief. A European multicenter prospective randomized controlled trial comparing kyphoplasty with the standard pharmacological therapy is underway (Ohlin 2004).

**Articles:** The search yielded 70 articles, most of which were review articles, discussion pieces and technical reports. There was no randomized controlled trial that compared the short and long-term outcomes with conservative therapies. The search revealed a recent nonrandomized study that compared kyphoplasty head-to-head with percutaneous vertebroplasty, as well as several small prospective case series, and retrospective reviews of cases that underwent the procedure. *The following controlled study, as well as the largest case series (N=222), were selected for critical appraisal:* Grohs JG, Matzner M, Trieb K, et al. Minimal invasive stabilization of osteoporotic vertebral fractures. A prospective nonrandomized comparison of vertebroplasty and balloon kyphoplasty. *J Spinal Disord Tech* 2005;18:238-242. See [Evidence Table](#). Majd ME, Farley S, and Holt RT. Preliminary outcomes and efficacy of the first 360 consecutive kyphoplasties for the treatment of painful osteoporotic vertebral compression fractures. *Spine J.* 2005;5:244-255. See [Evidence Table](#).

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **08/04/2008: MTAC REVIEW**

##### **Kyphoplasty**

**Evidence Conclusion:** The body of evidence on the safety and efficacy of balloon kyphoplasty (BKP) in the treatment of vertebral compression fractures consisted of multiple case series and few non-randomized studies that compared BKP to either vertebroplasty or the standard conservative therapy. Several authors pooled the results of these comparative and non-comparative series in a number of meta-analyses. However, the quality of meta-analyses and the strength of their conclusions depend on the quality of the included studies. The studies included in the published meta-analyses for BKP were too small, and had their methodological flaws and potential selection and observation bias. The comparative studies were non-randomized and the authors did not discuss how and why patients were selected for each of the procedures. There was evidence of publication bias as well as significant heterogeneity between the studies included in the meta-analyses. The studies differed their inclusion/exclusion criteria, outcome measures, scales used, and scoring systems, as well as duration and completeness of follow-up. Moreover the results were unblinded and many of the outcomes were subjective. The comparative studies published after the meta-analyses were also too small, non-randomized, unblinded, with relatively short follow-up duration, as well as other validity threats and do not allow making conclusions as regard the efficacy and safety of the procedure. In conclusion, the published literature does not provide sufficient evidence to determine the benefit of the procedure in relieving pain, improving function, and reducing rate of vertebral fractures. There is also insufficient evidence to determine its long lasting effect on pain relief or its adverse effects on the spine. Large well conducted randomized controlled trials, with long term follow-up duration are needed to objectively compare balloon kyphoplasty to conventional treatment and other percutaneous

techniques, and to determine its long-term safety and efficacy in improving function and reducing pain, disability, and complications associated with vertebral compression fractures.

**Articles:** The search yielded over 90 articles on balloon kyphoplasty. Many were reviews and technical reports. No randomized controlled trials that compared the procedure with vertebroplasty or conservative therapy were identified. There were four meta-analyses of non-randomized controlled studies and case series. All four included almost the same studies, and two were performed by the same group of authors. The search also revealed two non-randomized comparative studies published after the meta-analyses. One (N=21) compared kyphoplasty to vertebroplasty for the treatment of painful osteoporotic or traumatic VCFs, and the other (N=60) compared kyphoplasty with standard medical treatment of osteoporotic or traumatic VCF. The studies on the use of kyphoplasty for severe back pain due to metastatic disease were small case series with no control or comparison groups. The most recent meta-analysis and the two comparative studies were critically appraised. Taylor RS, Fritzell P, Taylor RJ. Balloon kyphoplasty in the management of vertebral compression fractures: an updated systematic review and meta-analysis. *Eur Spine J* 2007;16:1085-1100. See [Evidence Table](#). De Negri P, Tirri T, paternoster G, et al. Treatment of painful osteoporotic or traumatic vertebral compression fractures by percutaneous vertebral augmentation procedures. *Clin J Pain*. 2007;5:425-430. See [Evidence Table](#). Grafe IA, Fonseca KD, Hillmeier J, et al. Reduction of pain and fracture incidence after kyphoplasty: 1-year outcomes of a prospective controlled trial of patients with osteoporosis. *Osteoporos Int* 2005;16:2005-2012. See [Evidence Table](#).

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does not meet the *Group Health Medical Technology Assessment Criteria*.

## 12/07/2009: MTAC REVIEW

### Kyphoplasty

**Evidence Conclusion:** A recently published RCT (Wardlaw et al 2009) compared kyphoplasty plus standard medical therapy to medical therapy alone in 300 patients from 21 sites in eight countries. The trial was randomized and controlled, however kyphoplasty was not compared to a sham procedure or an alternative invasive or noninvasive surgical procedure. The medical therapy was not standardized and varied according to the standard practices of the participating centers, and neither the patients nor the investigators were blinded to the treatment received. Medtronic Spine LLC, the manufacturer of the kyphoplasty balloon technology was involved in the study design, data monitoring, analysis, and reporting of the results. The results of the trial shows that patients in the kyphoplasty group experienced greater reduction in pain and improved function at one month compared to the control group. The significant improvement observed at one month in the short form -36 physical component summary (SF-36 PCS) scale, the primary outcome the trial, declined along the following months and was statistically insignificant by the 12th months, when the controls showed improvement. The results also show a higher rate of vertebral fractures and/or worsening of fractures among the patients in the kyphoplasty group vs. the controls. The difference was not statistically significant, but the study was not powered to detect significant differences in fracture rates. The authors did not report on any cement leakage associated with kyphoplasty. In conclusion, the published literature does not provide sufficient evidence to determine that kyphoplasty is a safe and an appropriate procedure for relieving pain, improving function, reducing rate of vertebral fractures and disability in patients with vertebral compression fractures.

**Articles:** The search identified one recent randomized controlled trial (Wardlaw et al 2009) that compared balloon kyphoplasty with non-surgical care for vertebral compression fracture. No randomized controlled trials that compared the procedure with a sham treatment were identified. A relatively small RCT with only 6 months of follow-up compared the kyphoplasty to vertebroplasty in patients with osteoporotic vertebral fractures. Wardlaw et al's RCT was selected for critically appraised. Wardlaw D, Cummings SR, Van Meirhaeghe J. Efficacy and safety of balloon kyphoplasty compared with non-surgical care for vertebral compression fracture (FREE): a randomised controlled trial. *Lancet*. 2009;373:1016-24. See [Evidence Table](#).

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does meet the *Group Health Medical Technology Assessment Criteria*.

## 02/09/2015: MTAC REVIEW

### Kyphoplasty

**Evidence Conclusion:** *Effectiveness* In 2009, Wardlaw and colleagues reported results from an RCT comparing kyphoplasty to non-surgical management (NSM) in 300 patients from 21 sites in eight countries. The results of the trial indicate that patients in the kyphoplasty group experienced greater reduction in pain and improved function at one month compared to the control group. The significant improvement observed at one month in the short form-36 (SF-36) physical component summary (PCS) scale, the primary outcome the trial, declined along the following months and was statistically insignificant by 12 months. The kyphoplasty group also experienced statistically significant reductions in back pain and improvement in both back function and quality of life scales early on, however, this effect diminished over time (Wardlaw, Van Meirhaeghe et al. 2012). In 2010, Boonen and colleagues

expand on the results of the FREE-trial including an additional 12 months of follow-up. With the exception of pain and QoL, most criteria were no longer statistically significant at 24 months indicating that any benefit for both groups occurs within the first year. The investigators do note that averaged scores, across the 24 month period, did show significance when compared with NSM in physical symptoms, as assessed by the SF-36 PCS (3.24 points, 95% CI 1.47-5.01, p=0.0004), and on the QoL scale as assessed by the Euro quality-of-life questionnaire (EQ-5D) (0.12 points, 95% CI, 0.06 to 0.18, p=0.0002). The investigators concluded that, compared with NSM, kyphoplasty rapidly reduces pain and improves function, disability, and QoL over the course of two years (Boonen, Van Meirhaeghe et al. 2011). [Evidence Table 1]

**Safety** At 24 months, the investigators report that the overall frequency of patient with adverse events (AE) and serious adverse events (SAE) was similar between treatment groups. With that said, the investigators did report two serious adverse events, hematoma and urinary tract infection (UTI), that were considered to be related to the procedure. In addition, the investigators identified cement leakage in one patient who had undergone kyphoplasty. Finally, the kyphoplasty group had a higher rate of subsequent vertebral fractures when compared with the NSM group (47.5% vs. 44.1%; 3.4% difference, 95% CI -16.5 to 9.9, p=0.68), however, this difference was not statistically significant, and the study was not powered to detect significant differences in fracture rates. The FREE-trial has the advantage of being multi-centered, randomized and controlled. In addition, the analysis was based on intention-to-treat (ITT) and the study was adequately powered. Limitations of the study, however, include an inadequate comparator. Ideally, kyphoplasty should have been compared with a sham procedure or an alternative surgical procedure. Instead, the investigators compare the procedure to conservative management which, with 21 sites spanning eight different countries, was variable and not standardized. To add to this limitation, the differences in the treatment of the control and the intervention groups did not allow for blinding of both patients and the investigators opening the study up to selection and information bias. A further limitation of the study includes the investigators failure to stratify the data in analysis according to indication (osteoporosis vs. myeloma vs. metastasis) limiting the applicability of the results. Finally, it should be noted that the manufacturer of the kyphoplasty balloon technology, Medtronic Spine LLC, was involved in the study design, data monitoring, analysis, and reporting of results. For these reasons, the results of the study should be interpreted with caution and does not provide sufficient evidence to determine safety and effectiveness of kyphoplasty for treating VCF.

**Conclusions:** There is insufficient evidence to support the effectiveness of kyphoplasty over non-surgical management for the treatment of VCF caused by osteoporosis, myeloma or malignancy. There is insufficient evidence to support the safety of kyphoplasty for the treatment of VCF caused by osteoporosis, myeloma or malignancy.

**Articles:** The literature search sought to update the evidence from the end date of the last MTAC review. The search revealed a large quantity of publications including a variety of systematic reviews and retrospective observational studies. No RCTs were identified that compared kyphoplasty to sham treatment. The largest RCT to date, the fracture reduction evaluation (FREE), included 300 patients with 12 months follow-up and was critically appraised by MTAC in 2009 (Wardlaw, Van Meirhaeghe et al. 2012). Since then, Boonen and colleagues have published a follow-up analysis reporting the 24-month outcomes of the FREE trial. The following articles were selected for critical appraisal: Wardlaw D, Cummings SR, Van Meirhaeghe J, et al. Efficacy and safety of balloon kyphoplasty compared with non-surgical care for vertebral compression fracture (FREE): a randomized controlled trial. *Lancet*. 2009; 373(9668):1016-1024. [Evidence Table 1](#). Boonen S, Van Meirhaeghe J, Bastian L, et al. Balloon Kyphoplasty for the treatment of acute vertebral compression fractures: 2-year results from a randomized trial. *JBMR*. 2011; 26(7):1627-1637. [Evidence Table 1](#).

Kyphoplasty for the treatment of vertebral body compression fractures refractory to maximal medical management does meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Laser Treatments for Snoring and Sleep Apnea

- Cautery-Assisted Palatal Stiffening Operation (CAPSO)
- Laser-Assisted Uvulopalatoplasty (LAUP)
- Repose Procedure
- Somnoplasty

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Medical Necessity Review for these services is no longer required.

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe and/or provides better long term outcomes than current standard services/therapies. These treatments are found to be effective in the treatment of snoring; however, no Group Health or Group Health Options, Inc. plan covers interventions for the treatment of snoring.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Sleep-disordered breathing includes a spectrum of disorders ranging from primary snoring to obstructive sleep apnea (OSA). Obstructive Sleep Apnea Syndrome (OSAS) is defined as an apnea-hypopnea index of more than five events per hour, and often also have mental or physical effects such as excessive daytime sleepiness. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries and increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone.

Methods of treating OSA include weight loss, nasal continuous positive airway pressure (CPAP), surgical or laser resection of the uvula, tonsils or soft palate, or tracheostomy when all other treatments fail. Surgical treatment approach varies, and the results are affected by age, cause of obstruction, and severity of the disease. The best method of treatment remains controversial.

[Sleep Apnea – Repose Procedure](#)

[Somnoplasty for Treating Obstructive Sleep Apnea](#)

### Medical Technology Assessment Committee (MTAC)

#### ***Sleep Apnea – Cautery-Assisted Palatal Stiffening Operation (CAPSO)***

##### BACKGROUND

Obstructive sleep apnea has been treated with uvulopalatopharyngoplasty (UPPP), a surgical procedure on the soft palate using a scalpel. Cautery-assisted palatal stiffening operation (CAPSO) is a procedure that was first used to treat palatal snoring and is proposed as a new treatment for obstructive sleep apnea. With CAPSO, a midline strip of soft palate mucosa is removed and the wound is allowed to heal by secondary intention. This procedure stiffens the flaccid palate and causes a cessation of palatal snoring (Wassmuth, 2000). Other possible alternatives to UPPP are laser-assisted uvulopalatoplasty (LAUP) and somnoplasty (which uses radiofrequency

energy). Possible advantages of CAPSO, LAUP and somnoplasty compared to UPPP are that it is performed under local anesthetic and can be done as an outpatient procedure (Laube, 1999).

#### **08/08/2001: MTAC REVIEW**

##### **Cautery-Assisted Palatal Stiffening Operation (CAPSO)**

**Evidence Conclusion:** Only a single small case series is available to evaluate CAPSO for treating obstructive sleep apnea. This represents insufficient evidence to draw conclusions about the effect of CAPSO on health outcomes related to sleep apnea.

**Articles:** The search yielded 113 articles. Most of the articles were on uvulopalatopharyngoplasty or glossectomy. There were two empirical articles on CAPSO, both were case series. One of the case series (n=25) included patients with obstructive sleep apnea, while the other, report (n=206) included patients who complained of excessive habitual snoring, no attempt was made to diagnose sleep apnea. An evidence table was created for the case series with sleep apnea patients. Wassmuth Z, Mair E, Loube D, Leonard D. Cautery-assisted palatal stiffening operation for the treatment of obstructive sleep apnea syndrome. *Otolaryngol Head Neck Surg* 2000; 123: 55-60. See [Evidence Table](#).

The use of cauter-assisted palatal stiffening operation (CAPSO) in the treatment of sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

##### **Sleep Apnea: Repose Procedure**

###### **BACKGROUND**

The Repose system is one of several new treatments of obstructive sleep apnea (OSA). The Repose is a disposable surgical kit manufactured by Influence Medical Technologies, San Francisco. The kit contains: 1) a self-tapping screw with pre-attached double polypropylene No. 1 sutures; 2) a battery-operated screwdriver and; 3) a suture passer that aids passage of the suture through the tongue. The Repose procedure consists of anchoring the bone to soft-tissue to stabilize the base of the tongue (deRowe et al., 2000).

The Repose system is used under general anesthesia. A screw with pre-attached sutures is inserted at the base of the mandible. The sutures are passed through the tongue base; the two ends are tied together below the tongue mucosa and placed in the mouth floor that supports the tongue base. Tightness of the suspension is determined digitally.

#### **08/08/2001: MTAC REVIEW**

##### **Repose Procedure**

**Evidence Conclusion:** The existing scientific evidence does not permit conclusions about the efficacy of the Repose procedure on health outcomes. The best evidence is a case series of 16 individuals with data available on 14 of these. This report is subject to the limitations of case series (selection and observation bias likely).

**Articles:** The search yielded 113 articles. Most of the articles were on uvulopalatopharyngoplasty or glossectomy. There were three articles on the Repose procedure, one review/discussion piece and two small case series (n=9 and n=15). Because it was the best available evidence, an evidence table was created for the larger case series. DeRowe A, Gunther E, Fibbi A, Lehtimake K, Valatalo K., Maurer J, Ophir D. Tongue-based suspension with a soft tissue-to-bone anchor for obstructive sleep apnea: Preliminary clinical results of a new minimally invasive technique. *Otolaryngol Head Neck Surg* 2000; 122: 100-3. See [Evidence Table](#).

The use of repose procedure in the treatment of sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

##### **Somnoplasty for Treating Obstructive Sleep Apnea**

###### **BACKGROUND**

Sleep-disordered breathing includes a spectrum of disorders ranging from primary snoring to obstructive sleep apnea (OSA). Obstructive Sleep Apnea Syndrome (OSAS) is defined as an apnea-hypopnea index of more than five events per hour, and often also have mental or physical effects such as excessive daytime sleepiness. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries and increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone. Methods of treating OSA include weight loss, nasal continuous positive airway pressure (CPAP), surgical or laser resection of the uvula, tonsils or soft palate, or tracheostomy when all other treatments fail. Surgical treatment approach varies, and the results are affected by age, cause of obstruction, and severity of the disease. The best method of treatment remains controversial. Temperature-controlled radiofrequency tissue ablation (Somnoplasty) may be a less morbid alternative to other invasive surgical procedures. Somnoplasty is performed under local anesthesia in an outpatient setting. The commercially available device made by Gyrus Medical delivers 460 kHz using a radiofrequency generator. Radiofrequency energy is

delivered via 22-gauge electrodes with a 10-mm active tip. High-frequency alternating current flows into the tissue, creating ionic agitation. This agitation heats the tissue and, when the temperature rises above 47°C, protein coagulation and tissue necrosis take place. The target temperature is between 80°C and 85°C, with a maximum of less than 90°C. The maximum lesion size is two-thirds the diameter of the radiofrequency electrode, or approximately 7mm. During the three weeks following the procedure, there is inflammation, fibrosis and tissue volume reduction (Troell, 2003). The Gyrus Somnoplasty system was cleared by the FDA in 1998 for treating obstructive sleep apnea. Single-level radiofrequency ablation refers to creation of lesions in one area only (base of tongue, soft palate or turbinates). Multi-level radiofrequency ablation refers to its use in more than one area.

#### **04/14/1999: MTAC REVIEW**

##### **Somnus Somnoplasty System**

**Evidence Conclusion:** Evidence identification was conducted by searching MEDLINE from 1990 to February 1999 using the terms: somnoplasty, sleep apnea and radiofrequency. The Somnus Company was aware of only one published article related to the use of the Somnoplasty system for obstructive sleep apnea. This article (summarized below) reports data from a single case series of 22 patients treated for snoring, daytime sleepiness and mild obstructive sleep apnea. Results from this study show no changes in Respiratory Distress Index (RDI\*) following somnoplasty, statistically significant improvements in partner report of snoring and an improvement of 3.3 points (24 point scale) in self-report of sleepiness.

**Articles:** Powell, NB, et al *Chest*, 1998;113:1163-74. See [Evidence Table](#)

The use of the Somnus Somnoplasty System for the treatment of obstructive sleep apnea has been approved by the FDA and therefore meets *Group Health Medical Technology Assessment Criteria*.

#### **08/08/2001: MTAC REVIEW**

##### **Base of Tongue Somnoplasty in the Treatment of Sleep Apnea**

**Evidence Conclusion:** The evaluated study does not provide sufficient evidence to determine the efficacy of base of tongue somnoplasty, in the treatment of sleep apnea, due to its small sample size, together with the other limitations of case series.

**Articles:** The search yielded 113 articles. Most of the articles were on uvulopalatopharyngoplasty or glossectomy. There was a pilot study done for base of tongue somnoplasty on humans, and another study made on animals. *The best available article for critical appraisal was the pilot study:* Powell N B, Riley R W, et al. Radiofrequency Tongue Base Reduction In Sleep- Disordered Breathing: A Pilot Study. *Otolaryngol Head Neck Surg* 1999; 120: 656-64. See [Evidence Table](#).

The use of base of tongue somnoplasty in the treatment of sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **12/05/2005: MTAC REVIEW**

##### **Radiofrequency Tissue Ablation (Somnoplasty)**

**Evidence Conclusion:** *Efficacy of Multi-Level Base of Tongue and Soft Palate Procedure:* The best evidence is from a randomized controlled trial comparing radiofrequency ablation of the tongue and soft palate to CPAP and sham ablation (Woodson et al., 2003; Stewart et al., 2005). The three primary outcomes were slowest reaction time (SRT) and two quality of life (QOL) variables. There were no significant differences in the change in SRT in the radiofrequency ablation versus the placebo group, the CPAP group versus the placebo group or the radiofrequency ablation group vs. CPAP group. One of the two QOL variables improved significantly in the radiofrequency ablation group compared to placebo, but there was not a significant difference in QOL change in the radiofrequency ablation group versus the CPAP group. Among patients in the radiofrequency ablation group, those who had long-term follow-up had significant improvement in SRT, but not QOL compared to baseline. The 2005 publication did not report long-term findings for the CPAP or placebo groups.

*Efficacy of Single-Level Base of Tongue Procedure:* There were no randomized controlled trials. The best evidence is from a prospective non-randomized study comparing a group of patients who received base of tongue Somnoplasty and peri-operative use of CPAP to a group of patients receiving CPAP only (Woodson et al., 2001). There were no significant between-group differences in the change in subjective self-report outcomes (e.g. sleepiness, SF-36). Objective outcomes were only reported for the radiofrequency ablation group. In the group of 73 patients receiving radiofrequency ablation, the apnea-hypopnea index decreased significantly pre- to post-treatment. This study is subject to selection bias since patients were not randomized to treatment group; there was no between-group comparison for the objective outcomes. **Complications: Single and Multi-level:** Two single-center case series were reviewed; one included 136 patients and was conducted at Stanford University (Kerzirian et al., 2005) and the other included 322 patients and was conducted in Mannheim, Germany (Stuck et al., 2003). Both studies found relatively low complications rates. The Kerzirian study did not identify any moderate or severe

complications. The Stuck study found four moderate severity complications and one severe complication. Both of the studies included a combination of patients who received single-level and multi-level radiofrequency ablation, and both included patients who received treatment of the turbinates, as well as those with base of tongue or palate procedures. A limitation of both studies was that they were conducted at centers with extensive experience in somnoplasty and findings may not be generalizable to other institutions. **Overall Conclusions:** There is insufficient evidence on single level base of tongue somnoplasty to draw conclusions about the efficacy of the procedure compared to placebo or the standard treatment, CPAP. There were no RCTs on single level somnoplasty. One non-randomized comparative study did not find significant between-group differences on subjective outcomes. There is evidence from one RCT that multilevel (base of tongue and soft palate) does not improve outcomes compared to sham treatment or placebo. The RCT did not identify significant between-group differences in two of three primary outcomes including the objective outcome, slowest reaction time. Findings from case series suggest that there is a relatively low complication rate, at least in institutions with extensive experience with the technology.

**Articles:** One randomized controlled trial was identified in the literature search, a comparison of multilevel radiofrequency ablation, sham treatment, and CPAP. There were two publications on the RCT, initial outcomes (Woodson et al., 2003) and long-term follow-up of the active treatment group (Stewart et al., 2005). Both articles were critically appraised in the same evidence table. One other comparative study was identified and critically appraised. This was a non-randomized comparison of a patients receiving single-level base of tongue Somnoplasty and CPAP (Woodson et al., 2001). Several small case series (n<25) on the efficacy of Somnoplasty were identified, but not reviewed further. Two relatively large case series (n>100) on complications of Somnoplasty were identified; both were critically appraised (Kezirian et al., 2005; Stuck et al., 2003). *The articles critically appraised were:* Woodson BT, Steward DL, Weaver EM et al. A randomized trial of temperature-controlled radiofrequency, continuous positive airway pressure, and placebo for obstructive sleep apnea syndrome. Otolaryngol Head Neck Surg 2003; 128: 848-861. See [Evidence Table](#). Stewart DL, Weaver EM, Woodson BT. Multilevel temperature-controlled radiofrequency for obstructive sleep apnea: Extended follow-up. Otolaryngol Head Neck Surg 2005; 132: 630-635. Woodson BT, Nelson L, Mickelson S et al. A multi-institutional study of radiofrequency volumetric tissue reduction for OSAS. Otolaryngol Head Neck Surg 2001; 125: 303-311. See [Evidence Table](#). Kezirian EJ, Powell NB, Riley RW, Hester JE. Incidence of complications in radiofrequency treatment of the upper airway. Laryngoscope 2005; 115: 1298-1304. See [Evidence Table](#). Stuck BA, Starzak K, Verse T et al. Complications of temperature-controlled radiofrequency volumetric tissue reduction for sleep-disordered breathing. Acta Otolaryngol 2003; 123: 532-535. See [Evidence Table](#).

The use of Radiofrequency tissue ablation (somnoplasty) in the treatment of sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Peanut Challenge for Sensitized Infants

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

None

##### For Non-Medicare Members

- I. Infants, aged 4-11 months who have **ONE** of the following:
  - A. Siblings with peanut allergy OR
  - B. Previously diagnosed egg allergy OR
  - C. Significant eczema affecting more than 75% of skin

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Food allergy affects 1-3% of children in developing countries, and the prevalence of food allergy has increased dramatically in the past several decades. For many years scientists believed that delaying the introduction of allergenic foods into an infant's diet was beneficial, though more recent evidence has questioned this assumption. The "Learning Early About Peanut Allergy" (LEAP) Study, sponsored in part by FARE (Food Allergy Research And Education) and the National Institute of Allergy and Infectious Disease, hypothesized that the early introduction of peanuts into the diet of high risk infants may prevent peanut allergy. LEAP Study design: The LEAP study enrolled 640 "high risk" infants between age 4 months and 11 months. High risk was defined as having moderate to severe eczema (persistent rash affecting > 75% of skin) and/or egg allergy since children with these problems are more likely to develop peanut allergy. All of the infants were skin tested to peanut. Those who had a strongly positive skin test (> 4 mm welt from prick test) were not allowed to continue in the study because they were assumed to have peanut allergy. The rest of the infants were randomly assigned to either consume peanut at least 3 days a week until age 5 (equivalent of 6 tsp peanut butter per week) or to avoid peanuts until age 5. Importantly, all these high risk infants randomized to consume peanut underwent supervised oral challenge to peanut in the allergy clinic before feeding peanut at home.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The term 'seasonal affective disorder' (SAD) was first introduced by Rosenthal and colleagues in 1984 who described a series of patients with a history or recurrent depressions that occurred in the fall or winter and spontaneously remitted in the following spring or summer. Two seasonal patterns of SAD have been described; the summer-onset SAD and the fall-onset SAD. The latter, also known as "winter depression", is the most common pattern of the disorder. SAD affects about 5-6% of the population in the U.S. and its prevalence increases with latitude. This ranges from 1.4% in Florida to 9.7% in New Hampshire and 9.9% in Alaska. It is reported that SAD affects patients in their 20s, and that women are more likely than men to develop the disorder (Rohan 2013, Sanassi 2014).

SAD was previously classified as a mood disorder in which people with normal mental health throughout most of the year experience depressive symptoms in the winter or summer. The Diagnostic and Statistical Manual of Mental Disorders DSM-IV and DSM-5 no longer classifies SAD as a unique mood disorder, but describes it as a "specifier" or a subtype that can occur as part of unipolar major depression, bipolar I disorder, or bipolar II disorder. SAD is characterized by typical symptoms of major depression such as low mood, lack of drive, lack of concentration, and decrease in interest. In addition, patients exhibit more atypical depressive symptoms such as hypersomnia, increased appetite with carbohydrate craving, weight gain, irritability, and anger attacks. Symptoms usually resolve in the summer, and rarely progress to manic episodes of bipolar disorder (Pail 2011, Sanassi 2014).

The exact mechanism of SAD is still under investigation, but it is hypothesized that it is related to natural seasonal variations in light levels. According to this hypothesis "the phase shift hypothesis" fewer daylight hours in the winter causes a circadian misalignment between the biological clock and solar cycle leading to disturbances in the melatonin levels and longer periods of its synthesis at night. Melatonin, also called circadian hormone, peaks in the darkness and promotes sleep. It is believed that its increased daytime levels contribute to the depressive symptoms of SAD. Other neurotransmitters under circadian control e.g. serotonin, norepinephrine, and dopamine are also believed to have a role in the SAD mood alterations. However, no studies have established a causal relationship between decreasing daylight and the winter SAD (Sanassi 2014).

Three types of treatment are being used for patients with SAD: pharmacological therapy, cognitive behavioral therapy (CBT), and light therapy. Antidepressant medication is an accepted treatment for depression in general, and three SSRIs have shown favorable results with SAD. CBT may help reduce the risk of relapse of major depression, but only few small studies evaluated its effectiveness for SAD (Sanassi 2014).

Light therapy using light boxes was introduced as a treatment for SAD when the disorder was first described in 1984, based on the phase shift hypothesis. Early studies examined the effect of bright white light on circadian rhythm. Other research investigated less intense light and showed that it may have a larger capacity to regulate the biological clock than higher intensity light. A small study showed that blue light with an intensity of about 460 m may have a significant effect on melatonin suppression and circadian phase shifting (Shirani 2009, Meesters 2011, Sanassi 2014).

Currently there are a number of commercially available light therapy products. These include bright light boxes, lamps, light visors, and dawn simulators. Light boxes come in different shapes and sizes, and with varied features and intensities of light. There is no well-accepted standard protocol for light therapy. Commonly bright-light therapy (BLT) is applied using a light box containing fluorescent lamps, a reflector and a diffusing screen. For adequate treatment light intensities of 5,000-10,000 lux measured at the level of the eyes, and at a therapeutic distance of 60-80 cm from the light box is considered as a standard requirement. Patients do not need to look directly into the light source as long as the light meets the eye at an angle of 30-60°. Treatment is usually started with using a light intensity of 10,000 lux for 30 minutes. The duration of treatment may be increased in case of insufficient response or when using less powerful light boxes. It is reported that morning administration of BLT offers greater chance of remission, that compliance is the primary factor for success of the therapy, and that the therapeutic effect is demonstrated is 3-7 days, and disappears shortly after the treatment is discontinued (Pail 2011).

## Medical Technology Assessment Committee (MTAC)

### *Light Therapy in the Treatment of Seasonal Affective Disorder (SAD)*

06/02/2008: MTAC REVIEW

**Evidence Conclusion:** There is evidence from a meta-analysis of placebo-controlled RCTs (Golden et al., 2005) that bright light therapy and dawn simulation are both effective for treating SAD in non-geriatric adults. Strength of the meta-analysis was that the investigators used strict criteria to ensure that studies had a valid placebo control. Limitations are that studies tended to be small (all had <100 participants) and the minimum treatment duration was 4 days. Moreover, studies had different treatment protocols and thus conclusions cannot be drawn about the effectiveness of a particular approach to light therapy (e.g. lux, frequency of sessions, length of treatment). There is currently no generally accepted protocol for light therapy. When the two RCTs in the meta-analysis with the longest treatment durations and largest sample sizes were examined closely, bright light therapy did not clearly appear to be effective. Avery et al. (2001) did not find that bright light was significantly superior to placebo. Eastman et al. (2005) did not find a significant benefit to light therapy versus placebo for the outcomes change in SIGH-SAD score and response rate. They did find a significant benefit when examining the proportion of participants classified as near complete or complete responders. All of the studies on dawn simulation in the Golden et al. meta-analysis were conducted by the same research group. As the authors pointed out, the evidence would be strengthened if their findings could be replicated by different researchers in other locations. The largest study, Avery et al., (2001) found that dawn simulation was superior to both bright light and placebo for remission of SAD. The RCTs identified that compared light therapy to medication or cognitive-behavioral therapy did not have true placebo control groups and thus, intervention effectiveness beyond the placebo effect cannot be determined. The Rohan et al. 2007 study found a lower post-treatment SAD score in patients receiving light therapy, CBT or their combination compared to a wait-list control. However, being on a wait-list could have a 'reverse placebo effect' since patients are not expecting to improve before receiving treatment. The Lam et al. (2006) studies did not find significant differences in response rates in groups assigned to light therapy or fluoxetine treatment. Conclusion: A valid placebo group is important in RCTs of light therapy for SAD. A meta-analysis of placebo-controlled RCTs found a significant benefit of bright light and dawn simulation therapy. The meta-analysis was limited because studies tended to be small and of short duration. The largest RCTs in the meta-analysis did not find a significant benefit to bright light therapy. The evidence on dawn simulation is limited because all studies were done by the same research group and it is not known whether findings are generalizable. RCTs comparing light therapy to antidepressant treatment or psychotherapy did not include true placebo groups.

**Articles:** The ideal study would be a randomized controlled trial (RCT) or meta-analysis of RCTs that include a placebo or sham intervention. Studies comparing light therapy to medication therapy and/or psychotherapy should also have a placebo group. There was a protocol for a Cochrane review on light therapy for SAD. The protocol was published in 2003, and its status remains unchanged in Cochrane Library 2008, Issue 2. An estimated date for completion of the review is not available. One published meta-analysis was identified (Golden et al., 2005). The

Golden study searched the literature to July 2003, and included only placebo-controlled studies. Golden et al. and the two RCTs in the meta-analysis with the largest sample sizes per treatment group and the longest trial duration (Avery et al., 2001; Eastman et al., 1998) were critically appraised. No large placebo-controlled RCTs published after the Golden meta-analysis was identified. There was one newer RCT comparing light therapy to fluoxetine treatment (Lam et al., 2006) and another comparing light therapy to cognitive-behavioral therapy (Rohan et al. 2007). These two new RCTs were also critically appraised. References for studies reviewed are as follows: Golden RN, Gaynes BN, Ekstrom RD et al. The efficacy of light therapy in the treatment of mood disorders: A review and meta-analysis of the evidence. *Am J Psychiatry* 2005; 162: 656-662. See [Evidence Table](#). A randomized controlled trial of cognitive-behavioral therapy, light therapy and their combination for seasonal affective disorder. *J Consult Clin Psych* 2007; 75: 489-500. See [Evidence Table](#).

The use of light therapy in the treatment of Seasonal Affective Disorder (SAD) does not meet the *Group Health Medical Technology Assessment Criteria*.

## 12/21/2015: MTAC REVIEW

### Light Therapy for SAD

**Evidence Conclusion:** The ideal study for examining the effect of bright light therapy for SAD would be a double-blind randomized controlled trial that compares light therapy to a placebo or sham intervention. Studies comparing light therapy to pharmacological therapy or psychotherapy should also have a placebo group since there is limited evidence from placebo-controlled trials on the effectiveness of antidepressants or cognitive behavioral therapy on SAD. *Light therapy versus placebo* Martensson et al's meta-analysis, 2015 (Evidence table 1), pooled the results of 8 RCTs that compared light therapy to placebo (low negative air ions, dim red light, and dawn simulator placebo) to determine the effect bright white light (BWL) therapy on SAD. The authors performed two separate sets of meta-analyses; the first analyzed the results week-by-week, and the second analyzed the final results only. The pooled results suggest that BWL had a moderate effect on SAD symptoms compared to the controls (standardized mean difference [SMD] -0.54 (95% CI -0.95, -0.03), and that it reached statistical significance at week two and week three of treatment. The authors concluded that the BWL therapy seems to be effective, but they questioned the validity of the results due to the heterogeneity of the studies, lack of an appropriate placebo or sham light therapy control group, and other methodological limitations including the small sizes, short duration, and complex design of the trials. The results of Martensson et al's meta-analysis show a smaller effect size than that found in the Golden et al's meta-analysis reviewed earlier in MTAC (effect size 0.84, 95% CI 0.60, 1.08). As noted in the 2008 MTAC report, Golden et al's meta-analysis had the advantage of using strict criteria to ensure that studies had a valid placebo control, but was limited by the inclusion of very small studies with large treatment effect, short treatment durations, and the use different treatment protocols, which makes it difficult to draw any conclusion on the effectiveness of a particular approach to light therapy. When the two RCTs in the meta-analysis with the longest treatment durations and largest sample sizes were examined closely, bright light therapy did not clearly appear to be effective. *Light therapy versus antidepressants* In a Cochrane review on second-generation antidepressants for SAD, Thaler, et al (2011), pooled the results of two small trials (total N=136 participants) that compared light therapy to fluoxetine and found no significant difference between the two therapies in response or remission of SAD. The trials were small, with limitations and high dropout rates, and the overall response rate (>50% improvement on 24-item HAM-D SIGH-SAD) was 68/100 in the light therapy group and 67/100 in the fluoxetine group. The authors concluded that the overall quality of evidence is a low and insufficient to draw any conclusion on the use of second generation antidepressants for SAD. The only available RCT of fluoxetine vs. placebo showed a nonsignificant effect in favor of fluoxetine, and the two small trials that compared fluoxetine to light therapy showed no significant differences between the two therapies in the treatment of SAD. *Light therapy versus cognitive behavioral therapy* (evidence table 2) In a recent RCT, Rohan et al, 2015, compared the treatment outcomes of light therapy versus cognitive behavioral therapy for SAD. The trial randomized 177 participants to receive light therapy (using 23x15.5x3.25 in. SunRay that emits 10,000 lux of cool-white fluorescent light) immediately upon awakening, or to receive cognitive behavioral therapy (CBT-SAD) for 6 weeks. The primary endpoints of the trial were the change in depression severity SIGH-SAD during 6 weeks of therapy, and remission status after treatment. Overall, the results showed improvement in SAD symptoms in the two study groups with no significant differences between them at 6 weeks of treatment. There was no long-term follow-up to examine recurrence rates with each therapy. The trial was a relatively small, single center, RCT conducted mainly among white women. The participants were not blinded to the treatment allocation, which is a potential source of bias, and according to the authors, the primary investigator was the developer of CBT-SAD which is another potential source of bias. More importantly, light therapy was compared to CBT-SAD which has not been thoroughly

investigated as a treatment for SAD. Ideally the trial would include a sham light therapy and /or a placebo group to determine the placebo effect of each of the two therapies.

Conclusion: There is insufficient evidence to determine the effectiveness of light therapy for the treatment of SAD. Several national and international guidelines recommend light therapy for SAD giving it a level 1 evidence (Canadian guideline, 2009) or level 2 evidence (AAFP, 2013), others like the British NICE guideline (2009) and the World Federation of Societies of Biological Psychiatry (WFSBP, 2013) are uncertain about the evidence supporting light therapy for SAD.

**Articles:** The literature search for studies on light therapy for SAD published after the last MTAC review revealed a recent systematic review with meta-analyses on bright light therapy for depression including SAD, a Cochrane review on second-generation antidepressants for SAD, a randomized controlled trial of CBT vs. light therapy for SAD, a crossover RCT investigating the rapid effects of light therapy on SAD, and a retrospective study investigating the appropriate duration of light therapy. The search also identified three small to relatively small RCTs that compared standard bright light vs. dawn simulation, low-intensity blue-enriched white light, or negative air ions, as well as a more recent trial on different intensities of transcranial bright light treatment delivered via the ear canals for SAD. The meta-analysis and the RCT comparing bright light therapy to CBT were selected for critical appraisal. The pooled results of studies comparing antidepressants vs. light therapy in the Cochrane review were included. Mårtensson B, Pettersson A, Berglund L, et al. Bright white light therapy in depression: A critical review of the evidence. *J Affect Disord.* 2015 Aug 15; 182:1-7. See [Evidence Table 1](#). Rohan KJ, Mahon JN, Evans M, et al. Randomized Trial of Cognitive-Behavioral Therapy versus Light Therapy for Seasonal Affective Disorder: Acute Outcomes. *Am J Psychiatry.* 2015 Sep 1; 172(9):862-869. See [Evidence Table 2](#).

The use of light therapy in the treatment of Seasonal Affective Disorder (SAD) does not meet the *Group Health Medical Technology Assessment Criteria*.

**Living-Donor Liver Transplant: Adult-to-Adult**  
**Liver Transplant: Adult/Pediatric**

Group Health has elected to use the Liver Transplant (S-795) MCG\* for medical necessity determinations.

**\*MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Copy of final summary report from multidisciplinary transplant team

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Liver transplantation or hepatic transplantation is the replacement of a diseased liver with a healthy liver from another person (allograft). Liver transplantation is a viable treatment option for end-stage liver disease and acute liver failure. Group Health chose to use the MCG Liver Transplant criteria as they are nationally based and support requirements by most transplant centers.

### Evidence and Source Documents

The MCG evidence is used for this criteria document.

### Medical Technology and Assessment Committee (MTAC)

#### Living-Donor Liver Transplant – Adult-to-Adult

##### BACKGROUND

Living donor liver transplantation (LDLT) was developed as an alternative to cadaveric liver transplantations due to the dramatic shortage of available livers. LDLT to pediatric recipients was introduced into clinical practice in 1989 and the procedures are now performed worldwide. Adult-to-adult LDLT was initiated in the United States in the late 1990s. In 1997, one adult-to-adult LDLT was performed at one center in the U.S. and this grew to 266 procedures at 38 centers in 2000 (Brown et al, 2003). Left lateral segmentectomy, which uses approximately 20% of the hepatic mass, is generally used for LDLT to pediatric donors. However, these grafts provide insufficient liver mass for an average sized adult recipient. With adult recipients, a larger portion of the donor's liver must be taken which poses increased risks to the donor. Adult-to-adult liver transplantation involves either a full left or right hepatic lobe. Initially, all adult LDLT used the smaller left hepatic lobe. The hepatic mass was sufficient for some Asian recipients, but not for the average U.S. patient. Currently, adult-to-adult LDLTs in the U.S. use donation of the right

hepatic lobe, which represents about 60% of the hepatic mass. Risks to the donor in adult-to-adult LDLT include the possibility that the donor will not be left with sufficient hepatic function, the possibility of biliary complications, risks associated with blood transfusion, risks associated with surgery and unknown, long-term risks associated with major hepatic resection. (American Society of Transplant Surgeons: Ethics Committee, 2000; Renz and Roberts, 2000; Hayashi & Trotter, 2002). There is an ethical debate on adult-to-adult LDLT centering on the question of whether or not it is acceptable for a consenting healthy individual to undergo this surgery and take the risk of complication or death in order to potentially save the life of a loved one. LDLT programs conduct extensive physical and psychological examinations of donors. Related ethical issues are how to select adult recipients of LDLT (i.e. to what extent are they at risk of dying), how successful LDLT is in adult recipients (i.e. increased life expectancy in recipient vs. risk to donor) and how to allocate cadaveric livers.

#### **04/12/2000: MTAC REVIEW**

##### **Living-Donor Liver Transplant – Adult-to-Adult**

**Evidence Conclusion:** The limited amount of evidence available is not sufficient to determine the safety and efficacy of LRLT. Case series reports were the best available evidence. The published case studies have small sample sizes and were not rigorously performed (i.e. did not specify inclusion/exclusion criteria or outcome measurement, had variable and relatively short length of follow-up). In addition, the published studies report on different clinical techniques for performing LRLT and these individual techniques have not been systematically evaluated.

**Articles:** There were no randomized control trials, meta-analyses or cohort studies. Case series for adult-to-adult transplants all had small sample sizes (<50). Several larger case series included both adults and children as recipients and did not present results separately. Evidence tables were created for those with the largest sample sizes: (n=33) Hashikura, Y, Kawasaki, S, Miyagawa, S, Terada, M, Ikegami, T, Miwa, S, Kubota, T, Mita, A. Living-related donor liver transplantation in adults: Experience at Shinshu University Hospital. *Transplantation Proceedings* 1999; 31: 1953-4; (N=25) Marcos, A, Fisher, RA, Ham, JA, Shiffman, ML, Sanyal, AJ, Luketic, VAC, Sterling, RK, Posner, MP. Right lobe living donor liver transplantation. *Transplantation* 1999; 68: 798-803. Hashikura, Y, Kawasaki, S, Miyagawa, S, Terada, M, Ikegami, T, Miwa, S, Kubota, T, Mita, A. Living-related donor liver transplantation in adults: Experience at Shinshu University Hospital. *Transplantation Proceedings* 1999; 31: 1953-4. [See Evidence Table.](#) Marcos, A, Fisher, RA, Ham, JA, Shiffman, ML, Sanyal, AJ, Luketic, VAC, Sterling, RK, Posner, MP. Right lobe living donor liver transplantation. *Transplantation* 1999; 68: 798-803. [See Evidence Table.](#)

The use of Adult to Adult Living Related Donor Liver Transplant treatment of Liver Failure does not meet the *Group Health Medical Technology Assessment Criteria.*

#### **06/11/2003: MTAC REVIEW**

##### **Living-Donor Liver Transplant – Adult-to-Adult**

**Evidence Conclusion:** There is a lack of evidence on the effectiveness of adult-to-adult living-donor liver transplantation compared to cadaveric whole or split-liver transplantation and one small study (Liu) that addresses the effectiveness of LDLT compared to remaining on a wait list for cadaveric transplantation. Liu found a higher survival rate with right lobe LDLT than no transplantation among patients with acute liver failure; however, findings do not necessarily generalize to patients with other indications for transplantation. The remaining studies are case series. One-year recipient survival rates were 72% in the case series of 308 adults from Japan (Todo) in which 71% of the operations were left-lobe transplantations and 85% for 50 right-lobe operations in the U.S. (Miller). No peri-operative donor mortality was reported in the recent case series articles. Brown identified one donor death among 449 right-lobe adult-to-adult living-donor transplantations performed in the U.S. between 1997 and 2000. Brown's survey found a 14.5% donor complication rate including 6% experiencing biliary leakage and 4.5% needing re-operation. A limitation of the case series data and the Brown survey data is variability in the eligibility criteria and interventions across centers and within centers over time. There are no quality long-term data on outcomes among recipients or donors.

**Articles:** The search yielded 206 articles, many of which were reviews, opinion pieces or dealt with technical aspects of the procedure. There were no randomized controlled trials. The next preference was given to non-randomized comparative trials. There was one study that compared patients with acute liver failure who did and did not opt for LDLT; this study was reviewed. The remaining studies were case series. Other articles selected were the largest case series (conducted in Japan), the largest case series in the United States and a survey of transplantation programs focusing on donor outcomes. The following four articles were critically appraised: Liu CL, Fan ST, Lo CM et al. Right-lobe live donor liver transplantation improves survival of patients with acute liver failure. *Br J Surg* 2002; 89: 317-322. [See Evidence Table.](#) Todo S, Furukawa H, BonJin M et al. Living donor liver transplantation in adults: Outcome in Japan. *Liver Transplantation* 2000; 6 (Suppl 2): S66-S72. [See Evidence Table.](#) Miller CM, Gondolesi CE, Florman S. et al. One hundred nine living donor liver transplants in adults and

children: A single-center experience. *Ann Surg* 2001; 234: 301-012. Brown RS, Russo MW, Lai M. et al. A survey of liver transplantation from living adult donors in the United States. *N Engl J Med* 2003; 348: 818-825. [See Evidence Table.](#)

The use of Adult to Adult Living Related Donor Liver Transplant treatment of Liver Failure does not meet the *Group Health Medical Technology Assessment Criteria.*

### ***Kidney Transplantation in the treatment of HIV+***

#### **BACKGROUND**

HIV infected patients are at risk for end-stage renal disease caused by HIV-related disease such as HIV-associated nephropathy and hepatitis C infection. HIV-positive patients co-infected with hepatitis B or hepatitis C are also at risk of progression of liver disease (Roland & Stock; Fishman). Until recently, HIV-positive patients have been excluded from organ transplantation programs. A primary reason for this exclusion has been the belief that patients in an immuno-compromised state would be adversely affected by the immunosuppression required for transplantation. Several changes have occurred that have caused some transplant centers to question the exclusion based on HIV infection. Highly active anti-retroviral therapy (HAART) became available in the mid to late 1990s. HAART can prolong survival in HIV-positive patients, thereby increasing the number of patients with stable HIV infection who progress to end-stage organ failure. In addition, there have been improvements in immunosuppressive drug regimens and surgical techniques associated with transplantation. This review will evaluate the evidence published to date on the safety and efficacy of organ transplantation among HIV-positive patients in the HAART era. Kidney transplantation in HIV positive patients was previously reviewed by MTAC in December 2001. At that time, the evidence consisted of several case series with five or fewer HIV-positive patients and the item failed MTAC evaluation criteria. Other types of organ transplantation (liver, lung, heart) have not been reviewed by MTAC.

#### **12/12/2001: MTAC REVIEW**

##### ***Kidney Transplantation in the treatment of HIV+***

**Evidence Conclusion:** There is insufficient published evidence on which to base a conclusion about the effect of kidney transplant in HIV-positive patients on health outcomes. Although recent changes in the prognosis of HIV-positive individuals suggest that some may benefit from kidney transplant, there are no direct empirical data to support this claim.

**Articles:** The search yielded 64 articles, many of which dealt with other related procedures or populations or were review articles or opinion pieces. No articles with empirical data were included in the search. Three older case series were identified in the reference list of the Gow review article. Each of these case series included 5 or fewer HIV-positive patients receiving kidney transplants. None of the articles was suitable for critical appraisal.

The use of Kidney Transplantation in the treatment of HIV+ patients with renal failure does not meet the *Group Health Medical Technology Assessment Criteria.*

#### **08/11/2004: MTAC REVIEW**

##### ***Heart, Lung, Kidney, & Liver Transplantation in the treatment of HIV+***

**Evidence Conclusion:** There were two primary issues addressed in this review: 1) evidence on the safety and effectiveness of organ transplantation for HIV-positive individuals and; 2) evidence on whether survival among HIV-positive individuals who receive organ transplants is lower than among HIV-negative individuals. There is no published evidence on the safety and effectiveness of lung transplantation in HIV-positive individuals and only two case reports of heart transplants. There were no articles comparing transplantation to another intervention in HIV-positive patients with end-stage liver or kidney disease. The best published evidence on kidney and liver transplants in HIV-positive individuals is from cohort studies conducted in the HAART era. Abbott did a retrospective study comparing outcomes in HIV-positive and HIV-negative individuals, all of whom were identified in a national database of kidney transplants. Ragni compared survival in a prospective series of HIV-positive patients and a retrospective analysis of selected HIV-negative patients from the UNOS Scientific Registry for Liver Transplantation. In both studies, three-year survival rates did not differ significantly in the HIV-positive and HIV-negative groups. Limitations of both studies include: The relatively small sample sizes of HIV-positive patients, 24 in the Ragni study and 47 in the Abbott study. The HIV-positive and HIV-negative groups may have differed in ways that affected outcomes (despite statistical adjustment for confounding in the Abbott study). The authors commented that clinicians may have selected the healthiest HIV-positive patients for transplantation which might increase the likelihood of a successful outcome compared with the HIV-negative patients. The Abbott study was retrospective and the Ragni study included a prospective group of HIV-positive patients, but did a retrospective analysis of the HIV-negative control group. Prospective designs are preferred. A prospective, multi-center uncontrolled study to evaluate the safety and efficacy of kidney and liver transplants performed in HIV-positive

patients is currently in its early phases. The study is being coordinated by UCSF. The investigators anticipate enrolling up to 275 transplant recipients and following them for 2-5 years.

**Articles:** The search yielded 217 articles. Most were opinion pieces, on technical aspects of transplantation in HIV-positive patients and articles on related clinical topics. Empirical studies on specific types of organ transplantation were as follows: Lung There were no studies with empirical data. Heart There were two case reports, each reporting on a single case. The articles were ineligible for critical appraisal. Kidney and Liver There was one study on kidney transplants (Abbott et al., 2004) and one study on liver transplants (Ragni et al., 2003) that compared outcomes in HIV-positive patients to outcomes in HIV-negative patients. Data from HIV-negative patients were taken from national transplantation databases in both studies. These two studies were critically appraised. The largest published series from UCSF included 14 patients, 10 received kidney transplants and 3 received liver transplants (Stock et al. 2003). Newer reports with additional patients have been presented at conferences and discussed in review articles, but the data have not been published in empirical articles. The case series was not critically appraised due to the small sample and availability of comparative studies. There was also a retrospective cohort study evaluating data on kidney transplants from 1987-1997; this study was not critically appraised because it primarily included cases from the pre-HAART era.

*The studies reviewed were:* Abbott KC, Swanson SJ, Agodoa LYC et al. Human immunodeficiency virus infection and kidney transplantation in the era of highly active antiretroviral therapy and modern immunosuppression. *J Am Soc Nephrol* 2004; 15: 1633-1639. See [Evidence Table](#). Ragni MV, Belle SH, Im K et al. Survival of human immunodeficiency virus-infected liver transplant recipients. *J of Infect Dis* 2003; 188: 1412-1420. See [Evidence Table](#).

The use of Heart Transplantation in the treatment of HIV+ patients with heart failure does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of Lung Transplantation in the treatment of HIV+ patients with lung failure does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of Kidney Transplantation in the treatment of HIV+ patients with renal failure evidence is not sufficient to determine whether HIV infection should or should not be an exclusion for kidney transplantation.

The use of Liver Transplantation in the treatment of HIV+ patients with renal failure the evidence is not sufficient to determine whether HIV infection should or should not be an exclusion for liver transplantation.

Localization System for External Beam Radiation

- Calypso 4D Localization
• Electromagnetic Localization System
• GPS for the Body
• Tracking with Beacon Transponders during External Beam Radiation Therapy (Calypso Medical)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.

Criteria

For Medicare Members

Table with 2 columns: Source, Policy. Rows include CMS Coverage Manuals, National Coverage Determinations (NCD), Local Coverage Determinations (LCD), and Local Coverage Article.

For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

Background

Prostate cancer is the most commonly diagnosed cancer and second leading cause of death in men in the United States. The treatment options for early stage prostate cancer include radical prostatectomy, high dose brachytherapy, and high dose external beam radiation therapy (EBRT). Several studies showed improvement in biochemical progression free survival with radiation dose escalation. However, this comes at the cost of higher bladder and bowel toxicity. Investigators found that toxicity due to radiation therapy can be reduced by the use of intensity modulated radiotherapy (IMRT) techniques that focus a high dose radiation to the prostate while decreasing the dose to the bladder and rectum. With the higher doses being delivered with increased conformity, it is critical that the isocenter of the prostate treatment volume be placed with precision (Kuban 2008, Quigley 2009, Rajendran 2010).

The prostate gland is known to have some movement during the day as the bladder and rectum are filled at different volumes. Two types of motion have been described and may be an issue for treatment planning: 1. Interfraction motion from day-to-day, and 2. Intrafraction movement that is motion occurring while the patient is on the treatment table during radiation delivery. This is thought to be caused by breathing or other biological factors as contraction/relaxation of the pelvic floor and by rectal gas. Target localization during radiation therapy for prostate cancer has two aspects: the initial setup before delivering the radiation, and the subsequent real-time target position monitoring during the actual delivery of radiation. The interfraction position has been addressed by various techniques including ultrasound, infrared cameras, diagnostic CT imaging, and x-ray imaging. The use of implanted markers as gold is accepted as an accurate, reliable, and reproducible method to establish the position of the prostate gland during EBRT treatment. Other techniques used to estimate the motion of prostate during delivery of radiation include transabdominal ultrasound, X-rays, MRI, CT, and fluoroscopy. The use of these technologies may be limited as they may not be available in the treatment room or usable during radiation delivery, provide only a snapshot of the prostate position, result into additional radiation dose, are labor intensive and /or require user skill for image acquisition or interpretation (Kupelian 2006, Rajendran 2010).

In the last few years, the use of an implantable radiofrequency emitting device has been proposed as an alternative to radiopaque fiducial markers and radiographic localization to provide an objective, accurate real-time method of localizing and monitoring prostate position. The Calypso 4D Localization System is based on electromagnetic detection of implanted Beacon transponders that allows the three-dimensional position of the implanted transponders and target isocenter to be tracked at a frequency of 10Hz. This provides continuous real-time localization and monitoring of the prostate. The Calypso System (Calypso Medical, Seattle, WA) consists of three implantable wireless Beacon transponders approximately 8 mm in length and 2mm in diameter, an electromagnetic array, an infrared camera system, and a tracking station. Typically three transponders are implanted in the right and left base and the apex of the prostate gland under transrectal ultrasound guidance in a manner similar to needle biopsy. The coordinates of the Beacons and the isocenter are identified on the treatment planning CT and entered into the calypso tracking station. Similar to ultrasound localization, the initial localization with the Calypso System is performed using skin marks to align with room lasers. Calypso is used to localize the prostate and the system calculates the initial offset. The couch is shifted until the three offsets are zero. During treatment Calypso monitors and reports the offset between the actual and planned isocenter position (Santanam 2009, Foster 2010, Rajendran 2010).

Potential benefits of the Calypso system include its ability to continuously monitor target position during treatment, with no exposure to ionizing radiation to perform the localization, and without using complicated procedures of acquiring X-ray images. Potential disadvantages on the other hand, are the need for implantation, transponders stability within the implanted tissues, and the absence of any associated image of the targeted areas. The Calypso System has received 510 (K) clearance from the FDA in 2006.

## Medical Technology Assessment Committee (MTAC)

### Calypso 4D Localization System

#### 12/20/2010: MTAC REVIEW

**Evidence Conclusion:** The published literature on the Calypso system is very limited and do not provide sufficient evidence to determine the safety of the technology or its effect on patients with localized prostate cancer treated with radiation therapy. The published studies were small case series the majority of which were conducted by the same group of authors many of whom had financial interest with the manufacturer of the technology. The safety of the Calypso system and its effect on improving health outcomes were not examined in randomized controlled trials. Assessing the Impact of Margin Reduction (AIM) study was the largest case series on the Calypso System published to date, and the first with clinical outcomes. However, it was not randomized and used a historical comparison group. It had several other limitations including the significant baseline differences between study participants and the comparison groups, difference in the time of treatment, and variations in the radiation therapy received by the two groups, as well as the absence of long term follow-up to determine the effect of the technology on the incidence of late complications. Moreover only 83% of the participants were included in the analysis, and the study was funded by the manufacturer.

**Articles:** The published literature on the Calypso 4D localization system for the prostate is very limited. There are no published randomized controlled trials that compared the effect of the Calypso system versus other localization technologies on reducing radiation toxicity, or improving quality of life (QoL) in patients with prostate cancer. The literature search identified the 'Assessing the Impact of Margin Reduction (AIM)' study that assessed the effect of reducing the planning target volume margins while using real-time tumor tracking on the quality of life of patients with prostate cancer treated with radiation therapy. It did not include a comparison or control group. No trials on the safety of the technology were identified.

The AIM study was selected for critical appraisal: Sandler M, Liu P-Y, Dunn RL, et al. Reduction in patient-reported acute morbidity in prostate cancer patients treated with 81-Gy Intensity-modulated radiotherapy using reduced planning target volume margins and electromagnetic tracking: assessing the impact of margin reduction study. *Urology*. 2010 May;75(5):1004-8. Epub 2010 Feb 13. See [Evidence Table](#)

The use of Calypso 4D localization system (Calypso 4D localization and Tracking with Beacon transponders during external beam radiation therapy [Calypso Medical], GPS for the Body, electromagnetic localization system) does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Low-Dose CT Screening for Lung Cancer

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

##### National Coverage Determination (NCD)

Lung Cancer Screening with Low Dose Computed Tomography (LDCT) (210.14)

[Medicare Coverage of Screening for Lung Cancer with Low Dose Computed Tomography](#)

##### For Non-Medicare Members

Low-dose CT screening for lung cancer will be covered when the patient meets the following criteria:

**Ages 55 through 74:** Annual screening for lung cancer with low-dose computed tomography is recommended for patients who:

- Have at least a 30-year pack history,
- Currently smoke or quit less than 15 years ago, and
- Have no significant comorbidities that would preclude surgical treatment or limit life expectancy.

**Ages 75 through 79:** For patients who meet the above criteria, clinical judgment is recommended in deciding whether to initiate annual lung cancer screening with LDCT.

**Ages 80 and over:** Annual lung cancer screening with LDCT is not recommended.

##### Discontinuation

Discontinuation of lung cancer screening is recommended at 15 years following the patient's quit date, or as appropriate for health status.

##### Procedure codes:

- 71250- computerized axial tomography, thorax
- S8032- Low dose CT lung screening (new code released by CMS 10/1/2014)
- S8092- Electron beam computed tomography
- G0297 - Low dose CT scan (LDCT) for lung cancer screening

##### Diagnosis codes:

- V15.82 - Personal history of tobacco use
- Z87.891 - Personal history of nicotine dependence
- V76.0 - Special screening for malignant neoplasms of respiratory organs
- Z12.2 – Encounter for screening for malignant neoplasm of respiratory organs

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Lung cancer is the third most common cancer and the leading cause of cancer death in the United States. According to the U.S. Preventive Services Task Force (USPSTF), nearly 90% of individuals with lung cancer die of the disease. However, when detected at an early stage, non-small cell lung cancer (NSCLC) has a better prognosis and can be treated with surgical resection. (The majority of lung cancer cases are NSCLC.)

The most important risk factor for lung cancer is smoking, which results in approximately 85% of all U.S. lung cancer cases. The incidence of lung cancer increases with age, occurring most commonly in individuals aged 55

years or older. Increasing age and cumulative exposure to tobacco smoke are the two factors most strongly associated with the occurrence of lung cancer.

The USPSTF found adequate evidence that annual screening with low-dose computed tomography (LDCT) in current and former smokers aged 55 to 79 years who have significant cumulative tobacco smoke exposure can prevent a substantial number of lung cancer deaths. LDCT has greater sensitivity for detecting early-stage cancer than chest X-ray and sputum cytology; however, it also has a very high rate of false positives (about 95%). For the benefits to outweigh the harms, screening needs to be limited to those who are at the highest risk for lung cancer.

11/4 – MPC adopted the USPSTF guidelines for lung cancer screening

## Medical Technology Assessment Committee (MTAC)

### Low-Dose CT Screening for Lung Cancer

#### 12/12/2001: MTAC REVIEW

**Evidence Conclusion:** There is no evidence on the diagnostic accuracy of the low-dose CT test for lung cancer screening. That is, an independent, blind, comparison of the low-dose CT tests with a gold standard (e.g. high-dose CT) for an appropriate group of patients. In the Henschke study, only patients with certain findings on low-dose CT were recommended to have high-dose CT. There are also no studies comparing the diagnostic accuracy of low-dose CT screening to the current standard, chest radiography. The only available evidence on low-dose CT screening for lung cancer is prospective reports of screening programs. Henschke set up a protocol to screen individuals at increased risk of lung cancer. They found that more non-calcified nodules, malignant nodules and stage I malignant disease was found using low-dose CT than could be detected by chest radiography. These data suggest that low-dose CT may be useful for lung cancer screening. The data presented in the Henschke study are insufficient for evaluating the question of whether screening with low-dose CT reduces disease-specific mortality. Even though more nodules and more stage I nodules were identified than with chest radiography, it is not known whether this early identification will lead to decreased mortality from lung cancer. (Previous randomized controlled trials evaluating the effectiveness of chest radiography for lung cancer screening did not find a difference in mortality in the screened and unscreened groups). Alternatively, CT screening may not increase disease-specific survival due to lead-time bias and over diagnosis bias. Randomized controlled trials comparing CT screening to no screening would provide more rigorous information about its effectiveness as a screening strategy.

**Articles:** The search yielded 54 articles, many of which were review articles, opinion pieces or dealt with technical aspects of the procedure. There were no randomized controlled trials or meta-analyses. Five case series with relevant clinical outcomes were identified. Four were studies conducted in Japan and one was a study conducted at Cornell University. Of the four Japanese studies, there were two studies by Sone et al. and two studies by Kaneko et al. The Sone articles were an earlier and later report on the same project, as were the Kaneko articles. Neither of the Japanese screening projects had specific clinical inclusion and exclusion criteria. The Sone study screened the general population and the Kaneko study screened people who were members of a non-profit organization, the Anti-Lung Cancer Association (ACLA). In addition, neither Japanese screening project appeared to have a consistent protocol that was followed. The Cornell University study by Henschke et al. screened only individuals at high-risk of lung cancer and had clear eligibility criteria as well as screening and follow-up protocols. None of the articles were designed to evaluate the diagnostic characteristics of the low-dose CT test (e.g. sensitivity, specificity). *An evidence table was created for the Henschke study:* Henschke CI, McCauley DI, Yankelevitz DF, Naidich DP, McGuinness G, Miettinen OS, Libby DM, Pasmantier MW et al. Early Lung Cancer Action Project: Overall design and findings from baseline screening. *Lancet* 1999; 354: 99-105. See [Evidence Table](#)

The use of CT Scanning in the screening of lung cancer does not meet the *Group Health Medical Technology Assessment Criteria 2* for effectiveness of diagnostic test.

### Low-Dose CT Screening for Lung Cancer

#### 8/15/2011: MTAC REVIEW

**Evidence Conclusion:** The National Lung Screening Trial (NLST), a large RCT that included 53,454 participants, examined whether screening high-risk individuals for lung cancer annually for three years with either LDCT or chest x-ray would reduce lung cancer mortality. Results from the NLST suggest that in high-risk patients annual lung cancer screening for three years using LDCT reduced lung-cancer mortality with a number needed to screen to prevent one cancer death of 320. However, before recommending a screening test there are other factors to consider such as overdiagnosis, cost-effectiveness, false positive results, and other potential harms such as radiation-induced cancer. The effect of overdiagnosis and radiation-induced cancer could not be directly measured in this trial and cost-effectiveness analyses are currently underway. With regard to false positive results, across the three rounds of screening, 96.4% of the positive results in the LDCT and 94.5% in the x-ray group were false positive results. Additionally, 39.1% of subjects in the LDCT group and 16.0% in the x-ray group had at least one

positive screening test during the screening phase of the trial (NSLT 2011). A recent interim analysis from a RCT that included 2,472 men who were at high-risk for lung cancer examined whether yearly lung cancer screening using LDCT in combination with a medical interview and physical exam would reduce lung cancer mortality compared to yearly medical interview and physical exam alone. After approximately 3 years of follow-up, significantly more men in the intervention group were diagnosed with lung cancer [intervention 60 (4.7%) vs. control 34 (2.8%), P=0.02]. However, there was no significant difference in lung cancer mortality between the two groups [intervention 20 (1.6%) vs. control 20 (1.7%), P=0.84]. Conclusion: Results from the NLST suggest that screening high-risk patients with LDCT annually for three years may reduce lung-cancer mortality; however, despite these positive results there are many other questions that still need to be answered such as screening frequency and duration. In 2007, the California Technology Assessment Forum evaluated the use of low-dose spiral computed tomography (LDCT) screening for lung cancer. They concluded that while the use of LDCT to screen for lung cancer in high-risk populations appeared promising, there was insufficient published evidence to recommend the use of LDCT outside of the investigational setting. Since the 2007 technology assessment, two randomized controlled trials (RCTs) were selected for review that examined the effectiveness of screening high-risk individuals for lung cancer using LDCT compared to chest x-ray.

**Articles:** The following studies were critically appraised: National Lung Screening Trial (NLST). Reduced lung-cancer mortality with computed tomographic screening. *N Engl J Med* 2011. [Epub ahead of print] See [Evidence Table](#) Infante M, Cavuto S, Lutman FR, et al. A randomized study of lung cancer screening with spiral computed tomography: three year results from the DANTE trial. *Am J Respir Crit Care Med* 2009; 180:445. See [Evidence Table](#)

The use of CT Scanning in the screening of lung cancer does not meet the *Group Health Medical Technology Assessment Criteria 2* for effectiveness of diagnostic test.

### Low-Dose CT Screening for Lung Cancer

#### 10/15/2012: MTAC REVIEW

**Evidence Conclusion:** The Danish Lung Cancer Screening (DLCST), a RCT that included 4,104 participants, examined whether screening high-risk individuals yearly with LDCT would reduce lung cancer mortality compared to usual care (no screening). Results from this trial suggest that after 5 years of screening, LDCT did not reduce lung cancer mortality or all-cause mortality compared to usual care. Significantly more lung cancers were diagnosed in the screening group compared to the control group (69 vs. 24, P<0.001), and more were early stage (48 vs. 21, P=0.002). There was no significant difference in the number of late stage lung cancer (21 vs. 16, P=0.51). The diagnostic false positive rate was 7.9% at baseline, 1.7% at year 1, 2.0% at year 2, 1.6% year 3, and 1.9% year 4. One limitation of this trial is that the sample size may be insufficient and the duration of follow-up may not be long enough to detect a reduction in mortality (Saghir 2012) The Multicentric Italian Lung Detection (MILD), a RCT that included 4,099 participants, examined whether screening high-risk individuals yearly or every two years with LDCT would reduce lung cancer mortality compared to usual care (no screening). Results from this trial suggest that after 5 years of follow-up, annual or biennial screening with LDCT did not reduce lung cancer mortality compared to usual care. The incidence of lung cancer was significantly higher in LDCT screening groups compared to the control group (P=0.025), but not in the annual versus the biennial groups (P=0.24). Due to recruitment issues the trial may be underpowered to detect differences in mortality. Additionally, at baseline more subjects in the control group were current smokers (Pastorino 2012). Conclusion: Results from the NLST suggest that screening high-risk patients with LDCT annually for three years may reduce lung-cancer mortality; however, despite these positive results there are many other questions that still need to be answered such as screening frequency and duration, and the effects of cumulative radiation exposure. Results from other RCTs have not shown a mortality benefit; however, these trials may be underpowered.

**Articles:** Low-dose CT screening for lung cancer was previously reviewed in 2001 and 2011. Since the 2011 review, two randomized controlled trial were identified that assessed the benefits and harms of screening for lung cancer using low-dose CT in high risk patients. The following studies were critically appraised: Saghir Z, Dirksen A, Ashraf H, et al. CT screening for lung cancer brings forward early disease. The randomised Danish Lung Cancer Screening Trial: status after five annual screening rounds with low-dose CT. *Thorax*. 2012;67:296-301. See [Evidence Table](#) Pastorino U, Rossi M, Rosato V, et al. Annual or biennial CT screening versus observation in heavy smokers: 5-year results of the MILD trial. *Eur J Cancer Prev*. 2012;21:308-315. See [Evidence Table](#)

The use of CT Scanning in the screening of lung cancer does not meet the *Group Health Medical Technology Assessment Criteria 2* for effectiveness of diagnostic test.

CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Laser Procedures (140.5)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

Group Health has elected to use the Laser Therapy (A-0511) MCG\* for medical necessity determinations.

\*The MCG are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider &/or specialist

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Low level laser therapy (LLLT) is a light source treatment that generates light of a single wavelength and is thought to promote tissue regeneration, reduced inflammation, and relieve pain. Unlike many other medical laser procedures, LLLT emits no heat, sound, or vibration. Instead of producing a thermal effect, it is thought that LLLT works by eliciting photochemical reactions in cells. Although the exact mechanism of biological action is unknown, several theories have been proposed and include: increased mitochondrial ATP production, enhanced cellular proliferation, increased cellular oxygenation, increased serotonin and endorphin production, stimulation of angiogenesis, and suppression of inflammatory cytokines (Huang 2009, Lin 2010).

Ideal treatment characteristics are unknown; however, LLLT is defined by several parameters (Posten 2005):

- Power with a range of  $10^{-3}$  to  $10^{-1}$  Watts
- Wavelength between 300 and 10,600 nm
- Pulse rate of 0 (continuous) to 5,000 Hz
- Pulse duration of 1 to 500 milliseconds
- Total irradiation time to 10 to 3,000 seconds
- Intensity (power/area) of  $10^{-2}$  to  $10^0$  W/cm<sup>2</sup>
- Dose (power x irradiation time/area irradiated) of  $10^{-2}$  to  $10^2$  J/cm<sup>2</sup>

There are a variety of lasers used for administering LLLT. Different types of lasers emit light at different wavelengths. Common lasers used include: ruby, argon, helium-neon, krypton, gallium-aluminum-arsenide, and gallium-arsenide (Lin 2010). Several low level laser devices have received FDA approval.

#### Medical Technology Assessment Committee (MTAC)

12/20/2010: MTAC Review

Lower Level Laser Therapy for Pain

**Evidence Conclusion:** *Back pain* - A meta-analysis of 7 RCTs that included 384 participants assessed the effects of LLLT in patients with non-specific low-back. Because the studies included in the meta-analysis were heterogeneous with respect to population, intervention, and comparison group, it is difficult to draw conclusions on the clinical effect of LLLT for low back pain (Yousefi-Nooraie 2008). A double-blind RCT that included 80 participants was conducted after the meta-analysis and compared the effectiveness of LLLT on pain and functional capacity in patients with acute and chronic low back pain caused by lumbar disc herniation (LDH). Patients were randomized to one of four treatment groups: LLLT + hot pack (acute back pain), placebo LLLT + hot pack (acute back pain), LLLT + hot pack (chronic back pain), and placebo LLLT + hot pack (chronic back pain). After treatment, there were statistically significant improvements in pain, range of motion, and disability in all groups with respect to all outcome parameters. However, there was no statistically significant difference between the four treatment groups for any of the treatment parameters. This study had several limitations. The sample size may have been too small to detect between group differences and the follow-up duration was only 3 weeks (Ay 2010). *Neck pain* - A recent meta-analysis of 16 RCTs that included 820 participants assessed the safety and efficacy of LLLT in treating acute and chronic neck pain. Subjects with acute neck pain who were treated with LLLT were significantly more likely to experience an improvement in pain compared to subjects treated with placebo (RR 1.69, 95% CI 1.22 to 2.33). Patients with chronic neck pain treated with LLLT also experienced greater reductions in pain compared to patients receiving placebo (WMD 19.86, 95% CI 10.04 to 29.68). Results from this analysis also suggest that the effects of treatment may last as long as 22 weeks. Side-effects included tiredness, nausea, headache, and increased pain. Side-effects were generally mild and did not differ from those in the placebo group. Trials included in the meta-analysis were small RCTs that were heterogeneous with respect to laser parameters, application technique, and intended rationale for treatment (Chow 2009). A small double-blind RCT that included 60 participants investigated the clinical effects of LLLT in patients with acute neck pain with radiculopathy. Results from this study suggest that compared to placebo, patients treated with LLLT experienced significantly greater improvements in arm pain, disability, and neck mobility. There was no significant difference in neck pain between the two groups. All adverse events occurred in the LLLT group and included: transitional worsening of pain (6/30), persistent nausea (1/30), and increased blood pressure (1/30). Results from this study are generalizable to patients with acute neck pain with radiculopathy with severe levels of pain and moderate to severe levels of disability (Konstantinovic 2010). *Carpal tunnel syndrome - LLLT vs. placebo* A double-blind RCT that included 36 patient with mild to moderate carpal tunnel syndrome (CTS) evaluated the therapeutic effects of LLLT versus placebo for the treatment of CTS. The primary outcome measures included: pain, grip strength, symptom severity, functional status, and motor and sensory peak latency. After treatment there was no significant differences between LLLT and placebo for any of the outcomes except for pain. Patients who were treated with LLLT experienced a greater reduction in pain compared to patients treated with placebo. However, after 2 weeks of follow-up, patients who received LLLT showed significant improvement in pain, symptom severity, functional status, and grip strength. There was no significant difference in sensory peak latency or motor latency between the groups after treatment or after 2 weeks of follow-up. This was a small trial with a short duration of follow-up (Chang 2008). Another RCT that included 81 patients and compared LLLT to placebo found no significant difference with regard to pain and functional capacity between the two treatment groups after 12 weeks of follow-up (Evcik 2007). **LLLT vs. ultrasound** A RCT that included 50 patients with mild to moderate CTS (90 wrists) compared the efficacy of LLLT and ultrasound for the treatment of CTS. Results from this study suggest that compared to patients treated with LLLT, patients treated with ultrasound showed significant improvements in pain, pinch strength, grip strength, and electroneurographic measurements (Bakhtiary 2004). **Splinting vs. splinting + ultrasound vs. splinting + LLLT** A recent RCT that included 100 wrists of patients with mild to moderate CTS investigated the effectiveness of splinting, ultrasound, and LLLT for the management of CTS. The primary outcome measures were symptom severity, functional status, pain, median nerve sensory velocity, and median nerve motor distal latency. For all measurements, the combination of a splint plus ultrasound or LLLT was significantly better than the use of a splint alone. Patients who were treated with a splint plus LLLT experience significantly greater reductions in pain and symptom severity compared to patients treated with a splint plus ultrasound. Results from this study should be interpreted with caution as power was not addressed, it was not stated if an ITT analysis was performed, 4 patients did not finish therapy, 6 patients were lost to follow-up, and splint compliance was not addressed (Dincer 2009). *Conclusion:* There is insufficient evidence to determine the safety and efficacy of LLLT for the treatment of: Low back pain, Neck pain, and Carpal tunnel syndrome

**Articles:** A meta-analysis of RCT and a RCT published after the meta-analysis were identified that addressed the safety and efficacy of LLLT for the treatment of low back pain. The literature search also revealed a meta-analysis and RCT that looked at LLLT for the treatment of neck pain. Several RCT were identified that addressed the efficacy of LLLT for the treatment of carpal tunnel syndrome. Trials were selected for review if they had more than 25 participants and compared LLLT alone or in combination with another therapy to placebo or another active treatment. The following studies were critically appraised: Ay S, Doğan SK, and Evcik D. Is low-level laser therapy effective in acute or chronic low back pain? *Clin Rheumatol* 2010; 29:905-910. See [Evidence Table](#). Bakhtiary AH and Rashidy-Pour A. Ultrasound and laser therapy in the treatment of carpal tunnel syndrome. *Aust J Physiother* 2004; 50:147-151. See [Evidence Table](#). ##### For Non-Medicare Members

Group Health has elected to use the Lower Limb Prosthesis (GHC-0487) MCG\* for medical necessity determinations.

**\*MCG manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

A large number of lower limb prosthetic designs are now available. The choice of the most appropriate prosthetic depends on factors such as amputation level, height, weight, and activity level of the amputee. Prosthetics fall mainly under two broad functional groups: non-microprocessor controlled prosthetics and microprocessor controlled prosthetics. The normal gait cycle is comprised of the stance phase, the period when the leg is on the ground, and the swing phase, the period when the leg is off the ground. Non-microprocessor controlled prosthetics incorporate friction, pneumatic, or hydraulics in the joint to control the swing and stance phases of gait. While they have helped amputees gain mobility these prosthetics have limitations. Prosthetics that utilize friction to control the swing phase can only be adjusted for one walking speed. Pneumatic and hydraulics prosthetics allow amputees to change their walking speed; however, these prosthetics do not incorporate adaptive stance phase control. The lack of adaptive stance phase control requires the amputee to lock the knee mechanism in full extension during stance to avoid buckling. The limitations of the non-microprocessor controlled prosthetics result in gait asymmetries which may contribute to problems such as increased energy expenditure and secondary disabilities.

Microprocessor-controlled prosthetics incorporate sensors that measure angles and movement every 20 millisecond and alter the damping of the hydraulic unit for each phase of gait. This technology is intended to normalize the swing and stance phase of gait over a wide range of walking speeds. Potential benefits of this technology include: decreased effort in walking, improved gait symmetry, reduced need for muscular compensation on the contralateral limb, fewer falls, and more stable gait on uneven terrain, ramps, inclines, and stairs (Berry 2009, Segal 2006).

C-leg® is a microprocessor-controlled knee joint system with hydraulic stance and swing phase control. In 1999, C-Leg® (Otto Block Healthcare, Duderstadt, Germany) received FDA approval.

##### Lower Limb Prosthesis

## 08/11/2004: MTAC REVIEW

**Evidence Conclusion:** The few studies published in peer-reviewed journals, included a small number of selected active participants, and do not provide sufficient evidence on effectiveness of the microprocessor-controlled lower limb prosthesis.

**Articles:** The search yielded 32 articles. The majority dealt with the technical aspects and mechanisms of action of the prostheses. The search did not reveal any randomized controlled trials. There was a pilot study (N=10) that compared the cognitive demand of walking using the intelligent prosthesis with the conventional damped knees. Another open crossover study of six amputees that compared the gait symmetry, energy expenditure, and patient impressions of the intelligent prosthesis to the standard pneumatic swing-phase control knee was also identified. The other reports/studies revealed by the search were small descriptive case series with less than 25 participants. None of the articles was selected for critical appraisal.

The use of microprocessor-controlled lower limb prostheses in the treatment of lower limb amputation does not meet the *Group Health Medical Technology Assessment Criteria*.

## 08/07/2006: MTAC REVIEW

### Lower Limb Prosthesis

**Evidence Conclusion:** The few studies published in peer-reviewed journals, included small numbers of participants, and do not provide sufficient evidence to determine the effectiveness and benefit of the microprocessor-controlled lower limb prosthesis.

**Articles:** The search yielded 43 articles. The majority dealt with the technical aspects and mechanisms of action of the prostheses. The search identified one recent (Klute 2006)\* small randomized controlled that compared the functional mobility and daily activity level of microprocessor-controlled hydraulic knee vs. the nonmicroprocessor hydraulic knee. Eighteen transfemoral amputees agreed to enroll in the study, but the majority withdrew before randomization. Eight amputees were randomized, and only five completed the trial. The other reports/studies revealed by the search were small comparative non-randomized studies or case series with less than 10 participants each. *None of the articles were selected for critical appraisal.*

The use of microprocessor-controlled lower limb prostheses in the treatment of lower limb amputation does not meet the *Group Health Medical Technology Assessment Criteria*.

## 10/18/2010: MTAC REVIEW

### Lower Limb Prostheses

**Evidence Conclusion:** *Energy expenditure* - Two studies investigated the use of microprocessor-controlled prosthetics and non-microprocessor controlled prosthetics with respect to energy expenditure. Both studies used a non-randomized, non-blinded cross-over design. The first study found no significant difference in energy efficiency; however, there was an increase in physical activity related energy expenditure when subjects used the microprocessor-controlled prosthetic (Kaufman 2008). The second study compared energy expenditure at self-selected typical and fast walking paces on a motorized treadmill. There was no significant difference in heart rate at either pace; however, when subjects used the microprocessor-controlled prosthetic there was a small, but statistically significant decrease in energy expenditure (Seymour 2007). *Walking speed and dynamics* - Seymour and colleagues also found that on a standardized walking obstacle course when subjects wore the microprocessor-controlled prosthetic they were significantly faster, took less steps, and had less step-offs than when they used the non-microprocessor controlled prosthetic (Seymour 2007). Another study found that when subjects wore the microprocessor-controlled prosthetic walking speeds on a variety of surfaces improved and self-reported falls and stumbles decreased (Kahle 2008). Significant improvements in stair decent, hill decent time, hill affected side step length, and falls/stumbles were also found when subjects used a microprocessor-controlled prosthetic compared to when they used a mechanical prosthetic (Hafner 2007). Additionally, after receiving the microprocessor-controlled limb, subjects demonstrated significant improvements in gait and balance (Kaufman 2007). *Preference* - In a survey of 368 amputees, the majority of participants reported improvements with the microprocessor-controlled prosthetic compared to the non-microprocessor controlled prosthetic with regard to comfort, security, maneuverability, cosmetic attributes, adverse events, and safety (Berry 2009). The prosthesis evaluation questionnaire (PEQ) measures subjective prosthesis function and prosthesis-related quality of life. Three studies found improvement in PEQ scores when subjects used the microprocessor-controlled prosthetic (Hafner 2007, Kahle 2008, Kaufman 2008).

**Conclusion:** As the majority of the published studies to date are small and non-randomized it is hard to draw firm conclusions regarding the superiority of microprocessor-controlled prosthetics compared to non-microprocessor controlled prosthetics; however, results from the above studies suggest that the microprocessor-controlled prosthetics decreased energy expenditure, improved walking speed and dynamics, and improved PEQ scores.

**Articles:** The literature search revealed several studies that compared non-microprocessor controlled prosthetics and microprocessor controlled prosthetics. The majority of the studies were small comparative non-randomized studies or case series with less than 20 participants. Studies with more than 10 participants were reviewed. One randomized trial was identified; however, it was not selected for review as it included only 8 participants. The following studies were critically appraised: Berry D, Olson MD, and Larntz K. Perceived stability, function, and satisfaction among transfemoral amputees using microprocessor and non-microprocessor controlled knees: a multicenter survey. *J Prosthet Orthot* 2009; 21:32-42. [See Evidence Table](#). Hafner BJ, Willingham LL, Buell NC, et al. Evaluation of function, performance, and preference as transfemoral amputees transition from mechanical to microprocessor control of the prosthetic knee. *Arch Phys Med Rehabil* 2007; 88:207-217. [See Evidence Table](#). Kahle JT, Highsmith MJ, and Hubbard SL. Comparison of non-microprocessor knee mechanism versus C-Leg® on prosthesis evaluation questionnaire, stumbles, falls, walking tests, stair descent, and knee performance. *J Rehabil Res Dev* 2008; 45:1-14. [See Evidence Table](#). Kaufman KR, Levine JA, Brey RH, et al. Gait and balance of transfemoral amputees using passive mechanical and microprocessor-controlled prosthetic knees. *Gait Posture* 2007; 26:489-493. [See Evidence Table](#). Kaufman KR, Levine JA, Brey RH, et al. Energy expenditure and activity of transfemoral amputees using mechanical and microprocessor-controlled prosthetic knees. *Arch Phys Med Rehabil* 2008; 89:1380-1385. [See Evidence Table](#). CPT: L5000; L5010; L5020; L5050; L5060; L5100; L5105; L5150; L5160; L5200; L5210; L5220; L5230; L5250; L5270; L5280; L5301; L5312; L5321; L5331; L5341; L5400; L5410; L5420; L5430; L5450; L5500; L5505; L5510; L5520; L5530; L5535; L5540; L5560; L5570; L5580; L5585; L5590; L5595; L5600; L5610; L5611; L5613; L5614; L5616; L5617; L5618; L5620; L5622; L5624; L5626; L5628; L5629; L5630; L5631; L5632; L5634; L5636; L5637; L5638; L5639; L5640; L5642; L5643; L5644; L5645; L5646; L5647; L5648; L5649; L5650; L5651; L5652; L5653; L5654; L5655; L5656; L5658; L5661; L5665; L5666; L5668; L5670; L5671; L5672; L5673; L5676; L5677; L5678; L5679; L5680; L5681; L5682; L5683; L5684; L5685; L5686; L5688; L5690; L5692; L5694; L5695; L5696; L5697; L5698; L5699; L5700; L5701; L5702; L5703; L5704; L5705; L5706; L5707; L5710; L5711; L5712; L5714; L5716; L5718; L5722; L5724; L5726; L5728; L5780; L5781; L5782; L5785; L5790; L5795; L5810; L5811; L5812; L5814; L5816; L5818; L5822; L5824; L5826; L5828; L5830; L5840; L5845; L5848; L5850; L5855; L5856; L5857; L5858; L5859; L5910; L5920; L5925; L5930; L5940; L5950; L5960; L5962; L5964; L5966; L5968; L5969; L5970; L5971; L5972; L5973; L5974; L5975; L5976; L5978; L5979; L5980; L5981; L5982; L5984; L5985; L5986; L5987; L5988; L5990; L5999; L8400; L8410; L8417; L8420; L8430; L8440; L8460; L8470; L8480; L8499

## Clinical Review Criteria

### Low Vision Aides and Devices

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Per Noridian [2013 Jurisdiction List for DMEPOS HCPCS](#) Codes - Low Vision Aides and Devices are not covered.

##### For Non-Medicare Members

- A. To qualify for low vision aides or devices a member must have best corrected vision of 20/70 or worse in the better eye with glasses or contacts on.
1. The following codes are identified and coverable per contract for low vision aides and devices:
    - o **V2600** – Hand held low vision aides and other non-specific mounted aids.
    - o **V2610** – Single Lens Spectacles mounted low vision aids
    - o **V2615** – Telescope and other compound lens system, including distance vision telescopic, near vision telescopic and compound microscopic lens system.
    - o **92354** – Fitting of spectacle mounted low vision aid: single element system
    - o **92355** – Fitting of spectacle mounted low vision aid: Telescopic or compound lens system

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

A wide variety of rehabilitation options are available to help people with low vision live and/or work more effectively, efficiently, and safely. Most people can be helped with one or more low vision treatment options. The more commonly prescribed devices are: Hand held low vision aides and other nonspectacle mounted aids, Single lens spectacle mounted low vision aids, Telescopic and other compound lens system, including distance vision telescopic, near vision telescopes and compound microscopic lens system.

## Clinical Review Criteria

### Laparoscopic Uterine Nerve Ablation (LUNA) for Dysmenorrhea

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Non-Medicare Members

Group Health has elected to use the Laparoscopic Uterosacral Nerve Ablation (LUNA) (A-0284) MCG\* 20<sup>th</sup> edition for medical necessity determinations.

**\*MCG manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Last 6 months of clinical notes from requesting provider &/or specialist

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Dysmenorrhea refers to painful cramping in the lower abdomen that occurs during or just before the menses. The cramping sensation is often accompanied by other symptoms, including sweating, headaches, nausea and vomiting. Dysmenorrhea is sometimes divided into two sub-categories. Primary dysmenorrhea is menstrual pain without any identifiable organic pathology and generally first occurs in women younger than 20. Secondary dysmenorrhea is menstrual pain associated with an identifiable pathological condition, such as endometriosis, cervical stenosis or pelvic adhesions, and is most often seen in women over 20 (Stenchever, 2001).

Non-steroidal anti-inflammatory drugs (NSAIDs) are the standard therapy for primary dysmenorrhea. These act by suppressing prostaglandin levels. Although the pathogenesis of primary dysmenorrhea is still not known, there is a close association between dysmenorrhea symptoms and an elevated level of prostaglandin F2a. Oral contraceptive pills (OCPs) are also a commonly prescribed medication treatment for primary dysmenorrhea. OCPs may relieve dysmenorrhea because of a modulating effect on the hypothalamus or a direct reduction in the amount of endometrium present (Stenchever, 2001). Treatment of secondary dysmenorrhea generally involves treating the underlying condition.

Pelvic nerve surgery can be used to treat primary dysmenorrhea that fails to respond to medical therapy, and can be used in conjunction with other surgical procedures for secondary dysmenorrhea, such as operative laparoscopy for endometriosis. Laparoscopic uterine nerve ablation (LUNA) involves the use of laser or cauterization to destroy nerves in the uterosacral ligaments, at the point where they insert into the cervix. Doyle first reported that vaginal transection of the uterosacral nerves could be effective for dysmenorrhea in 1955. LUNA is generally associated with few side effects. Potential rare complications include uterine prolapse and bladder dysfunction. There is also a second type of pelvic nerve surgery, laparoscopic presacral neurectomy (LPN). This involves the total removal of the presacral nerves that lie within the boundary of the interiliac triangle and is generally believed to have more side effects than LUNA. More radical surgery, such as hysterectomy, is the treatment of last resort for patients with persistent dysmenorrhea (Proctor et al., 2006; Johnson et al., 2004).

LUNA for dysmenorrhea has not been previously reviewed for MTAC.

#### Medical Technology Assessment Committee (MTAC)

Date Sent: February 28, 2017

## Laparoscopic Uterine Nerve Ablation

### 04/03/2006: MTAC REVIEW

**Evidence Conclusion:** Evidence from the two largest and highest quality RCTs (Johnson et al., 2004; Vercellini et al., 2003) suggests that laparoscopic uterine nerve ablation (LUNA) is not an effective treatment for secondary dysmenorrhea (dysmenorrhea among women with symptoms of endometriosis). The Vercellini study was limited by lack of an intention to treat analysis on pain outcomes. There is insufficient evidence to draw conclusions about laparoscopic uterine nerve ablation (LUNA) as a treatment for primary dysmenorrhea. There is evidence from only one well-done RCT comparing LUNA to a control group (Johnson et al., 2004). However, this study was designed to evaluate LUNA for pelvic pain, not specifically dysmenorrhea. The study included some women who did not present with dysmenorrhea and results were not stratified according to baseline dysmenorrhea status. There were four main pain outcomes. In addition to dysmenorrhea, these were non-menstrual pelvic pain, deep dyspareunia and dyschezia. In the intention to treat analysis, the Johnson study found one statistically significant outcome at  $p < 0.05$ . This was reduction in dysmenorrhea, favoring the LUNA group ( $p = 0.045$ ). If the investigators had adjusted for multiple comparisons (i.e. the four primary pain outcomes), the difference in treatment success between the LUNA and control groups would not have been statistically significant.

**Articles:** There was a Cochrane Collaboration systematic review on surgical interruption of pelvic nerve pathways for dysmenorrhea. The Cochrane literature search identified two high-quality RCTs on LUNA for dysmenorrhea. These two RCTs, which were also identified in the Medline search, were critically appraised. The remainder of the RCTs identified by Cochrane were small and had methodological flaws. The Cochrane Collaboration investigators searched the literature through June, 2004. No RCTs on LUNA for dysmenorrhea were identified that were published after the Cochrane search data. *The RCTs reviewed were:* Johnson NP, Farquhar CM, Crossley S et al. A double-blind randomized controlled trial of laparoscopic uterine nerve ablation for women with chronic pelvic pain. BJOG 2004; 111: 950-959. See [Evidence Table](#)

The use of laparoscopic uterine nerve ablation in the evaluation of dysmenorrhea does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Lung Transplant

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Must be provided by a Medicare certified provider and meet the provider criteria for eligibility.

See [Medicare Approved Transplant Programs](#)

##### For Non-Medicare Members

Group Health has elected to use the Inpatient and Surgical Care Guidelines Clinical Indications for Lung Transplant (S-1300) (MCG)\* for medical necessity determinations.

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed for heart transplant eligibility, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Copy of final summary report from multidisciplinary transplant team

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Lung transplant is a last resort treatment for end stage lung disease. The first human transplant was conducted in 1965. The first successful single lung transplant was done in 1983.

The diseases treated by lung transplants include:

- chronic obstructive pulmonary disease (COPD), including emphysema;
- idiopathic pulmonary fibrosis;
- cystic fibrosis;
- idiopathic (formerly known as "primary") pulmonary hypertension;
- alpha 1-antitrypsin deficiency;
- replacing previously transplanted lungs that have since failed;
- other causes, including bronchiectasis and sarcoidosis.

Prior to 2005, donor lungs were allocated by the United Network for Organ Sharing on a first-come, first-serve basis to patients on the transplant list. This was replaced by the current system, in which prospective lung recipients of age of 12 and older are assigned a lung allocation score or LAS, which takes into account various measures of the patient's health. The new system allocates donated lungs according to the immediacy of need rather than how long a patient has been on the transplant list. Patients who are under the age of 12 are still given priority based on how long they have been on the transplant waitlist. The length of time spent on the list is also the deciding factor when multiple patients have the same lung allocation score.

Patients who are accepted as good potential transplant candidates must carry a pager with them at all times in case a donor organ becomes available. These patients must also be prepared to move to their chosen transplant center at a moment's notice and relocate to within close proximity of the center. Such patients may be encouraged to limit their travel within a certain geographical region in order to facilitate rapid transport to a transplant center.

## Evidence and Source Documents

The scientific literature is periodically reviewed and patient selection criteria are updated when new efficacy data becomes available.

Group Health Committee on Medically Emerging Technology:

Transplant, Lung, Double-7/12/91-Double lung transplantation is efficacious for appropriately selected patients.

Transplant, Lung, Single-7/12/91 Single lung transplantation is efficacious for appropriately selected patients.

## Clinical Review Criteria

### Lung Volume Reduction Surgery (Reduction Pneumoplasty)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

National Coverage Determination (NCD)

[Lung Volume Reduction Surgery \(Reduction Pneumoplasty\) \(240.1\)](#)

##### For Non-Medicare Members

Medical necessity review is no longer required for this service.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Lung Volume Reduction Surgery (LVRS) is a general term that includes several surgical techniques used to treat chronic obstructive lung disease (COPD) due to emphysema. LVRS and similar surgical procedures are based on the premise that patients with severe emphysema have lungs that have become too large relative to their chest size. In LVRS, 20-30% of a patient's lungs are removed. Alternatives to surgery (medical management) include smoking cessation interventions, bronchodilators, anti-inflammatory agents, oxygen, mucolytic drugs, antibiotics, pulmonary exercise rehabilitation and  $\alpha_1$ -antitrypsin replacement therapy in deficient patients.

LVRS was first reported in 1957, but lack of objective evidence of benefit and an operative mortality rate of 18% prevented the procedure from becoming accepted at that time. Renewed interest in the procedure was generated by the work of Cooper and co-workers who began performing LVRS in 1993 with no operative mortality in their initial report; their first peer-reviewed manuscript on LVRS was published in 1995. Also in 1995, staff for the US Health Care Financing Administration (HCFA), decided that there was insufficient evidence about the effectiveness of LVRS to have this procedure covered by Medicare. Instead, HCFA decided to fund a randomized controlled trial, the National Emphysema Treatment Trial or NETT.

MTAC initially reviewed LVRS in 2000, before completion of the NETT. Results of the NETT were published in May, 2003 and will be evaluated in the current review. The LVRS technique considered in this review is the procedure included in the NETT, the bilateral stapled procedure.

#### Medical Technology Assessment Committee (MTAC)

##### *Lung Volume Reductions Surgery in the treatment of Chronic Obstructive Lung Disease*

##### **06/14/2000: MTAC REVIEW**

**Evidence Conclusion:** Recent studies do not provide sufficient evidence to make conclusions about the efficacy of LVRS in improving lung function and survival in patients with COPD, due to emphysema. There is still a lack of evidence about the effectiveness of LVRS compared to medical management. In addition, in the published studies the issue of LVRS efficacy is confounded by pulmonary rehabilitation. Most surgical patients also received rehabilitation; without a control group of patients who did not receive surgery, it is not possible to know whether intervention effects were due to LVRS or rehabilitation. The one RCT (Criner et al., 1999) that purported to examine LVRS compared to medical treatment (in this case, pulmonary rehabilitation) had serious flaws. The two intervention groups were not compared in analysis, patients in the LVRS group did not all receive the same intervention (some had 3 additional months of rehabilitation), and the sample size was small (total n=37). The Meyers et al. (1998) study gathered information from patients who were and were not approved by Medicare to receive LVRS. The Meyers study provides weak evidence of improved outcomes with LVRS; threats to validity include selection bias (patients were not randomized and could choose surgery if they could afford it), the lack of consistent medical management in the comparison group and the small number of patients who did not receive surgery (n=22).

**Articles:** The literature search yielded 97 articles. Articles were selected based on study type and relevancy to the purpose of this review. Articles were excluded that were reviews or commentaries, examined technical aspects of the LVRS procedure, or were case series with small samples sizes (<50). Also excluded were articles that compared laser vs. stapled LVRS, or unilateral vs. bilateral LVRS because this review was limited to bilateral stapled LVRS. *Articles selected for critical appraisal include:* An RCT comparing LVRS to pulmonary rehabilitation: Criner, GJ, Cordova, FC, Furukawa, S, Kuzma, AM, Travaline, JM, Leyenson, V, O'Brian, GM. Prospective randomized trial comparing bilateral lung volume reduction surgery to pulmonary rehabilitation in severe chronic obstructive pulmonary disease. Am J Respir Crit Care Med 1999; 160: 2018-2027. See [Evidence Table](#). A meta-analysis of case series studies: Young, J, Fry-Smith, A, Hyde, C. Lung volume reduction surgery (LVRS) for chronic obstructive pulmonary disease (COPD) with underlying severe emphysema. Thorax 1999; 54: 779-89. See [Evidence Table](#). A cohort study comparing LVRS candidates who did and did not receive LVRS due to changes in Medicare coverage policy: Meyers, BF, Yusen, RD, Lefrak, SS, Patterson, GA, Pohl, MS, Richardson, VJ, Cooper, JD. Outcome of medicare patients with emphysema selected for, but denied, a lung volume reduction operation. Ann Thorac Surg 1998; 66: 331-6. See [Evidence Table](#). A large case series study of bilateral, staple LVRS with longer-term follow-up: Brenner, M, McKenna, RJ, Chen, JC, Osann, K, Powell, L, Gelb, AF, Fischel, RJ, Wilson, AF. Survival following lung volume reduction surgery for emphysema. Chest 1999; 115: 390-396. See [Evidence Table](#).

The use of Lung Volume Reductions Surgery in the treatment of Chronic Obstructive Lung Disease due to emphysema does not meet the *Group Health Medical Technology Assessment Criteria*.

**04/14/2004: MTAC REVIEW**

**Lung Volume Reductions Surgery in the treatment of Chronic Obstructive Lung Disease**

**Evidence Conclusion:** The best evidence is from the National Emphysema Treatment Trial (NETT), a large randomized controlled trial comparing LVRS in addition to pulmonary rehabilitation and medical management to pulmonary rehabilitation and medical management alone. The main findings of the study were that there was no overall difference in mortality between the two groups, but there was a greater improvement in exercise capacity at 2 years with LVRS than medical treatment. There were also better outcomes in health-related quality of life, distance walked in 6 minutes, percentage of the predicted value for FEV<sub>1</sub>, and degree of dyspnea in the LVRS group (with high-risk patients excluded). A limitation of the study design was that it was not-blinded which could introduce bias, especially for subjective outcomes such as quality of life. The authors defined four subgroups by location of emphysema and exercise capacity. Compared to the medical treatment group, there was a lower mortality rate in patients with predominantly upper lobe-emphysema and low-exercise capacity who received LVRS, and a higher mortality rate in patients with predominantly non-upper-lobe emphysema who had high exercise capacity. There were no significant differences in mortality in the other two sub-groups. These sub-group findings can be considered preliminary and would need to be confirmed in additional studies.

**Articles:** The search yielded 183 articles, many of which were reviews, editorials or commentaries. There were three randomized controlled trials; the National Emphysema Treatment Trial with more than 1200 participants and two smaller RCTs, each with fewer than 100 individuals. The NETT was critically appraised. National Emphysema Treatment Trial Research Group. A randomized trial comparing lung-volume-reduction surgery with medical therapy for severe emphysema. N Engl J Med 2003; 348: 2059-2073. (Methodological information taken from earlier NETT publications) See [Evidence Table](#).

The use of Lung Volume Reductions Surgery in the treatment of Chronic Obstructive Lung Disease due to emphysema does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Lymphedema Therapy

- Comprehensive Decongestive Therapy (CDT) Training for Lymphedema
- Lymphatic Venous Anastomosis (LVA) for the Treatment of Lymphedema

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None
Local Coverage Article	<a href="#">Lymphedema Decongestive Treatment (A52959)</a> . Used for services billed with HCFA 1500. <a href="#">Lymphedema Decongestive Treatment (A52958)</a> . Used for services billed with on a UB

##### For Non-Medicare Members

##### Comprehensive Decongestive Therapy (CDT):

- A. For members to qualify for Comprehensive Decongestive Therapy (CDT) they must meet **ALL of the following**:
1. The treating or consulting practitioner (within the scope of their practice) documents a diagnosis of primary or secondary lymphedema and specifically orders CDT training. Primary lymphedema is a relatively uncommon, chronic condition that may be due to such causes as Milroy's Disease or congenital anomalies. Secondary lymphedema, which is much more common, results from the destruction of or damage to formerly functioning lymphatic channels. This includes surgical removal of lymph nodes, post radiation fibrosis, or other conditions that result in destruction or obstruction of lymphatic channels. There are other forms for secondary lymphedema that are not covered. GHC will only cover CDT for surgical removal or radiation of lymph nodes.
  2. The presence of lymphedema must be documented. CDT training is not covered prophylactically.
  3. Documentation that the lymphedema is not reversible by exercise or elevation of the affected area.
  4. The patient or patient's caregiver has the ability to understand and provide home-based CDT. The goal of the CDT training is to promptly transfer responsibility for on-going CDT to the patient or patient caregiver.
  5. CDT training services must be performed by a licensed PT or OT that has received specific training for this service.
  6. The frequency and duration of services must be necessary and reasonable. CDT training services are comprised of 8-10 sessions over a 2-4 week period. In the event that treatment is interrupted by chemotherapy or radiation therapy the course of treatment can be adjusted to accommodate for this interruption.

The goal of therapy is not to achieve maximum volume reduction but to ultimately transfer the responsibility for the care from the provider to the patient and/or caregiver, generally within a 1-3 week time period. There is only temporary benefit from the treatment unless the patient and/or caregiver are able to complete treatments at home on an ongoing basis. The end of treatment is not when the edema resolves or stabilizes but when the patient and/or caregiver are able to continue the treatments at home. The key issue is whether the skills of a therapist are needed, or whether the services can be carried out by the patient and/or caregiver after sufficient training. The medical record must clearly indicate the patient's condition before, during, and after the therapy episode to support that the patient significantly benefitted from ongoing therapy services and that the progress

was sustainable and of practical value when measured against the patient's condition at the start of treatment. Documentation should indicate clear objective evidence of improvement generally within the first week or 10 days of therapy (changes in weight, extremity circumference, etc.).

CDT Training should include instruction in assessment for lymphedema, manual decompressive therapy techniques and the application of compressive bandages or garments if applicable.

A CDT course of training is generally expected to occur no more than once per lifetime. In general, refresher training will be 1-2 sessions to review CDT techniques.

Please note: While some Comprehensive Decongestive Therapy will be provided by the therapist initially in the course of training, CDT is covered only when it is being provided for the purposes of training. If CDT is requested for ongoing-treatment for lymphedema (not for training in CDT technique) this would be considered maintenance therapy and is not covered.

Denial of coverage should be considered when any of the following are true:

- 1) Therapy is limited to exercise or elevation of the affected area and is not CDT.
- 2) Therapy does not include ongoing patient education.
- 3) Therapy treatment is designed principally for temporary benefit.
- 4) The patient or patient caregiver does not have the capacity to learn CDT techniques within a reasonable amount of time.

### **Lymphatic Venous Anastomosis (LVA) for the Treatment of Lymphedema:**

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## **Background**

Lymphedema is an accumulation of protein-rich fluid that occurs when lymphatic drainage is interrupted, usually due to lymph node dissection or radiation or both. A smaller number of patients develop primary lymphedema, which has a genetic basis. In women with breast cancer the risk of developing lymphedema increases with irradiation of the axilla and the extent of axillary dissection. Affected patients can experience pain, swelling, tightness and heaviness, and recurrent skin infections. Lymphedema remains a problem even with modern treatment modalities. There is a lack of prospective randomized trials evaluating the different treatment options for lymphedema. The strongest evidence available supports the use of compression garments. There is some evidence to support the use of complex decongestive physiotherapy, which is a treatment regimen that includes meticulous skin hygiene, manual lymph drainage, bandaging, exercises, and compression garments. Several physical and occupational therapists throughout the Group Health system have received training in the use of complex decongestive physiotherapy.

The goal of therapy is not to achieve maximum volume reduction but to ultimately transfer the responsibility for the care from the provider to the patient and/or caregiver, generally within a 1-3 week time period. There is only temporary benefit from the treatment unless the patient and/or caregiver are able to complete treatments at home on an ongoing basis. The end of treatment is not when the edema resolves or stabilizes but when the patient and/or caregiver are able to continue the treatments at home. The key issue is whether the skills of a therapist are needed, or whether the services can be carried out by the patient and/or caregiver after sufficient training. The medical record must clearly indicate the patient's condition before, during, and after the therapy episode to support that the patient significantly benefitted from ongoing therapy services and that the progress was sustainable and of practical value when measured against the patient's condition at the start of treatment. Documentation should indicate clear objective evidence of improvement generally within the first week or 10 days of therapy (changes in weight, extremity circumference, etc.).

Medicare B Issues Notice 177, Page 14, 15, 16

### ***Lymphatic Venous Anastomosis (LVA) for the Treatment of Lymphedema*** **BACKGROUND**

Lymphedema is a condition of localized fluid retention and tissue swelling caused by impairment of the lymphatic transport capacity. Primary lymphedema occurs in patients with a congenital dysfunction or abnormality of the lymphatic system, while secondary lymphedema is an acquired condition that results from disruption or obstruction of the normal lymphatic system. The most common cause of secondary lymphedema in the U.S. is malignancies and their related treatment. The overall incidence of arm lymphedema can range from 8% to 56% within 2 years following surgery for breast cancer, depending on the extent of axillary node dissection and the use of radiotherapy. Breast cancer-related lymphedema (BCRL) is characterized by an abnormal accumulation of lymph in the interstitial spaces leading to swelling in the affected arm, shoulder, neck, breast, thoracic area, or any combination of these. The condition may develop gradually or suddenly, and can cause physical discomfort, pain, impaired function, and emotional distress (Damstra 2009, Fu 2009, Haghghat 2010).

There is no cure for lymphedema in terms of total subsidence of edema and restoration of the shape of the extremity. It may however, be controlled by a combination of conservative treatments that include meticulous skin care, manual lymph drainage, multilayer compression bandage, elastic compression garments, specialized massages, and physical therapy. The goal of these treatment modalities is to reduce capillary filtration, and improve drainage of interstitial fluid and macromolecules, which in turn reduces swelling, inflammation, and improves the quality of life. The effectiveness of conservative therapies is dependent on strict patient compliance, which is often poor due to the complex treatment regimens, and the life-long use of uncomfortable compressive garments that is required to prevent progression of the lymphedema (Olszewski 1988, Damstra 2009).

Surgical management of lymphedema is usually reserved for patients who are refractory to conventional measures. Traditional surgical management of lymphedema is divided into two categories: excisional and physiologic. Excisional or debulking surgery decreases the limb volume by resection. Complications associated with this type of surgery include poor wound healing, extensive scarring, ulceration, poor cosmetic outcome, sensory nerve damage, and worsening of edema. Surgical techniques that aim at restoring physiologic lymphatic function include lympho-venous-lymphatic (LVL) transplant, lymph vessels transplantation, and lymphovenous anastomosis (LVA) which is the most commonly used technique (Damstra 2009, Avraham 2010).

Lymphaticovenous shunt was first described for the surgical treatment of lymphedema by Nielubowicz and Olszewski in 1968. Since then, several modifications have been made, and different microsurgical techniques of the lymphatic venous anastomosis (LVA) were described. LVA involves anatomizing lymphatic vessels to a collateral branch of the main vein. The technique described by Campisi and colleagues (2010) involves performing multiple microsurgical LVA, by directly introducing healthy appearing lymphatics (at the site of the surgical operation) together into the vein by a U shaped stitch, then fixing them to the cut end of the vein by means of additional stitches between the vein border and the perilymphatic adipose tissue. With the use of Patent Blue dye, properly functioning lymphatics appear blue, and the passage of blue lymph into the vein branch verifies the patency of the LVA under the operating microscope when the anastomosis is completed. For upper limb lymphedema, LVA is performed at the medium third of the flexor surface of the arm, using both superficial and deep lymphatic collectors, evidenced by the blue dye (Campisi 2001, 2010 Avraham 2010).

## Medical Technology Assessment Committee (MTAC)

### Lymphatic Venous Anastomosis

#### 06/20/2011: MTAC REVIEW

**Evidence Conclusion:** There is insufficient published evidence to determine the efficacy and safety of lymphatic venous anastomosis in the treatment breast cancer-related lymphedema.

**Articles:** The literature on the on lymphatic venous anastomosis (LVA) for the treatment of breast cancer-related lymphedema (BCRL) is very limited; the search did not reveal any meta-analyses or randomized controlled trials that evaluated efficacy or safety of the procedure. The empirical study published on the LVA for the treatment (BCRL) was a small case series with ten patients.

The use of lymphatic venous anastomosis (LVA) for the treatment of post-breast cancer lymphedema does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Magna Bloc™ Technology for Low-Back Pain

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies (and/or) provides better long term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The Magna Bloc™ is a non-pharmacologic, noninvasive magnetic device, approximately 3.5cm in diameter. It contains four magnets arranged in alternating polarity that, according to the manufacturer (Holcomb Health Care, Nashville, TN), creates a very steep three-dimensional field gradient that differentiates Magna Bloc™ from other magnetic devices. The manufacturer states that the “steep three-dimensional field gradient is responsible for biological effects such as calcium and sodium channel blockade, stabilization of abnormal cell function...and effects on certain enzyme systems”. Magna Bloc™ is currently being studied at Vanderbilt University for the treatment of refractory pain syndromes.

#### Medical Technology Assessment Committee (MTAC)

##### Magna Bloc™ Technology

##### 10/09/2002: MTAC REVIEW

**Evidence Conclusion:** There is insufficient evidence to determine the effectiveness of Magna Bloc Technology for the treatment of low-back pain.

**Articles:** The search yielded 3 articles on the treatment of pain with static magnetic fields. There was a case report (n=2) and two randomized controlled trials (RCTs). One of the RCTs studied a different magnetic technology (magnetic sleep pads) for the treatment of fibromyalgia. The other RCT examined the efficacy of the Magna Bloc™ device for treating rheumatoid arthritis of the knee. Magna Bloc™ was not found to be more effective than a sham device. There were no studies on the use of Magna Bloc™ technology for treating back pain.

The use of Magna Bloc™ Technology in the treatment of low-back pain does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Medicare Members

Local Coverage Determination (LCD)

[Non-Covered Services \(L35008\)](#)

And for facility-based services billed using a UB form, see [Non-Covered Services \(L34886\)](#)

##### For Non-Medicare

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies (and/or) provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Uterine fibroids (or leiomyoma) are benign tumors of the uterus with a rich blood supply that may cause excessive bleeding and pelvic pain. The prevalence of uterine fibroids is estimated to be 20-40% in women older than 35. Hysterectomy is the standard permanent treatment for women who do not have a strong desire to retain their uterus. Other treatments include watchful waiting, medical management with hormonal therapy, myomectomy (local surgical removal) and uterine artery embolization (UAE). UAE is covered for GHC members when recommended by a GHC physician.

The ExAblate 2000 system (Insightec Ltd., Israel) is a minimally invasive, uterine-sparing treatment for uterine fibroids. The system is used in conjunction with a commercially available MRI scanner, the GE Signa 1.5T MR imaging system. A special coil is required to use the GE device with the ExAblate system. The MRI is used for planning, and also for monitoring during the procedure. The treatment is also known as MR guided focused ultrasound (MRI-FUS or MRgFUS).

During the procedure, focused ultrasound waves heat the targeted fibroid tissue to approximately 65-85o C. causing cell necrosis. Over time, the necrotic tissue is absorbed by the body. The treatment can take several hours, and it requires collaboration between a gynecologist and a radiologist.

The ExAblate system was approved by the FDA in October, 2004 for ablation of uterine fibroid tissue in pre- or peri- menopausal women with symptomatic uterine fibroids who want a uterine sparing procedure. Patients must have a uterine size of <24 weeks' gestation and have completed child-bearing. Prior to commercial availability in the U.S., the ExAblate system was used in Europe (since 2002) and, to a limited extent, in Japan.

The ExAblate 2000 technology for ablation of uterine fibroids has not been reviewed previously by MTAC.

#### Medical Technology Assessment Committee (MTAC)

##### *Magnetic Resonance Guided Focused Ultrasound in the Treatment of Uterine Fibroids*

**06/04/2008: MTAC REVIEW**

**Evidence Conclusion:** In the FDA pivotal study in which 109 women were treated using the ExAblate 2000 technology (Stewart et al., 2006), there was a statistically significant improvement in self-reported symptoms pre- and post-treatment. The Funaki et al. (2007) case series did not report pre- and post-comparisons. 25 out of 69

women (53%) reported improving a great deal or being symptom-free 3 months after being treated. An additional 17 women (28%) said their symptoms were somewhat improved. In both studies, the main outcomes were self-report measures. A sham or comparison group is needed in this type of study to evaluate the extent to which treatment with ExAblate had a placebo effect on women's perception of their symptoms. None of the published studies focused on objective health outcomes such as bleeding or anemia. There is insufficient evidence to draw conclusions about the safety and effectiveness of the ExAblate 2000 technology for ablation of uterine fibroids. The empirical literature consists of case series. There are no studies comparing this technology to sham treatment or other accepted treatments such as UAE and myomectomy.

**Articles:** The Medline search yielded 35 articles. There was also an unpublished FDA document from October 2004, entitled, "Summary of safety and effectiveness data". The pivotal study submitted by InSightec to the FDA was a cohort study with n=109 receiving MRI-FUS with ExAblate and n=83 receiving hysterectomy. The FDA document describes pre- and post-treatment findings in each group, but does not present statistical comparisons comparing results in the two groups. Several subsequent published articles described subjective treatment effects in the 109 patients who received ExAblate in the FDA pivotal study. These include Hindley et al., 2004 (short-term outcomes) and Stewart et al., 2006 (6- and 12- month outcomes). No published articles were identified that compared the ExAblate and hysterectomy groups in the FDA pivotal study. No published randomized or non-randomized controlled studies were identified that compared ExAblate to sham or to a less invasive alternative treatment such as uterine artery embolization or myomectomy. Two studies were identified that compared different protocols of MRI-FUS. One was a small study in which one of the two groups received a GnRh agonist pre-treatment and the other evaluated compared a standard and slightly modified treatment guideline with the ExAblate system. Stewart et al. also published an article in 2007 that combined and re-evaluated data from the FDA study and other case series sponsored by Insightec. This article included selected data and post-hoc analyses which can be misleading and thus was not evaluated further. The Stewart et al., 2006 study reporting the clinical outcomes from the FDA pivotal trial was critically appraised. In addition, a case series from Japan with a reasonably large sample size was critically appraised. References are: Stewart EA et al. Clinical outcomes of focused ultrasound surgery for treatment of uterine fibroids. *Fertil and Steril* 2006; 85: 22-29. See [Evidence Table](#).

The use of Magnetic resonance guided focused ultrasound in the treatment of uterine fibroids does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Massage Therapy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None

Medicare covers massage when delivered by a physical therapist as part of the rehabilitation plan of care. It is not covered when delivered by a massage therapist who is not licensed as a physical therapist.

#### For Non-Medicare Members

- A. Massage therapy is indicated when **ALL of the following** are met:
1. An assessment and diagnosis documents objective physical and functional limitations.
  2. It will have physical therapeutic benefits.
  3. It has been ordered by the treating physician.
  4. The condition or the level of function can be expected to improve significantly within a reasonable and generally predictable period of time with massage treatment.

OR

- B. The patient is terminally ill and the therapy is needed for comfort.

#### Massage therapy is not covered when:

1. It is provided for prevention, recreation (spa therapy) or stress reduction.
2. It is directed at the maintenance of current level of functioning.
3. The patient has achieved therapeutic goals or is not showing meaningful progress.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

This service is covered when it is described as a benefit in the consumer's coverage contract and the consumer receives a health plan referral. Special work groups that have included licensed massage therapists identified the clinical conditions and screening criteria in order to determine clinical appropriateness for the service.

Low back pain (LBP) is a major health problem in the modern society. More than two thirds of the population will experience low back pain at some time in their lives. LBP is usually benign and self-limiting; almost 90% of all patients with acute low back pain will get better quickly regardless of therapy. The remaining 10% may develop chronic back pain and disability.

LBP is associated with a complex dysfunction and impaired endurance of the paraspinal muscles. Different therapies including exercise and spinal manipulation are often recommended, yet their clinical effectiveness has not been documented. Research on the effectiveness of these therapies has yielded inconsistent results.

The use of massage therapy for back pain has a long history. Massage therapy may have the potential to increase the blood flow in the muscles, enhance muscle tone, reduce muscle fatigability, and improve muscle endurance. It may relax the mind and increase the pain threshold. Massage is considered a safe treatment with no risk or

adverse effects. It is, however, contraindicated when several other conditions are present, including acute inflammations, skin infections, unhealed fractures, and burns.

Massage is rubbing or kneading part of the body usually with the hands to stimulate circulation and make the muscles or joints more supple. It is also defined as soft tissue manipulation using the hands or a mechanical device. Massage can be applied to the lumbar region only or to the whole body. It is usually used as an adjunct therapy for other physical treatments; however, many massage therapists use it as the only intervention. Examples of soft tissue massage are Shiatsu, Rolfing, Swedish massage, reflexology, myofascial release, craniosacral therapy, and Bindegewebsmassage. Massage therapy is applied through various techniques including friction, kneading, hacking, petrissage, neuromuscular, trigger, and pressure points.

Massage therapists are licensed by the state of Washington. Licensure requires a minimum of 500 hours of training at an accredited school of massage therapy.

## Medical Technology Assessment Committee (MTAC)

### Massage Therapy in the Treatment of Chronic Neck and Back Pain

#### 11/2001: MTAC REVIEW

**Evidence Conclusion:** Two of the studies reviewed show that massage is an effective therapy for non-specific subacute and chronic low back pain (Cherkin, Preyde). Cherkin’s study did not compare massage to a placebo or no treatment. Preyde’s study, which compared massage to sham treatment, had a short follow-up duration. On the other hand, Pope et al found no significant difference between massage, spinal manipulation, corset, and transcutaneous muscle stimulation (TMS). Various confounding factors may affect the outcome of massage therapy including the type of massage given, number and duration of treatment sessions, experience of the therapists, size of massage area, amount of pressure, as well as the type of injury or problem, chronicity, level of stress, and other aggravating factors. Many of the studies reviewed did not address or adjust for these variables. Further research is needed to study the patients’ variables and to help ascertain which type of low back pain will respond best to massage therapy. Studies with a longer-term follow-up are also needed to determine the elements and techniques of massage therapy that will give the most benefit. Use of a control group with a placebo or no treatment would also strengthen the validity of the results.

**Articles:** The search yielded 32 articles. There were two systematic reviews, with no statistical pooling or meta-analysis due to the heterogeneity of the studies. There were eight randomized, controlled trials. Massage was the main therapy under investigation in only two of the RCTs revealed by the search. *The studies selected for critical appraisal were:* Cherkin, D., Eisenberg, D., et al. Randomized trial comparing traditional Chinese medical acupuncture, therapeutic massage, and self-care education for chronic low back pain. Arch Intern Med 2001; 161: 1081-1088 See [Evidence Table](#). Preyde, M., Effectiveness of massage therapy for subacute low-back pain: a randomized controlled trial. CMAJ 2000; 162: 1815-20 See [Evidence Table](#). Pope, M.H., et al. A prospective randomized three-week trial of spinal manipulation, transcutaneous muscle stimulation, massage, and corset in the treatment of subacute low back pain. Spine 1994; 22: 2571-2577 See [Evidence Table](#).

The use of massage therapy in the treatment of chronic neck and back pain meets the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Cardiac Ambulatory Monitoring For Extended Duration (Cardionet®, CardioNet ECG Monitor, eVolution ,Zio®Patch)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

See the [NCD Manual, Part 1 – Electrocardiographic Services](#), and the [NCD for Electrocardiographic Services \(20.15\)](#)

##### For Non-Medicare Members

Cardiac ambulatory monitoring includes the following devices:

- a) An external intermittent cardiac event monitor (i.e., external loop recorder)
- b) An external intermittent cardiac event monitor with real-time data transmission and analysis
- c) External ECG monitoring by continuous rhythm recording and storage (e.g. – ZioPatch)

Use of the above devices is considered medically necessary when **ONE of the following** is met:

- a. To evaluate syncope or episodic lightheadedness or to document an arrhythmia in persons with a non-diagnostic Holter monitor, or in persons whose symptoms occur infrequently (less frequently than daily) such that the arrhythmia is unlikely to be diagnosed by Holter monitoring **or**
- b. To document ST segment depression for suspected ischemia; **or**
- c. To document the benefit after initiating drug therapy for an arrhythmia; **or**
- d. To document the recurrence of an arrhythmia after discontinuation of drug therapy; **or**
- e. To document the results after an ablation procedure for arrhythmia;

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Cardiac rhythm abnormalities are common. Many are harmless, but some cause symptoms such as palpitation, chest pain, pre-syncope and syncope, and others may be a signal for potential stroke or cardiac arrest. Electrodiacardiographic (ECG) documentation of the cardiac rhythm during symptoms is necessary for making accurate diagnosis, therapeutic decisions, assessing the effectiveness of suppression, and monitoring adverse drug effects. However, symptoms of arrhythmia are often infrequent and episodic, and the underlying heart rhythm may not be detected during physical examination and routine ECG that permits a few seconds of recording. It is thus essential to have extended periods of ECG recording while the patients are pursuing their normal routine.

Devices used:

- *Holter monitors* are portable devices that record heart rhythms continuously for up to 48 hours. These devices are used to record events that occur at least once a day.

- *Non-implantable cardiac event monitors* are portable devices that record heart rhythms intermittently for up to 30 days. These devices capture ECG data before, during and after the time of activation.
- *Standard loop recorders* have just a few minutes of memory. Newer, more sophisticated devices have extended memory features that can store up to several hours of ECG data. Recording can be patient-activated when symptoms occur or automatically triggered based on a computer algorithm designed to detect arrhythmias. These devices are used to record infrequent or irregular events.
- *External mobile cardiovascular telemetry* consists of a monitor that continuously records the electrocardiographic rhythm from external electrodes placed on the patient's body. Segments of the ECG data are automatically (i.e., without patient intervention) transmitted to a remote surveillance location by cellular or landline telephone signal. The transmitted events are triggered automatically by preprogrammed algorithms or by the patient during a symptomatic episode. There is continuous, real-time data analysis in the device and attended surveillance of the transmitted rhythm segments by a surveillance center technician. The surveillance center technician reviews the data and notifies the physician depending on the prescribed criteria. These devices are used to record suspected asymptomatic arrhythmias.

The most commonly used method for extended ECG recording is the Holter monitor which records an ECG continuously for 24 to 48 hours via leads placed on the chest to yield 2 or 3 channels of ECG data. The Holter monitor provides complete rhythm recording and excellent quality tracing. However, it has a diagnostic yield of only 5-28% due to its limited time of recording which is usually too short to capture infrequent arrhythmias. In addition, some clinically important arrhythmias such as atrial fibrillation may be asymptomatic and pass unnoticed by the Holter recording (Kowey 2003, Naccarelli 2007, Rothman 2007, Saarel 2008).

External patient-activated loop event monitoring (LOOP) devices were found by researchers to improve the diagnostic yield of arrhythmias up to 63%. These may be used for up to 30 days; however, they have limited storage, and require appropriate patient activation during the occurrence of symptoms. Patient activation may be a difficult task for the elderly or those whose arrhythmias cause functional impairment. It was reported that one in four patients does not activate the recorder during symptomatic episodes despite the education received on operating the device. Developments are continuously being made to improve the diagnostic yield of the rhythm monitors. Newer loop recorders continually record and erase so that data gathered from 1 to 4 minutes before, and those recorded 30-60 seconds after activation of the device can be retained. Other loop monitors are automatically activated and start the recording once an abnormal rhythm of any kind is detected, without patient activation. An implantable form of continuous-loop event recorder is also currently available. It is a small device in the size of pacemaker that is implanted subcutaneously to the right or left side of the sternum, and is triggered by placing an activator over it. The device has a programmable antegrade and retrograde memory, and may be left in place for up to 18 months and can be explanted once the diagnosis is made or battery life has ended. Data from the device however, cannot be transmitted wirelessly (Zimetbaum 1999, Kowey 2003, Naccarelli 2007 Rothman 2007).

Mobile Cardiac Outpatient Telemetry (MCOT, Cardionet®, CardioNet device or recorder) was introduced in 1999 for continuous real-time ambulatory electrographic monitoring and analysis. The device consists of a three-electrode, and a two-channel sensor that transmits wirelessly to a small PDA sized portable monitor which can be clipped to the waist or worn on a strap around the neck. Rhythm strips are recorded continuously and analyzed by an automated arrhythmia analysis algorithm. When an arrhythmia is detected (according to the physicians'predesignated thresholds) the monitor can transmit the ECG data to the monitoring center utilizing a cellular modem or telephone data line. Patients are monitored for 24 hours/day for up to 30 days, by central station technicians with immediate referral to the prescribing physician for evaluation of rate and rhythm changes and their symptoms. The patient can also initiate the recording and transmission of ECG data if symptoms are felt. MCOT thus potentially improves diagnosis of arrhythmias by allowing continuous monitoring of

cardiac rhythm for extended periods of time, detecting asymptomatic arrhythmias, and allowing the patients to submit their symptoms and level of activity from a menu to the device (FDA web page, Rothman 2007, Naccarelli 2007).

The CardioNet ECG monitor was approved by the Food and Drug Administration in 2002 for cardiac monitoring for non-life-threatening arrhythmia detection, its evaluation, and monitoring of antiarrhythmic therapy.

## Medical Technology Assessment Committee (MTAC)

Date	Evidence Conclusion	Outcome
06/04/08	<p>The literature search revealed only one randomized controlled study (Rothman 2007), and several observational studies. Rothman and colleagues' study was a multicenter, randomized, controlled study that compared the diagnostic yield of the mobile cardiac outpatient telemetry (MCOT) system (CardioNet, USA) with the patient-activated external loop devices (LOOP). Patients with symptoms of syncope, pre-syncope or severe palpitations, and a nondiagnostic 24-hour Holter, were randomized to receive one of the two monitoring devices for up to 30 days. The patients and investigators were not blinded to the monitor received, but the electrophysiologist who reviewed the monitor strips and verified the diagnosis was blinded to the patient allocation. There was a higher noncompliance rate in the MCOT group, and 14% of all participants did not complete the study. The study compared the MCOT (CardioNet) system with the patient-activated external loop device and not to the auto-triggered or the implanted loop systems which are known to have better diagnostic yield.</p> <p>Overall, the results of the study show that diagnosis (confirmation or exclusion) of arrhythmias was made in 88% of the patients randomized to the MCOT group, vs. 75% of the patients in the LOOP group (P&lt;0.001). A significant difference was also observed for patients with syncope or presyncope, where a diagnosis was made in 89% of patients in the MCOT group vs. 69% in the LOOP group (p=0.008).</p> <p>Conclusion:</p> <ul style="list-style-type: none"> <li>• There is fair evidence from one RCT with limitations, that CardioNet system may have a higher diagnostic yield compared to the patient-activated external loop device for up to one month.</li> <li>• There is no published evidence to date to determine that the device is superior to the auto-triggered loop system that was found to have better diagnostic yield, or to the implanted loop system.</li> <li>• There is insufficient evidence to determine the efficacy and safety of the CardioNet system for detecting less frequent syncopal episodes.</li> <li>• There is insufficient evidence on the efficacy of CardioNet system in assessing the safety and efficacy of antiarrhythmic agents, or outpatient monitoring for medication titration and dose adjustments.</li> </ul>	The use of Mobile Cardiac Outpatient Telemetry (MCOT) in the detection of arrhythmias does not meet the Group Health <b>Medical Technology Assessment Criteria</b> .
08/03/09	<p>There is no new published evidence that would alter the conclusion of the previous MTAC review.</p> <p>The only published RCT (Rothman 2007) that compared mobile cardiac outpatient telemetry to LOOP event monitoring was reviewed earlier in 2008. The study was randomized, controlled and multicenter. However, it was not blinded, had a 14% drop-out rate, non-compliance was more common in the MCOT group, and analysis was not based on intention to treat. Moreover, the mobile cardiac outpatient telemetry (MCOT) system (CardioNet, USA) was compared with the patient-activated external looping event recorders. The study did not compare MCOT with the implanted loop recorders, and was not designed to compare it with the auto-trigger loop</p>	The use of Mobile Cardiac Outpatient Telemetry (MCOT) in the detection of arrhythmias does not meet the Group Health <b>Medical Technology Assessment Criteria</b> .

	<p>recorders which were used in only 16% of the patients in the LOOP group. Both the implanted and auto-trigger loop recorders are reported to have higher diagnostic yield than the patient activated loop recorders. Overall the results of the study indicate that MCOT was superior to loop recordings with a diagnosis made in 88% MCOT patients vs. 75% LOOP patients (p=0.008). A significant difference in the diagnostic yield was also observed for patients with syncope or presyncope (89% vs. 69% respectively, p=0.008).</p> <p>More recently only retrospective case series (Saarel 2008, and Tayal 2008) on the use of MCOT for the detection of suspected arrhythmias were published.</p> <p>Saarel and colleagues (2008) reported on the use of MCOT among 54 children and adolescents with suspected arrhythmia. Thirty three subjects transmitted ECGs during symptoms yielding a diagnostic rate of 61%. The remaining 21 (39%) failed to transmit ECG while experiencing symptoms. Comparing the diagnostic yield of MCOT with historical data from transtelephonic electrocardiographic event monitors (TTMs) showed no significant differences between the two systems.</p> <p>Tayal and colleagues (2008) performed a retrospective analysis of 56 patients with cryptogenic stroke (undetermined cause). This showed that MCOT detected 27 asymptomatic atrial fibrillation in thirteen patients (23%). 23 (85%) of these episodes were less than 30 seconds in duration, and the remaining 4 (15%) were 4-24 hours in duration.</p> <p>None of the published studies to date indicate that the MCOT (CardioNet system) is superior to the auto-trigger LOOP device currently used, or that it leads to an improvement in net health outcome.</p> <p>Conclusion:</p> <ul style="list-style-type: none"> <li>• There is fair evidence from one RCT with limitations, that CardioNet system may have a higher diagnostic yield compared to the patient-activated external loop device for up to one month. There is insufficient evidence however to determine that the device is superior to the auto-triggered or the implanted loop systems that were found to have better diagnostic yield than the patient-activated external loop monitors.</li> <li>• There is insufficient evidence to determine that CardioNet system improves the management of patients e.g. monitoring for medication titration and dose adjustments.</li> <li>• There is insufficient evidence to determine that CardioNet system improves patients' health outcomes.</li> </ul>	
12/16/2013	<p>There is a lack of published literature on the use of Zio@Patch for detecting atrial fibrillation and other arrhythmias in asymptomatic or symptomatic patients.</p> <p>A pilot study conducted by Rosenberg and colleagues (2013) compared the Zio@Patch with the traditional 24 hours Holter monitor in 74 patients with paroxysmal atrial fibrillation who were referred to Holter monitoring for evaluation. The Zio@Patch was well tolerated and had a mean monitoring period of 10.8 +2.8 days (range 4-14 days). During the simultaneous 24 hour recording time when the patients wore both devices, there was a strong correlation between the Zio@Patch and the Holter monitor (r=0.96) for identifying AV events and estimation AF burden. 18 additional cardiac events were recorded with the Zio@Patch due to longer duration of use. Other clinically relevant cardiac events recorded by the Zio@Patch after the 24 hours of monitoring, including symptomatic ventricular pauses, led to change in medications or referrals for pacemaker placement. Overall clinical management was changed in 28.4% of the patients as a result of the Zio@Patch findings. The authors concluded that the Zio@Patch was well tolerated and allowed longer monitoring that resulted in meaningful changes in clinical management. They indicated that more studies are needed to</p>	<p>The use of Zio@Patch the detection of arrhythmias does not meet the Group Health <b>Medical Technology Assessment Criteria</b>.</p>

	<p>examine the long-term impact of the device in AF management.</p> <p>The other published study (Turakhia et al, 2013) was only a retrospective analysis of data obtained from the device manufacturer. No comparison was made with Holter monitor or any other ambulatory cardiac rhythm monitor.</p> <p>There are no published studies, to date, that compared the Zio®Patch to any of the other longer-term outpatient ambulatory cardiac rhythm monitors.</p> <p>Conclusion:</p> <ul style="list-style-type: none"> <li>• There is weak evidence from one small single-center pilot study that Zio®Patch was well tolerated and allowed longer monitoring than Holter monitoring. This resulted in the detection of more AF episodes and cardiac events in symptomatic patients and making changes in the clinical management among more than one fourth of the study participants.</li> <li>• There is insufficient published evidence on the use of Zio®Patch for detecting atrial fibrillation and other arrhythmias in asymptomatic patients with AF.</li> <li>• There is insufficient evidence to determine the equivalence or superiority of Zio®Patch to any of the other longer-term outpatient ambulatory cardiac rhythm monitors.</li> </ul>	
--	---	--

## Evidence/ Source Documents

Date of Literature Search	Articles
6/4/2008	<p>The search yielded around 50 articles. Many were reviews, or articles that dealt with the analysis of data or feasibility of using the device. Only one randomized controlled study (Rothman 2007) that compared the diagnostic yield of MCOT to the external patient-activated loop event monitoring up to 30 days, was identified. There were a few other relatively small observational prospective and retrospective studies that evaluated the safety and diagnostic yield of the CardioNet system. Rothman and colleagues' RCT was selected for critical appraisal.</p> <p>Rothman SA, Laughlin JC, Seltzer J, et al. The diagnosis of cardiac arrhythmias: A prospective multi-center randomized study comparing mobile cardiac outpatient telemetry versus standard loop event monitoring. <i>J Cardiovasc Electrophysiol</i> 2007;18:241-247. See <a href="#">Evidence Table</a></p>
8/3/2009	<p>The search did not reveal any controlled trial on MCOT published after the RCT reviewed earlier in MTAC. Only two relatively small retrospective case series were identified; one reported on the use of MCOT among adult patients with stroke, and the other evaluated its use among children and adolescents with suspected arrhythmias. None were selected for critical appraisal.</p>
12/16/2013	<p>The literature search revealed only two published studies on the use of Zio®Patch as a noninvasive monitoring device for arrhythmias in general in one study, and for atrial fibrillation in the other. A retrospective study among 285 patients seen in emergency departments was identified from a review article, but it was not published in a peer review journal; it was only presented in a conference. The two published studies were critically appraised.</p> <p>Rosenberg MA, Samuel M, Thosani A, et al. #### For Non-Medicare Members

Group Health has elected to use the Microvolt T-Wave Alternans (MTWA) (A-0399) MCG\* for medical necessity determinations. This service is not covered per MCG guidelines.

**If requesting this service, please send the following documentation to support medical necessity:**

- Last 6 months of clinical notes from requesting provider &/or specialist

**\*The MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

The term alternans applies to conditions characterized by the sudden appearance of a periodic beat-to-beat change in some aspect of cardiac electrical or mechanical behavior. Many different examples of electrical alternans have been described clinically; a number of others have been reported in the laboratory.

T-wave alternans has long been recognized as a marker of electrical instability in acute ischemia, where it may precede ventricular tachyarrhythmia. Studies have shown that T wave (or ST-T) alternans can also precede non-ischemic ventricular tachyarrhythmias. Considerable interest has recently been shown in the detection of microvolt T wave alternans as a noninvasive marker of the risk of ventricular tachyarrhythmia in patients with chronic heart disease.

Assessment of left ventricular ejection fraction (LVEF), Holter monitoring, and signal-averaged late potentials are the principal non-invasive means of determining the risk of ventricular arrhythmias after myocardial infarction (MI). However, these measures of vulnerability to arrhythmias have been found to be less predictive of arrhythmic events than invasive electrophysiologic testing.

Microvolt T-wave alternans testing is performed by placing high-resolution electrodes, designed to reduce electrical interference, on a patient's chest prior to a period of controlled exercise (CMS, 2005). These electrodes detect tiny beat-to-beat changes, on the order of one-millionth of volt, in the EKG T-wave. Spectral analysis is used to calculate these minute voltage changes. Spectral analysis is a sensitive mathematical method of measuring and comparing time and the electrocardiogram signals. Software then analyzes these microvolt changes and produces a report to be interpreted by a physician.

Minimally Invasive Lumbar Decompression

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.

Criteria

For Medicare Members

Table with 2 columns: Source, Policy. Rows include CMS Coverage Manuals, National Coverage Determinations (NCD), Local Coverage Determinations (LCD), and Local Coverage Article.

For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

Background

Lumbar spinal stenosis (LSS) is one of the most common degenerative diseases of the lumbar spine, and the most common indication for spinal surgery in elderly patients. LSS is a condition where the dural sac and nerve roots are compressed by a combination of degenerative features including bulging of the intervertebral discs, hypertrophy of the facet joints, and thickening of the ligamentum flavum.

Conservative therapies for LSS include rest, pain medication, and physical therapy with or without epidural steroid injections. If these therapies fail, the patient may be advanced to more invasive surgical procedures. The goal of any surgical treatment of LSS is the relief of symptoms by adequate neural decompression while preserving as much of the anatomy, stability, and biomechanics of the lumbar spine as possible.

A number of less-invasive surgical techniques have been developed in recent years as an alternative to the traditional spine surgeries to limit the injury to the patient's native anatomy and reduce complication rates. These procedures are particularly attractive to spine surgeons for their small-skin incision, minimization of soft tissue injury, reduction of blood loss, infection rates, hospitalization time, narcotic usage, and minimization of physiological stress on the patient.

The mild® (Minimally Invasive Lumbar Decompression) procedure (Vertos Medical Inc., Aliso Viejo, California) is a minimally invasive alternative to open or endoscopic lumbar decompression in the treatment of lumbar spinal stenosis. Mild® treats LSS by removing small but adequate portions of the interlaminar bone (laminotomy) and

partial excision (debulking) of the ligamentum flavum (LF) to restore space in the spinal canal while minimizing trauma to the surrounding tissue and bony structure. The procedure is typically performed under intravenous sedation monitored anesthesia and fluoroscopic guidance. The *mild*<sup>®</sup> device kit is comprised of a single-use 6 gauge (5.1 mm diameter) *mild*<sup>®</sup> portal cannula with trocar to access into the soft tissue of the posterior lumbar spine, followed by a Bone Sculpter Ronguer which is used to precisely sculpt small pieces of lamina prior to tissue resection of the hypertrophic ligamentum flavum, then the *mild*<sup>®</sup> Tissue Sculpture is used to remove ligamentous and fibrous tissues from the hypertrophic ligamentum flavum (Deer 2010, 2011, Wong 2012).

The Vertos Medical *mild*<sup>®</sup> Device Kit was FDA approved through the 510k process as a set of specialized surgical instruments intended to be used to perform lumbar decompressive procedures for the treatment of various spinal conditions (FDA website accessed June 26, 2012).

## Medical Technology Assessment Committee (MTAC)

### Minimally Invasive Lumbar Decompression

#### 08/20/2012: MTAC REVIEW

**Evidence Conclusion:** There is insufficient published evidence to determine that *mild*<sup>®</sup> Vertos procedure leads to similar or better outcomes than traditional surgery among in patients with symptomatic spinal stenosis who failed conservative therapy. There is limited published literature on the procedure. No published randomized controlled trials compared the procedure to the traditional surgical approach, or to other less invasive surgical techniques. The only published RCT to date was a small study that compared the outcomes of *mild*<sup>®</sup> procedure to epidural steroid injection (ESI) in patients with symptomatic spinal stenosis and painful lower limb neurogenic claudication. The authors indicated that patients had to fail conservative therapy to be included in the trial, yet the procedure was compared to epidural steroid injection (ESI), which is considered a conservative management. In addition, the epidural steroid was delivered through interlaminar injections and not the preferable transforminal route to maintain blinding (according to the author). The other published studies were prospective or retrospective case series with potential biases, and were all funded by Vertos Medical the manufacturer of *mild*<sup>®</sup> device.

**Articles:** The literature search revealed one small RCT that compared the *mild*<sup>®</sup> procedure with epidural steroid injection, two multicenter observational studies with no control group, and few small prospective and retrospective case series. The RCT and the prospective multicenter observational study with one-year follow-up were selected for critical appraisal: Brown LL. A double-blind, randomized, prospective study of epidural steroid injection vs. the *mild*<sup>®</sup> procedure in patients with symptomatic lumbar spinal stenosis. *Pain Practice*. 2012;12:333-341. See [Evidence Table](#) . Mekhail N, Vallejo R, Coleman MH, et al. Long-term results of percutaneous lumbar decompression *mild*<sup>®</sup> for spinal stenosis. *Pain Practice*.2012;12:184-193. See [Evidence Table](#).

The use of minimally invasive lumbar decompression for treatment of spinal stenosis does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Transcatheter Mitral Valve Repair (TMVR)

- **MitraClip**

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

National Coverage Determination (NCD)

[NCD for Transcatheter Mitral Valve Repair \(TMVR\) \(20.33\)](#)

##### For Non-Medicare Members

The MitraClip Clip Delivery System is indicated for the percutaneous reduction of significant symptomatic, degenerative mitral regurgitation (MR $\geq$ 3+) in patients who have been determined by a cardiac surgeon to be too high risk for open mitral valve surgery and in whom existing comorbidities would not preclude the expected benefit from correction of the mitral regurgitation.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Transcatheter mitral valve repair (TMVR) is used in the treatment of mitral regurgitation. A TMVR device involves clipping together a portion of the mitral valve leaflets as treatment for reducing mitral regurgitation (MR); currently MitraClipR is the only one with Food and Drug Administration (FDA) approval.

U.S. FDA—MitraClip Clip Delivery System (MitraClip CDS) (Abbott Vascular, Menlo Park, CA): The MitraClip CDS received FDA approval through the PMA process on October 24, 2013. It is indicated for the percutaneous reduction of significant symptomatic mitral regurgitation (MR  $\geq$  3+) due to primary abnormality of the mitral apparatus (degenerative MR) in patients who have been determined to be at prohibitive risk for mitral valve surgery by a heart team, which includes a cardiac surgeon experienced in mitral valve surgery and a cardiologist experienced in mitral valve disease, and in whom existing comorbidities would not preclude the expected benefit from reduction of the mitral regurgitation. The device is contraindicated in patients who cannot tolerate procedural anticoagulation or post procedural antiplatelet regimen, and those with active endocarditis of the mitral valve, rheumatic mitral valve disease, or evidence of intracardiac, inferior vena cava or femoral venous thrombus. The MitraClip system consists of implant catheters and the MitraClip device, a permanent implant that attaches to the mitral valve leaflets. The procedure results in a double opening of the mitral valve that allows greater closure and reduces mitral regurgitation.

#### Medical Technology Assessment Committee (MTAC)

##### **MitraClip System**

##### BACKGROUND

Mitral regurgitation (MR) is the second most common valvular heart disease after aortic stenosis. The natural history of severe MR without surgical intervention is poor, leading to worsening LV failure, pulmonary hypertension, atrial fibrillation and death. It is reported that without surgical treatment, patients with severe symptomatic MR have an annual mortality rate of 5% per year, and as high as 60% at 5 years if associated with significant heart failure (Mauri 2010).

MR is broadly categorized as primary or secondary. Primary MR, also known as degenerative MR (DMR), describes an abnormality of the leaflets varying from a prolapse of an isolated segment in a normally shaped valve, to multiple segment prolapse involving one or both leaflets in a valve with significant excessive tissue and large annular size. Secondary MR, also known as functional MR (FMR), is secondary to left ventricular (LV) remodeling with structurally preserved mitral leaflets. Surgical mitral valve repair/replacement remains the gold standard for the treatment of symptomatic MR, though it has some controversy in FMR due to the lack of clear

survival benefit and high recurrence rates of MR at 1 year after surgery. Current guidelines recommend MV surgery in patients with moderate to severe (grade 3+) or severe (4+) MR associated with symptoms or evidence of LV dysfunction. Surgical repair of the valve before the onset of limiting symptoms or LV dysfunction can restore normal life expectancy and quality of life. The conventional surgery for MV repair/replacement is an open-heart surgery performed under cardiopulmonary bypass. It is reported that as many as 49% of patients in need of MR repair or replacement are considered at high surgical risk and are denied surgical treatment due to their age, advanced LV systolic dysfunction, previous bypass surgeries, or significant comorbidities. Patients who do not qualify for surgical correction of the MV are treated with medical therapy alone, which may reduce their symptoms, but does not stop the disease progression (Estevez-Loureiro 2013 Mauri 2013, Vakil 2013, Wan 2013, Munkholm-Larsen 2014). In the past 15 years, percutaneous valve therapy have been advancing rapidly especially for the aortic and pulmonic valve replacement. This development of percutaneous mitral valve (MV) therapies has been slower due to the anatomy of the MV and its relationship with the left ventricle. A number of devices for MV repair have been introduced as potential alternatives to open surgical procedures; many have failed and more are at different stages of investigation. Percutaneous or minimally invasive repair systems target the MV leaflets, annulus or the left ventricle, e.g. the NeoChord DS1000, the Carillon Mitral Contour System, and the MitraClip system. The latter is the only one in clinical use across the United States and Europe (Munkholm-Larsen 2014, Rana 2015). The concept of the MitraClip system (Abbott Vascular, Menlo Park, California) is based on the edge-to-edge repair technique developed by Alfieri and colleagues in the early 2000s. This technique involves suturing of the middle scallops of the anterior and posterior MV leaflets resulting in a double orifice valve. The MitraClip is a single-sized system that consists of a 4mm wide cobalt chromium clip with two foldable arms designed to grasp the moving leaflets; a 10Fr delivery catheter, with a radiopaque distal tip, and a 24-Fr steerable sleeve. The procedure is performed in the cardiac catheterization laboratory under general anesthesia, anticoagulation, and fluoroscopic and transesophageal echocardiographic guidance. The MV is accessed via the femoral vein and right atrium then to the left atrium via a transseptal puncture. The system is advanced into the left ventricle and the clip is deployed for permanent approximation of the anterior and posterior MV leaflets creating a double orifice MV during diastole. Reduction in MR is assessed by echocardiography during the procedure, and more than one clip may be used at the operator's discretion. At the end, the catheters are withdrawn, and the patient treated with aspirin for 6 months and clopidogrel for 30 days (Wan 2013, Vakil 2013, Munkholm-Larsen 2014, Rana 2015). Several anatomic parameters must be satisfied to determine the appropriate patients for the procedure. These differ for patients with DMR and FMR. Anatomical criteria for DMV include flail width and gap size, prolapse location, length of posterior MV leaflet (PMVL) and MV orifice size. The criteria for MV anatomy include coaptation depth and length, the MV orifice size, and the MV transvalvular gradient. Lesions ideal for MitraClip lie within the central portion at the coaptation line, have a flail width <15 mm with a flail gap <10mm, and as the MitraClip reduces the MV orifice, the preimplantation area should be >40 mm<sup>2</sup>. A hypoplastic posterior leaflet is a contraindication, and heavy calcification, fibrosis, or deep clefts within the clip grasping area have potential for clip implantation failure. The percutaneous MV repair with the MitraClip system depends heavily on echo-imaging during the implantation and early on for assessing the suitability for clip placement, which is the cornerstone for the success of the technique. It has been reported that some technical aspects of the MitraClip implantation remain operator dependent and have not been fully standardized, and that the correct strategy for patients with complex valve anatomy remains controversial (Paranskaya 2013, Rana 2015). The MitraClip treatment of MR is less invasive than surgery, but may be associated with potentially life-threatening complications. The incidence of the reported procedure-related complications is generally low, and varies considerably between studies. These included bleeding that require >2 units of blood transfusion (the most common), vascular access site complications, transseptal puncture (which may also cause to aortic root needle puncture), partial clip detachment, clip attachment to a single leaflet, leaflet injury or laceration, mitral valve stenosis, mitral valve injury, acute heart failure, and stroke (Bakker 2013). According to the device manufacturer and the FDA (approval in October, 2013), MitraClip implantation is indicated for the percutaneous reduction of significant symptomatic mitral regurgitation (MR ≥ 3+) due to primary abnormality of the mitral valve (degenerative MR), who have been determined to be at prohibitive risk for mitral valve surgery by a heart team, which includes a cardiac surgeon experienced in mitral valve surgery and a cardiologist experienced in mitral valve disease, and in whom existing comorbidities would not preclude the expected benefit from reduction of the mitral regurgitation. It is contraindicated in patients who cannot tolerate anticoagulation required during the procedure or antiplatelet therapy required after the procedure; in patients with active MV endocarditis; rheumatic MV disease; and in patients with evidence of femoral venous, inferior vena cava, or intracardiac thrombus. (<http://mitraclip.com>, and FDA webpage accessed July 17, 2015)

## **08/17/2015: MTAC REVIEW**

### **MitraClip System**

#### **Evidence Conclusion:**

There is evidence from EVEREST II RCT with 4 years of follow-up, that the implantation of MitraClip is less effective than surgery in improving the mitral regurgitation in patients with moderate or severe symptomatic mitral

valve regurgitation who are suitable candidates for conventional surgery. The is low quality, but consistent evidence from observational studies and registries that implantation of MitraClip in patients with symptomatic moderate or severe symptomatic mitral valve regurgitation who are at high surgical risk, is feasible and is associated with clinical improvement and relatively low risk of major adverse events. However, there is no evidence to date to determine the durability of clinical improvements and optimal criteria for patient selection. There is insufficient evidence to determine the outcomes of MitraClip device by etiology of mitral regurgitation (FMR or DMR). Two ongoing RCTs (COPAT in the US, and RESHAPE-HF trial in Europe) are comparing MitraClip implantation versus medical therapy in high surgical risk patients, and their results may provide more evidence on the relative safety and efficacy of implanting the device in these patients.

**Articles:** The literature search revealed EVEREST I feasibility trial; EVEREST II randomized controlled with four publications (the last of which reported on 4-years follow-up outcomes); 4 other nonrandomized comparative studies with retrospective controls including EVEREST II High Risk Study (HRS); a number of uncontrolled studies; a meta-analysis that pooled the results of the RCT and comparative studies; 3 systematic reviews (2 on the safety and efficacy of MitraClip in patients at high surgical risk, and one for patients with severe MR); and a number of industry-supported or industry-independent registries (REALISM, ACCESS Europe, Everest High-risk register) TRAMI German registry, and GRASP registry), The EVEREST II RCT, the EVEREST II HRS, and the meta-analysis that examined the safety and efficacy of MitraClip for patients at high surgical risk were selected for critical appraisal. Feldman T, Foster E, Glower DD, et al for the EVEREST II Investigators. Percutaneous repair or surgery for mitral regurgitation. *N Engl J Med*. 2011 Apr 14; 364(15):1395-406. ## Clinical Review Criteria

### Monitored Anesthesia Care (MAC) for Gastrointestinal Endoscopic Procedures

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	<a href="#">Monitored Anesthesia Care (MAC) (L34100)</a> .
Local Coverage Article	None

##### For Non-Medicare Members

Monitored anesthesia care (MAC) is considered medically necessary during gastrointestinal endoscopic procedures when there is documentation by the operating physician and the anesthesiologist that demonstrates any of the following higher risk situations exist:

- Prolonged or therapeutic endoscopic procedure requiring deep sedation\*\*; or
- A history of or anticipated intolerance to standard sedatives (e.g., patient on chronic high dose narcotics or high dose benzodiazepines, or has an unstable neuropsychiatric disorder which would prevent cooperation); or
- Increased risk for complication due to severe comorbidity. American Society of Anesthesiologists ASA class III physical status or greater (as documented by Anesthesia)
- Pediatric age group (16 years and younger); or
- Pregnancy; or
- History of active drug or alcohol abuse; or
- Morbid obesity (BMI>50); or
- Uncooperative or acutely agitated patients (e.g., delirium, organic brain disease, senile dementia); or
- Spasticity or movement disorder complicating procedure; or
- Increased risk for airway obstruction due to anatomic variant including any of the following:
  - Documented history of previous problems with anesthesia or sedation; or
  - History of stridor or severe sleep apnea requiring oxygen **and** bipap; or
  - Dysmorphic facial features, such as Pierre-Robin syndrome or trisomy-21; or
  - Presence of oral abnormalities including but not limited to a small oral opening (less than 3 cm in an adult), high arched palate, macroglossia, tonsillar hypertrophy, or a non-visible uvula (not visible when tongue is protruded with patient in sitting position e.g., Mallampati class greater than II) as documented by Anesthesia; or
  - Neck abnormalities including but not limited to short neck, obesity involving the neck and facial structures, limited neck extension, decreased hyoid-mental distance (less than 3 cm in an adult), neck mass, cervical spine disease or trauma, tracheal deviation, or advanced rheumatoid arthritis as documented by Anesthesia; or
  - Jaw abnormalities including but not limited to micrognathia, retrognathia, trismus, or significant malocclusion as documented by Anesthesia

(ASA, 2002; American Society for Gastrointestinal Endoscopy [ASGE], 2002, 2003, 2012)

\*\* Having consecutive upper and lower scopes on the same day does not in and of itself qualify as a prolonged endoscopic procedure

#### Not Medically Necessary:

The routine assistance of an anesthesiologist or Certified Registered Nurse Anesthetist (CRNA) for patients not meeting the above criteria who are undergoing standard upper or lower gastrointestinal endoscopic procedures is

considered not medically necessary. (American College of Gastroenterology [ACG], American Gastroenterological Association [AGA] & ASGE, 2004; ASGE, 2002, 2003, 20012).

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Each year in the United States, 145,000 people will be diagnosed with colon cancer; 54,000 will die. Getting recommended colorectal cancer screening could potentially save the lives of up to 60% of these patients. Increasing patient participation in routine screening is a matter of serious concern.

With the increased emphasis on prevention and the importance of the role of colonoscopy as a tool there is a need to evaluate the use of monitored anesthesia care in conjunction with endoscopic evaluation. Group Health has developed this policy in response to our findings.

## Medical Technology Assessment Committee (MTAC)

### *Monitored Anesthesia Care (MAC) for Gastrointestinal Endoscopic Procedures*

#### **2/22/2010: MTAC REVIEW**

**Evidence Conclusion:** The following are conclusions based on a review of several systematic reviews, meta-analyses, randomized controlled trials, and published internal data on sedation involving propofol compared to standard sedation: There is good evidence of improved patient satisfaction and reductions in discharge and recovery times with propofol used alone or in combination with other agents compared to standard sedation for colonoscopy exams. There is fair evidence from a KP SCAL-based comparative study of improved cecal intubation rates with propofol used as a single agent for sedation during colonoscopy. The evidence is of insufficient quantity or quality to draw definitive conclusions on differences in polyp detection. There is less comparative data on EGD procedures, but some evidence of improved recovery and patient satisfaction with propofol sedation. The evidence is of insufficient quantity and/or quality to draw definitive conclusions on comparative risk of serious adverse events, including death, neurologic injury, endotracheal intubations, bleeding, and colonic perforations during these procedures. There does not appear to be a significant difference in the risk of cardiopulmonary and respiratory events with propofol compared to standard sedation and no evidence of greater risk for serious adverse events for either colonoscopy or EGD procedures in lower risk patients (ASA I or II). Following the review of one systematic review and two comparative observational studies, the evidence is of insufficient quantity and quality to draw definitive conclusions on the safety of anesthesiologist- versus non anesthesiologist-directed or administered propofol sedation in GI endoscopy. Controlled prospective studies with standardized protocols, patient selection, and reporting are needed. Serious Adverse Events. The best available comparative evidence from the United States is a large observational registry study that suggests comparable rates of serious adverse events for anesthesiologist-directed propofol under monitored anesthesia care and gastroenterologist-administered propofol during colonoscopy procedures (0.16% and 0.14%) but a significantly increase risk of serious adverse events with gastroenterologist-administered propofol for upper endoscopy procedures, including EGDs (0.16% vs 0.5%). However, it is likely that these events differentially occurred in higher risk patients (ASA III) who were also included in the study. Overall Cardiopulmonary Adverse Events. There is evidence from the same study of a significant increased risk of overall cardiopulmonary events with endoscopic-administered propofol in ASA I or II patients undergoing colonoscopy and upper endoscopy. The majority of the cardiopulmonary events are most likely to be of minor clinical consequence, but the challenge remains to identify which cardiopulmonary events are more likely to result in serious adverse events and what risk factors are specific to upper versus lower endoscopy procedures. The evidence is of insufficient quantity and quality to draw conclusions on the safety of RN-administered propofol as compared to standard sedation for colonoscopy and EGD in ASA I and II patients. Based on a review of several systematic reviews and randomized controlled trials, there is no evidence of a significant increase in risk of adverse events with propofol compared to standard sedation and the risks appear to be comparable. However, these studies were not adequately sampled to detect or compare rates of serious adverse events. Comparative data from large and well-designed observational studies is needed. The existing series of RN-administered propofol are large and report low rates of adverse events.

#### Background

Biliary diseases and conditions associated with biliary obstruction are major causes of morbidity and mortality in North America. The accurate diagnosis of the presence and cause of biliary obstruction is the key to an effective work-up of patients with suspected biliary disease. Various clinical, biochemical, and investigative procedures may be used to identify ductal calculi. However, since its introduction in the late 1960s, endoscopic retrograde cholangiopancreatography (ERCP) is considered the gold standard for evaluation of the pancreatobiliary tree. It is the most accurate procedure for common bile duct (CBD) stones especially when wire-guided intraductal ultrasonography (IDUS) is performed simultaneously. It can also remove CBD stones either by endoscopic papillary balloon dilatation or endoscopic sphincterectomy. ERCP however is invasive, inconvenient for the patient, require sedation and contrast, is highly dependent on the operator skill and experience, and associated with a small but not negligible risk of complications such as bleeding, perforation, sepsis, pancreatitis and cholangitis, which may be potentially life threatening. The reported morbidity and mortality associated with ERCP are 1-2% and 0.7-0.9% respectively (Romagnuolo 2003, Kondo 2005, Shanmugam 2005, Ledro-Cano 2007, Hekimoglu 2008).

Less invasive modalities for the confirmation of CBD stones in indefinite cases include ultrasonography and computed tomography (CT). These are not highly sensitive in detecting CBD stones (reported sensitivity 18-74% for ultrasonography, and 50-90% for CT imaging). Imaging modalities developed more recently include endoscopic ultrasonography (EUS), helical computed tomography (HCT-C), and magnetic resonance cholangiopancreatography (MRCP). These are presumed to have higher sensitivity for CBD stones than ultrasound and conventional CT, while remaining less invasive than ERCP. EUS provides better visualization of the entire extrahepatic biliary tree with a high sensitivity and specificity. If stones are demonstrated by EUS, therapeutic ERCP can be performed immediately after completion of the EUS while the patient is still sedated, and potentially by the same endoscopists. EUS requires sedation, specialized expertise to perform, is not widely available, and is associated with some risk of bleeding and perforation. MRCP does not require routine sedation, ionizing radiation, or intravenous iodinated contrast; it also has no radiation exposure, and is more available than EUS (Verma 2006, Halefoglu 2007, Hekimoglu 2008).

The basic principle underlying MRCP is that by using heavily T2 weighted MR sequences, the signal of static or slow-moving fluid-filled structures such as bile and pancreatic ducts is greatly increased, resulting in increased duct to background contrast. MRCP combines the advantages of projectional imaging with those of cross-sectional imaging. It can be used patients with altered anatomy (e.g. choledochal or pancreaticojejunostomy, Billroth 2) and it is not operator dependent (Verma 2006, Halefoglu 2007, Hekimoglu 2008).

Common indications for MRCP include contraindication to ERCP, unsuccessful ERCP, or the presence of biliary-enteric anastomosis. It may also be indicated in patients with suspected solid extraductal or cystic masses that do

not communicate with the duct system. In some institutions MRCP is used as the initial imaging tool for the biliary system, with ERCP reserved for therapeutic indications. MRCP is time consuming, requires a high level of patient cooperation, and is not well tolerated by 1-5% of the patients because of claustrophobia. Moreover, the equipment for MRCP is costly, and the technology is still under development.

Variations among MRCP techniques and /or patient conditions e.g. image reconstruction artifacts, motion artifacts, intraductal artifacts, CBD sludge, or limited spatial resolution, may mask or simulate pathological findings leading to false positive or false negative results. Moreover, MRCP has a relatively low spatial resolution compared to ERCP, which limits the visualization of small stones (2-3mm in diameter), non-dilated pancreatic duct side branches, and characterization of strictures. It may thus be unable to assess small duct disease e.g. sclerosing cholangitis, side branch changes of mild chronic pancreatitis, intrahepatic duct changes, and others. In addition, MRCP requires a high level of technical expertise to accurately review the images (Romagnuolo 2003, Verma 2006, Ledro-Cano 2007).

## Medical Technology Assessment Committee (MTAC)

### *Magnetic Resonance Cholangiopancreatography (MRCP)*

#### 04/19/2010: MTAC REVIEW

**Evidence Conclusion:** There is evidence from several published prospective studies and meta-analyses that MRCP has a high diagnostic accuracy in detecting pancreatobiliary disease when compared with ERCP and other tests. MRCP however, is less sensitive in detecting stones than in identifying the presence and level of obstruction. Romagnuolo and colleagues' meta-analysis 2003, evaluated the performance of MRCP, and Verma and colleagues' (2006) as well as Ledro-Cano's (2007) meta-analyses compared its accuracy to endoscopic ultrasound using gold standards mainly ERCP. Among the limitations of all three meta-analyses is pooling the results of studies with variable methodological quality, clinical context in which MRCP studies were performed, and using different MRCP techniques and gold standards for confirming the results. Romagnuolo and colleagues' meta-analysis showed that MRCP is accurate for diagnosing biliary tract obstruction compared to ERCP and other tests. It had 97% sensitivity and 98% specificity in identifying the presence of obstruction, and 98% for both the sensitivity and specificity in identifying its level. It was less sensitive in diagnosing stones (92%), and distinguishing between benign and malignant obstruction (88%). In a more recent prospective study, Hekimoglu and colleagues (2008), compared MRCP using a recent technique (TSE sequence) to ERCP in evaluating biliary pathologies and showed that MRCP was 100% sensitive and specific in detecting hepatobiliary malignancies but less sensitive (88.9%) and highly specific (100%) in diagnosing a biliary stone disease. Verma and colleagues' 2006, and Ledro-Cano et al's, 2007 meta-analyses compared the performances of EUS and MRCP in diagnosing choledocholithiasis using ERCP or intraoperative cholangiography as gold standards. Verma and colleagues' meta-analysis pooled the results of 5 prospective studies, and Ledro-Cano's analysis included the same five studies in addition to two more, but did not pool the sensitivities and specificities, instead they were presented in ranges. The results showed that both modalities had generally similar diagnostic accuracies and likelihood ratios, but EUS had significantly higher sensitivity in detecting CBD stones. The pooled sensitivities and specificities for detecting CBD stones in Verma et al's analysis were 85% and 93% for MRCP respectively and 93% and 96% for EUS respectively. A smaller study with 99 patients (Pungpapong 2007) on the accuracy of MRCP and EUS for the diagnosis of chronic pancreatitis compared to ERCP as the gold standard, showed that when used alone MRCP had a sensitivity of 65%, and specificity of 90%, and EUS had 93% for both sensitivity and specificity. The combination of both MRCP and EUS increased the sensitivity to 98% and specificity to 100%.

**Articles:** The literature search revealed over eight hundred publications on MRCP. Many were reviews, articles that dealt with the technical aspects of the tests, or that were unrelated to the current review. There was one meta-analysis on the test performance of MRCP in suspected biliary disease, and two others that compared MRCP vs. EUS for the detection of choledocholithiasis, as well as a number of prospective studies that mainly compared MRCP vs. EUS using ERCP or other diagnostic tests as gold standards. Many of the prospective studies were included in the meta-analyses. The three meta-analysis and a relatively large prospective studies not included in any of the meta-analyses were selected for critical appraisal. Ledro-Cano D. Suspected choledocholithiasis: endoscopic ultrasound or magnetic resonance cholangio-pancreatography? A systematic review. *Europ J Gastroenterol Hepatol* 2007;19:1007-1011. See [Evidence Table](#) Romagnuolo J, Bardou M, Rahme E, et al. magnetic resonance cholangiopancreatography: A meta-analysis of test performance in suspected biliary disease. *Ann Intern Med* 2003;139:547-557. See [Evidence Table](#) Verma D, Kapadia A, Eisen GM, et al. EUS vs. MRCP for detection of choledocholithiasis .Systematic review. *Gastrointest Endosc* 2006;64:248-254. See [Evidence Table](#) Hekimoglu K, Ustundag Y, Dusak A, et al. MRCP vs. ERCP in the evaluation of biliary pathologies. *J Digest Dis* 2008;9:162-169. See [Evidence Table](#)

The use of Magnetic Resonance Cholangiopancreatography (MRCP) for the diagnosis of biliary obstruction does meet the *Group Health Medical Technology Assessment Criteria*.

CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Magnetic Resonance Imaging (MRI) (220.2)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Crohn's disease is a chronic inflammatory disease of the gastrointestinal tract. In 80% of cases it involves the small bowel, more specifically the ileum, and is characterized by luminal, transmural and mesenteric abnormalities. Crohn's usually manifests in early adulthood and typically runs a relapsing and remitting course. Initial diagnosis aims at establishing and characterizing the disease including the location, extent of inflammation, and the presence of stenosis, fistulae or abscesses. Several modalities such as radiology, endoscopy, and serologic markers are being used to diagnose and assess the disease activity. None is recognized as a gold standard, but radiological procedures including small bowel series and fluoroscopic enteroclysis continue to lead the diagnostic tools that examine the small bowel in its entirety. Because there is no known cure, and the condition is typically relapsing, patients with Crohn's disease normally undergo several radiological investigations during the course of the disease to monitor the treatment response, recurrence, and /or development of complications (Negaard 2007, 2008, Masselli 2006, Lin 2008).

Celiac disease is a gluten-sensitive enteropathy of the gastrointestinal tract that affects the small intestine in genetically susceptible individuals at any age. The disease is relatively common in European countries and occurs less frequently in the US. Celiac disease has a wide range of nonspecific clinical manifestations which make it challenging to diagnose. It may be silent and go clinically undetected or present with symptoms that range from fatigue and abdominal pain to weight loss, diarrhea, and malabsorption with steatorrhea. In children it may be associated with apathy, anorexia, and muscle wasting. It is reported that a small-intestine biopsy is mandatory to confirm the diagnosis of celiac disease. Imaging plays a role in suggesting celiac disease in adults with intestinal disorders, and in ruling out complicating lesions in patients with known disease (Paolantonio 2007).

The traditional imaging techniques used to evaluate the small bowel are the conventional barium studies e.g. small bowel follow-through or conventional enteroclysis (CE) Historically CE has been the radiological method of choice. It was found to be highly accurate for diagnosing Crohn's disease and detecting partially or non-obstructive lesions that may not be demonstrated by cross-sectional imaging techniques. The procedure involves distension of the entire small bowel with barium suspension which when adequate, would allow the radiological demonstration of mucosal abnormalities and provide functional information on the ability of the small bowel to distend. CE however, exposes the patient to ionizing radiation, may be hindered by the overlapping bowel loops, and does not provide information on the transmural and extramural extension, or other complications of the disease such as fistulae and abscesses (Schreyer 2004, Bernstein 2005, Masselli 2008).

Computed tomographic (CT) enterography, magnetic resonance (MR) enterography, and MR enteroclysis are emerging techniques for small bowel imaging. They have a benefit over traditional barium fluoroscopic techniques in their ability to visualize superimposed bowel loops and extraluminal extensions, and complications. CT provides excellent temporal and spatial high resolution images of the small bowel, and is less susceptible to motion artifacts than MRI, but at the cost of radiation exposure. MRI on the other hand, has several advantages over CT, such as its superior tissue contrast, ability to provide direct cross-sectional imaging in multiple planes, functional or real-time examination of the bowel, and lack of ionizing radiation exposure which is particularly important in Crohn's patients who need repeated evaluation. The real-time imaging can be helpful in evaluating the progress of bowel filling with contrast agents during enteroclysis, determining the ability of the narrowed areas to distend, and improving differentiation of contractions from strictures. In addition the gadolinium contrast agents used in MRI are known to have an excellent safety profile and can be used in patients with iodine contrast allergies, renal insufficiency, or during pregnancy. MRI however, has inferior spatial and temporal resolution compared to CT, and its image quality may be degraded by artifacts from bowel peristalsis. Other reported constraints for MRI use include the limited number and access to MR scanners as well as its high cost (Rieber 2000, Bruining 2006, Fidler 2007).

MRI for small bowel disease may be performed by MR enteroclysis (luminal contrast) or MR enterography (MRI per OS, oral contrast). MR enteroclysis requires the fluoroscopic passage of a nasojejunal catheter and controlled administration of significant volumes (up to 3 liters) of enteric contrast agents. The small bowel can be filled with manual injection or hand-held infusion pumps while the patient is in the scanner. The procedure is associated with significant patient discomfort particularly due to the catheter introduction and manipulation, as well as the profuse diarrhea which results from the infused contrast medium. Moreover, the continuous infusion of the contrast agent may result in gastro-esophageal reflux especially in the obstructed patient, leading to potential vomiting and aspiration (Negaard 2007, Lohan 2007).

To achieve a compromise between patient tolerability and reproducible diagnostic image acquisition, MRI techniques with oral contrast (MR enterography) have been introduced. For this procedure, the patient is required to ingest a large amount of fluid (1.5-2 liters) to distend the stomach and small bowel in continuity. Various substances and volumes have been added to the oral solutions to increase the bowel distension. It is reported that there is no agreement on the optimal oral contrast, but investigators found that high osmolality of the contrast e.g. mannitol, improves the bowel distension. MR enterography may be associated with adverse effects such as diarrhea, nausea, abdominal pain, ileus due to the increased fluid content, and other side effects (Masselli 2006, Lohan 2007).

## Medical Technology Assessment Committee (MTAC)

### *Magnetic Resonance Enterography (MR per OS)*

#### 02/02/2009: MTAC REVIEW

**Evidence Conclusion:** Most of the published studies on MR imaging of the small bowel used the enteroclysis technique that requires intubation of the proximal small bowel followed by the administration of contrast agent. Few studies performed MR enterography where the contrast material is ingested orally. Different modalities for the diagnosis of Crohn's disease were used as reference standards, as there is no non-surgical gold standard to date. In the studies reviewed, MR imaging was used for patients with suspected or confirmed Crohn's disease to characterize the disease, assess the extent and severity of bowel inflammation, and detect any stenosis, fistula, or other associated lesions. In both MR techniques, good distension of the small bowel loops during examination is essential to accurately evaluate the bowel wall pathology because collapsed loops may hide the disease or falsely identify a collapsed segment as a thickened wall. Negaard et al's study (2007) included 40 participants with known or suspected Crohn's. All participants were examined with both MR techniques, and the diagnosis of the disease was based on clinical evaluation, ileoscopy with histopathology, capsule endoscopy, or surgery. The study had several limitations, no comparison was made to with conventional enteroclysis, and lesions in jejunum and proximal ileum were not evaluated. Moreover, the reference standards were performed 2-3 months after the MR imaging, which may affect the presence or absence of some disease-related findings. The overall results of the study show that bowel distension was statistically significantly inferior in MR enterography compared to MR enteroclysis at both the jejunal and ileal levels. The difference was however, insignificant for the terminal ileum. The accuracy of the two MR imaging techniques had similar sensitivity in assessing the intestinal wall thickness, enhancement and ulcer detection, when compared to reference standards used in the study. MR enteroclysis was more sensitive and specific than MR enterography in detecting intestinal stenosis, but less specific for the three other measures. MR enterography was associated with bowel obstruction in two patients one of which required abdominal surgery to treat the condition. Masselli and colleagues' study (2008) compared the diagnostic accuracy of MR enterography, with MR enteroclysis, and conventional enteroclysis as a reference standard in 40 patients with histologically proven Crohn's disease. All participants underwent conventional enteroclysis and either the MR

enteroclysis or enterography on an alternating basis. The study was small, and had several limitations. Its overall results show that conventional enteroclysis detected significantly more mucosal and mural abnormalities, but less mesenteric findings vs. MR enteroclysis and MR enterography. There were no significant difference between the two MR imaging techniques in the image quality, or assessment of mural stenosis and fistulae. However, MR enterography was statistically significantly inferior in bowel distension vs. MR or conventional enteroclysis. It was also inferior to MR enteroclysis in detecting the involved affected segments, superficial erosions, and deep ulcers. Conclusions: The published studies indicate that MR enterography may be inferior to conventional and MR enteroclysis in bowel distension, and detection of some associated lesions. There is insufficient evidence to determine the role of MR enterography in the diagnosis or assessment of celiac disease. There is insufficient evidence to determine the role of MR enterography in monitoring patients with Crohn's or celiac disease. There is insufficient evidence to determine the safety of the MR enterography in patients with Crohn's or celiac disease.

**Articles:** The literature search revealed over three hundred publications. The majority was reviews, articles that dealt with the technical aspects of the tests, or that were unrelated to the current review. The studies on the use of MR imaging for the evaluation of small bowel diseases mainly included patients with Crohn's disease; only one small retrospective case series evaluated the test for patients with celiac disease. The literature on MR enterography was very limited compared to MR enteroclysis. One study compared both MR techniques (enteroclysis and enterography) to conventional enteroclysis, and one to a combination of reference standards. The technology was also compared to capsule endoscopy or CT enterography in two small studies. The test was mainly used for the initial assessment of known or suspected Crohn's. Only one small study that included patients with recurrent disease was identified, but there were no published studies on the use of MR enterography for monitoring treatment response. The studies that compared MR enterography of the small bowel to conventional enteroclysis and/or MR enteroclysis, and that had more valid methodology and data analysis, were selected for critical appraisal. Negaard A, Paulson V, Sandvick L, et al. A prospective randomized comparison between two MRI studies of the small bowel in Crohn's disease, the oral contrast methods and MR enteroclysis. *Eur Radiol* 2007;17:2294-2301. [See Evidence Table](#). Masselli G, Casciani E, Poletini E, et al. Comparison of MR enteroclysis with MR enterography and conventional enteroclysis in patients with Crohn's disease. *Eur Radiol*. 2008;18:438-47. [See Evidence Table](#).

The use of Magnetic Resonance Enterography (MR per OS) for the diagnosis and monitoring of Crohn's and celiac diseases does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Breast MRI with and without Computer-Aided Detection (CAD)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Magnetic Resonance Imaging (MRI)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

- I. Breast MRI may be indicated for 1 or more of the following:
  - A. Breast abnormality evaluation needed, as indicated by 1 or more of the following:
    1. Anatomic guidance during biopsy of breast lesion exclusively detected by contrast-enhanced MRI which cannot be visualized with mammography or ultrasonography
    2. A single 6 month MRI for f/u if requested by the radiologist who attempted or performed the original MRI guided biopsy
    3. Breast MRI is covered for members with suspected silicone (not saline) implant leaks or rupture when all of the following have been met:
      - a. Implants were placed as a result of one of the following:
        - medically necessary lumpectomy or complete or partial mastectomy due to disease, injury or illness (such as breast cancer, chronic and severe fibrocystic disease, or infection unresponsive to medical therapy, chest wall surgery, or trauma) resulting in significant deformity;
        - prophylactic mastectomy to prevent the onset of breast cancer when a clinical determination has been made that there is a high risk for breast cancer
      - b. Records must document need for this test for evaluation and management
      - c. A recent mammogram does not confirm leakage
      - d. The leakage is not the result of a cosmetically placed implant as this would be a complication of a non-covered service
      - e. It is not being requested for routine surveillance of a silicone implant
  - B. Breast cancer diagnosis (new within the last 3 months) and 1 or more of the following:
    1. After positive nipple-areolar biopsy for Paget disease, to define extent of disease and identify additional disease
    2. Assessment of tumor response to neoadjuvant (preoperative) chemotherapy to determine appropriateness of breast-conserving surgery to assist with surgical planning
    3. Evaluation of a newly diagnosed invasive breast cancer (eg, lobular, ductal)
    4. Evaluation of a newly diagnosed DCIS and there is documentation that the patient is requesting breast conserving surgery
    5. Post lumpectomy, (within 6 weeks) for assessment of residual disease with the finding of close or positive margins on pathology.
  - C. Occult breast cancer, suspected (eg, unknown primary), as indicated by ALL of the following:
    1. Diagnosis of adenocarcinoma or carcinoma not otherwise specified in 1 or more of the following:
      - a. Axillary lymph nodes
      - b. Supraclavicular lymph nodes
    2. Mammogram and breast ultrasound show no evidence of cancer.

3. No palpable breast mass suitable for biopsy
- D. Annual MRI for breast cancer screening and 1 or more of the following:
1. A lifetime risk of 20% or greater, as defined by validated models such as the following models: i) Tyrer-Cuzick Gail Model, BRCAPro, Claus.
    - a. The specific risk model must be documented in the clinical notes
    - b. If member has had breast or ovarian cancer, calculate the risk prior to the diagnosis
  2. Breast cancer screening needed and 1 or more of the following:
    - a. BRCA1 or BRCA2 mutation carrier
    - b. Personal history of radiation to chest between ages 10 and 30 years
    - c. Other high-risk family history of breast cancer, as indicated by 1 or more of the following(35):
      - Male relative with breast cancer
      - Untested first-degree relative [A] of BRCA1 or BRCA2 mutation carrier
      - Woman not of Ashkenazi Jewish ancestry, with 1 or more of the following:
        - i. First-degree [A] or second-degree [B] relative with breast cancer and 1 or more of the following:
          - Diagnosed at age 45 years or younger(29)
          - Diagnosed at age 50 years or younger, with limited family history [C]
          - Diagnosed at age 50 years or younger, who in turn has one or more close blood relatives [D] with breast cancer, with at least one diagnosed at age 50 years or younger(29)
          - Diagnosed at age 50 years or younger, who in turn has one or more close blood relatives [D] with epithelial ovarian [E] cancer diagnosed at any age(29)
          - Diagnosed at age 60 years or younger, with triple-negative breast cancer [F]
          - Epithelial ovarian [E] cancer(29)
        - First-degree [A] or second-degree [B] relative with 2 breast primaries, [G] with the first primary diagnosed at age 50 years or younger(29)
        - First-degree [A] or second-degree [B] relative with breast cancer diagnosed at any age, who in turn has 1 or more of the following:
          - i. Two or more close blood relatives [D] with breast or epithelial ovarian [E] cancer diagnosed at any age(29)
          - ii. One or more close male blood relatives [D] with breast cancer(29)
        - First-degree [A] or second-degree relative [B] with breast cancer who is of ethnicity associated with deleterious mutations, including Icelandic, Hungarian, Swedish, and Dutch(29)
        - First-degree [A] or second-degree relative [B] with breast or ovarian cancer diagnosed at any age, who in turn has 2 or more close blood relatives [D] with pancreatic cancer diagnosed at any age
      - d. First-degree [A] or second-degree relative [B] with pancreatic cancer diagnosed at any age, who in turn has 2 or more close blood relatives [D] with 1 or more of the following:
        - Breast cancer diagnosed at any age
        - Ovarian cancer diagnosed at any age
        - Pancreatic cancer diagnosed at any age
      - e. Third-degree relative [H] with breast or epithelial ovarian [E] cancer, who in turn has 1 or more of the following:
        - One close blood relative [D] with epithelial ovarian [E] cancer and another close blood relative [D] with breast cancer diagnosed at age 50 years or younger(29)
        - Two or more close blood relatives [D] with breast cancer, with at least one diagnosed at age 50 years or younger(29)
        - Two or more close blood relatives [D] with epithelial ovarian [E] cancer(29)
      - f. Woman of Ashkenazi Jewish ancestry, with 1 or more of the following:
        - One or more first-degree relatives [A] with breast cancer or epithelial ovarian cancer(38)
        - Two or more second-degree relatives, [B] on same side of family, [I] with breast cancer(38)
        - Two or more second-degree relatives, [B] on same side of family, [I] with epithelial ovarian cancer(38)
      - g. Patient has diagnosis of, or has first-degree relative [A] with, 1 or more of the following(35):
        - Bannayan-Riley-Ruvalcaba syndrome
        - Cowden syndrome
        - Li-Fraumeni syndrome

### **Routine Surveillance of Silicone Breast Implants**

Breast MRI is not covered for routine surveillance of silicone breast implants. The FDA made a recommendation (not a requirement) when they re-approved silicone implant use that members receive periodic breast MRIs. The FDA did not fund this screening. The choice of silicone vs saline is a patient preference and the use of MRI in this case cannot be described as medically necessary.

### **Computer-aided detection applied to breast MRI**

No criteria were developed at this time for Commercial Members. There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies (and/or) provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## **Background**

### **Breast Cancer Screening and Lesions:**

Mammography has been the standard tool used for breast cancer imaging. Community breast cancer screening programs have found an overall sensitivity of 75% and a specificity of 92%. The sensitivity of mammography in randomized trials is in the range of 68-88% (Elmore et al., 2005).

Due to limitations in the sensitivity of mammography, there has been research into alternative imaging modalities, particularly for women at high-risk of breast cancer. Interest in more accurate screening tests has grown since the identification of the BRCA1 and BRCA2 genes in the mid-1990s. Population-based studies have found that women with BRCA1 mutations have an approximately 65% risk of developing breast cancer by age 70, and women with BRCA2 mutations have a 45% risk (Saslow et al., 2006). Mammography may not be adequate for detecting breast cancer in women with the BRCA1/2 mutation. In a study of BRCA1/2 mutation carriers who underwent annual mammography, screening detected only 5 out of 9 cases of breast cancer; the remaining were interval cancers (Brekelmans et al., 2001).

Contrast-enhanced magnetic resonance imaging (MRI) is proposed as an adjunct to mammography for women at high-risk of breast cancer. Breast MRI involves the injection of a contrast agent, usually gadolinium. Breast carcinomas tend to enhance, or get brighter, following injection of the contrast agent. MRI may be able to detect small breast lesions missed by mammography. However, contrast-enhanced MRI may not be able to distinguish between breast carcinoma and benign disease which also enhance, thus reducing the specificity of MRI.

The American Cancer Society (ACS) issued guidelines in May, 2007 on breast screening with MRI as an adjunct to mammography (Saslow et al., 2007). The recommendations include:

- Annual screening for women with a lifetime risk of  $\geq 20$ -25%, BRCA mutation or untested first-degree relative of BRCA carrier.
- No recommendation for or against screening women with a lifetime risk of 15-20%.
- Recommendation against screening women with <15% lifetime risk due to insufficient evidence.

The ACS recommends the BRCAPRO or other model largely dependent on family history be used to determine lifetime risk. BRCAPRO is a computer program on a statistical model for estimating an individual's probability of carrying a BRCA1/2 mutation on the basis of their own cancer status, and the history of breast and ovarian cancer among her first- and second-degree relatives (Berry et al., 2002). Other risk models, such as the Gail model risk calculator which is also based on family history, may be easier to use in the primary care setting. An individual's risk level may vary with the different models (Saslow et al., 2007).

The Group Health breast clinic already generally recommends MRI screening for women with known BRCA mutations, who are a first-degree relative of a BRCA carrier but are untested, or have a 30-49% lifetime risk.

### **Silicone Implant Leakage:**

Silicone-gel breast implants were first available for commercial use in the early 1960s. It is estimated that 1.5 to 2 million women in the United States have received an artificial breast implant, and the number is growing. Almost four-fifths of these women received the implant for cosmetic purposes to enhance or remodel breast shape, or to correct traumatic or congenital deformities. In only 20% of the cases they received it for breast reconstruction after mastectomy. At least three major generations and over 200 models of silicone gel-filled breast implants have been manufactured. The differences between the generations are primarily in the types of silicone gel and thickness of elastomeric shell. The first generation of silicone gel-filled implants (early 1960s to the mid 1970s) had a thick

elastometric shell with firm silicone gel. The second generation (mid 1970s to late 1980s) had a thin elastometric shell, and a less viscous gel. The third generation (mid 1980s to date) has a multilayer shell with a barrier layer and thick cohesive viscous silicone gel. In 1993 a newer generation of highly cohesive silicone implants (Style 410) was developed, however it is widely used in Europe and other countries, but not in the US (Brown 2002, Belli 2002, Scaranelo 2004, Gamper 2007, Gorczyca 2007).

Silicone implants may have psychological benefits, but could be associated with local complications and systemic effects. Local implant-related complications include wound infection, hematomas, sensory nerve injury, capsular contracture, and implant rupture. The latter is a well known complication, and could range from focal rupture involving pinhole sized holes, through large visible tears, to complete disintegration of the implant shell. Implant rupture can be divided into two major categories: intracapsular (80-90% of all ruptures) and extracapsular. Unlike rupture, gel bleed is microscopic escape of silicone particles through the intact silicone envelope, in the absence of gross holes or tears. This is usually confined to the fibrous capsule that forms around the implant. Implant age, and design were found to be the most important factors associated with rupture. Other potential causes of rupture include trauma, mammography, and history of closed capsulotomy. The age of implant at rupture varied between reports between 4 and 22 years, with means also varying between studies from 11 to 16 years (Cher 2001, Samuels 1994, Gorczyca 2007).

Silicone gel-implant rupture may be clinically silent and pass unnoticed by the patient and the physician. It could remain undetected for years especially when it is contained within the fibrous capsule. A symptomatic rupture may present with local symptoms as breast pain, nodules, capsular contracture, and change in symmetry, size, or shape of the breast. Silicone gel granulomas and chronic disseminated granulomatous inflammation have been associated with implant rupture and gel migration. The potential health implications of silicone implant rupture are greatly debated. Some researchers reported that seepage of silicone and distant migration of the free silicone may lead to serious symptoms and foreign body reactions. Others indicated that it is harmless and does not lead to significant clinical symptoms or activate the humoral immune system (Ahn 2003, Holmich 2004, Gampper 2007).

The clinical diagnosis of asymptomatic implant rupture can be challenging. It was reported that less than one third of ruptures in asymptomatic patients can accurately be detected by experienced plastic surgeons. The gold standard for diagnosing an implant rupture is removal and examination of the implant. Mammography, ultrasonography, computed tomography, and magnetic resonance imaging have all been used in the diagnosis of silicone breast implant rupture. Each was reported to have its specific indications, advantages, and limitations. The type of silicone implant may also be a factor in choosing the modality for evaluating its integrity.

Mammography is a rapid inexpensive test, used routinely for screening, and can easily detect free silicone within the breast parenchyma due to extracapsular rupture. It however, has a small radiation risk, and limited ability to detect intracapsular rupture which accounts for 80-90% of implant failures. The dense silicone is not easily penetrated by the X-ray energies used for typical screening mammography (Samuels 1994, Gampper 2007, Gorczyca 2007).

Ultrasonography is inexpensive, does not use ionizing radiation, can detect intracapsular rupture, and may also detect small amounts of free silicone mixed within the surrounding breast tissues. However, its usefulness for detecting implant rupture depends on the experience of the operator, type of equipment used, as well as other technical factors. It was also reported that ultrasonography may have its limitations in the evaluation of the posterior aspect of the implant, pectoralis muscle and chest wall (Belli 2002, Gorczyca 2007).

MRI does not use ionizing radiation, has the ability to detect implant rupture, and to localize extensive free silicone. It can also be used with severe capsular contracture. Specialized breast coils increase the image quality and reduce scan time. However, it was reported that MRI cannot detect microscopic silicone leakage (gel bleeds). It is expensive, less available, less comfortable for the patient, and cannot be used among those with pacemakers, or other internal metallic devices that are not compatible with the MRI. Some patients may be claustrophobic and are unable to complete the examination (Beekman 1999, Gorczyca 2007, Gampper 2007)

FDA recommends MRI, with a dedicated breast coil and a magnet of at least 1.5 Tesla, as the current method of choice for detecting silent rupture of silicone gel implant. This is recommended to be performed three years after the implant, then every 2 years thereafter. The FDA also recommends the removal of ruptured breast implants.

With Computer-Aided Detection (CAD):

(Background information quoted from Blue Cross Blue Shield Association Technology Evaluation Center, BCBSA TEC report, June 2006)

Over the past decade, MRI of the breast has been studied in a variety of clinical settings, including both benign and malignant conditions of the breast...While MRI has a very high sensitivity for detecting lesions, its specificity is variable and often quite low because of the difficulty in distinguishing between benign and malignant lesions. The sensitivity for detection of invasive carcinoma overall is above 90%, while specificities between 37% and 90% have been reported (Deurloo et al. 2005a). The low specificity is particularly challenging in younger women, who are more likely to have enhancing benign lesions (Gilhuijs et al., 2002)...

Some investigators have incorporated additional criteria into the determination of MRI results in an attempt to increase the specificity without compromising sensitivity (Lieberman 2004; Nunes et al. 2001). Descriptive features of lesion morphology such as those used in X-ray mammography may be helpful in this regard. For example, lesions with irregular or spiculated margins are characteristically malignant, while lesions with smooth, regular margins are usually benign (Nunes et al. 1997a)...CAD systems for MRI... provide easier ways of interpreting the patterns of contrast enhancement and washout across a series of images, which in turn may help identify lesions and their likelihood of being malignant. In contrast to CAD systems used with mammography, CAD for MRI is not aimed primarily at identifying lesions for consideration by a radiologist. Unlike the subtle appearance of lesions on mammography, most cancers enhance on MRI. The challenge is determining which lesions are benign and which are malignant. A large number of images are produced during MRI of the breast: images are taken at varying 'depths' throughout each breast multiplied by the number of times the breast is imaged to capture different time points in the enhancement process... Radiologists view the images to detect suspicious areas, and then they can pick a region of interest and look at the enhancement pattern. However, there may be variations across radiologists in the regions of interest selected and in the precise definition of the region of interest. CAD systems, in contrast, use color-coding and differences in hue to indicate the patterns of enhancement for each pixel in the breast image. It thereby may allow the radiologist to analyze the enhancement patterns systematically, although there is some question about how effective it is in reducing interobserver variability (Gabriel et al. 2005). Some CAD programs apparently incorporate morphological characteristics as well to estimate a probability of malignancy..."

There are several FDA-approved CAD systems for use with MRI of the breast. These include:

- CADstream (Confirma, Inc. Kirkland, WA). Originally cleared in 2003. CADstream version 4.0 was cleared in 2008.
- MRI Soft Tissue Motion Correction Software (Siemens Medical Solutions. Malvern, PA). Cleared September 2005.
- Z3D (Clario Medical Imaging): Cleared September 2008.

## Medical Technology Assessment Committee (MTAC)

### *MRI in the Diagnosis of Breast Cancer and Breast Lesion*

#### 02/13/2002: MTAC REVIEW

**Evidence Conclusion:** All studies reviewed were retrospective, had several limitations, and data were obtained from records. Tan's study showed that MRI had an impact on the clinical management in almost one fifth of the patients. MRI findings were false positive among 61.5 % of the patients who underwent an additional surgery, which was a mastectomy in one case. Olson's study showed that MRI had a sensitivity of 95%, and specificity of 80%. These were based on data obtained from patients who underwent additional breast surgery, not all the sample. The clinical usefulness of a diagnostic test depends not only on its accuracy but also its reliability i.e. the consistency of interpretation on different occasions and by different observers. Mussurakis' study shows that all readers achieved a high sensitivity in cancer detection, their specificity however was much lower. The study also revealed a significant inter-observer variability in the interpretation of breast MRI. The high false positive rates, i.e. low specificity, and high inter-observer variability indicate that MRI, with its current limitations, is not an accurate or a reliable technology, compared to the gold standard of biopsy. Randomized trials, with a large study population will be required to confirm the findings and define the patients most likely to benefit from MRI. Moreover, further efforts are needed to improve, and standardize the indications, techniques, and image interpretation.

**Articles:** The search yielded 63 articles. Selection was based on study type. The majority were reviews, editorials, letters, and commentaries. The literature did not reveal any randomized controlled trials or longitudinal studies.

*The following articles were selected for critical appraisal:* Tan J E, Schnall M D, et al. Role of magnetic resonance imaging and magnetic resonance imaging-guided surgery in the evaluation of patients with early-stage breast cancer for breast conservation treatment. *Am J Clin Oncol* 1999; 22(4): 414-18 See [Evidence Table](#). Olson JA, Morris EA, et al. Magnetic resonance imaging facilitates breast conservation for occult breast cancer. *Annals of Surgical Oncology* 2000; 7(6): 411-15 See [Evidence Table](#). Mussurakis S et al. Observer variability in the interpretation of contrast enhanced MRI of the breast. *The British Journal of Radiology* 1996; 69: 1009-16. See [Evidence Table](#).

The use of MRI in the diagnosis of breast cancer and breast lesions does not meet the *Group Health Medical Technology Assessment Criteria*.

## 06/04/2007: MTAC REVIEW

### MRI in the Diagnosis of Breast Cancer and Breast Lesion

**Evidence Conclusion:** The major prospective studies comparing screening asymptomatic women at moderate-to-high risk of breast cancer with MRI and mammography are summarized in Table 1. All of these studies were judged to be of reasonable validity. All studies were prospective and eligibility criteria included an assessment of risk based on genetic and family history factors. In addition, all of the studies included an independent evaluation of MRI and mammograms. The gold standard was biopsy/histology for positive tests in all studies. Gold standards for negative tests varied. Most studies used 1 year follow-up of negative tests to identify false negatives; Kuhl et al., 2005 used 6 months' follow-up. The Lehman et al., 2005 study was the weakest for several reasons. This is the only study in which the authors did not attempt to verify the accuracy of negative tests. In addition, only 4 cases of cancer were identified, a number too small for statistical analysis. The absolute difference in the breast cancer detection rate between combined testing with MRI and mammography and mammography alone ranged from 1% (Kriege et al., 2004) to 5% (Warner et al., 2004; Kuhl et al. 2005). The Kriege study included moderate-to-high risk women ( $\geq 15\%$  lifetime risk) whereas the other two studies included only high-risk women. None of the studies reported whether the difference in the breast cancer detection rate with MRI plus mammography versus mammography alone was statistically significant. The recall rate (proportion of women called back for follow-up testing) ranged from 4% to 8% higher with MRI screening than with mammography-alone screening. None of the studies reported the recall rate with combined screening, but this would likely reflect the higher MRI rates. The sensitivity and specificity of combined screening with MRI and mammography versus mammography alone was reported in two studies. Leach et al., 2005 found a higher sensitivity with combined screening (94% versus 40%) and a lower specificity (77% versus 93%). Kuhl et al. (2005) also found a higher sensitivity with combined testing than mammography alone (93% versus 33%) and similar levels of specificity with the two methods (96% and 97%). Neither study reported p-values for the difference in sensitivity and specificity. The Kuhl et al., 2005 study did a sub-analysis by level of risk (see Table 2). The risk categories were moderate-risk (20% lifetime risk) and high-risk (21-40% lifetime risk). The sensitivity of combined screening was 100% in both the moderate and high-risk groups. This was substantially higher than the sensitivity with mammography alone, 50% for the moderate risk group and 25% for the high-risk group. Specificities of combined screening and mammography alone were similar for both risk levels. This analysis is limited in that it is based on a small number of cancer cases, only 6 for the moderate-risk group. This results in imprecise and unreliable statistics, and should be viewed as preliminary data. For example, mammography correctly detected 3/6 cancers (50%); if only one additional cancer had been identified, the sensitivity would be dramatically altered to 4/6 (67%). **Conclusion** There is no high-grade evidence on whether the combined screening with MRI and mammography improves health outcomes such as breast cancer mortality or overall mortality. The available evidence from 6 prospective studies suggests that combined screening of asymptomatic women at moderate-to-high risk of breast cancer with MRI plus mammography results in a 1-5% absolute increase in the cancer detection rate over mammography alone. The recall rate is substantially higher with MRI alone (4-8%), and would thus be higher with combined screening. Findings of 2 prospective studies are that combined screening substantially improves sensitivity compared to mammography alone and may decrease specificity. Data on women at moderate risk of breast cancer ( $\leq 20\%$  lifetime risk) are insufficient to draw conclusions about detection rate or diagnostic accuracy.

**Articles:** There were no randomized or non-randomized controlled trials that compared health outcomes in high-risk women who received screening with mammography alone versus screening with mammography plus MRI. As reported in the American Cancer Society review (Saslow et al., 2007), there were 6 published prospective studies examining diagnostic yield and/or sensitivity/specificity of mammography compared to MRI for asymptomatic women at moderate-to-high risk of breast cancer. These 6 studies were critically appraised and presented in a joint evidence table. The Kaiser Permanente national breast cancer screening guideline included the topic of breast MRI screening for high-risk women. They identified additional observational studies comparing mammography to MRI. These studies were not included in the MTAC review due to methodological limitations such as a retrospective design, small sample size or only a minority of the study population underwent MRI screening. *The studies reviewed include:* Kriege M et al. for the MRI Screening Study Group. Efficacy of MRI and mammography for breast-cancer screening in women with a familial or genetic predisposition. *NEJM* 2004; 351: 427-437. See [Evidence Table](#). Kuhl CK et al. Mammography, breast ultrasound, and magnetic resonance imaging for surveillance of women at high familial risk of breast cancer. *J Clin Oncol* 2005; 23: 8469-8476. See [Evidence Table](#). Leach MO et al. for the MARIBS Study Group. Screening with magnetic resonance imaging and mammography of a UK population at high familial risk of breast cancer: a prospective multicentre cohort study (MARIBS). *Lancet* 2005; 365: 1769-1778. See [Evidence Table](#). Lehman CD et al. for the International Breast MRI Consortium Working Group. Screening women at high risk of breast cancer with mammography and magnetic resonance imaging. *Cancer* 2005; 103: 1898-1895. See [Evidence Table](#). Sardanelli F et al. for the High Breast Cancer Italian Trial (HIBCRIT). Multicenter comparative multimodality surveillance of women at genetic-familial

high risk for breast cancer (HIBCRIT Study). Radiology 2007; 242: 698-715. See [Evidence Table](#). Warner E et al. Surveillance of BRCA1 and BRCA2 mutation carriers with magnetic resonance imaging, ultrasound and mammography, and clinical breast examination. JAMA 2004; 292: 1317-1325. See [Evidence Table](#).

The use of MRI in the screening of high risk patients for breast cancer and breast lesions does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 04/08/2008: MTAC REVIEW

##### **MRI in the Diagnosis of Breast Cancer and Breast Lesion**

**Evidence Conclusion:** *Diagnostic accuracy:* It is hard to determine the diagnostic accuracy of imaging studies used to assess the integrity of breast implants. Visual inspection of the implant after its surgical removal is considered the gold standard for ruptured implants. However, this would not apply to asymptomatic women, as it would not be appropriate or ethical to remove an implant with no evidence of leak or rupture. The majority of the studies on the diagnostic accuracy of MRI or other imaging tests were thus conducted among symptomatic women who requested, or were advised to remove the implants. The meta-analysis and the studies reviewed show wide variations in the accuracy of MRI and its predictive values in detecting an implant rupture in symptomatic women. The studies had differences in the equipment used, imaging protocol, description of positive MRI, and surgical criteria for a diagnosis of rupture. There were also some interobserver variations as seen in Collis and colleagues study (2007). Different generations of implants were used. These varied by manufacturer, model, longevity, long-term integrity of the implant, as well as the implantation site and position. The authors of the majority of studies did not indicate the generation of implants used. Only one study (Collis 2007) included patients who exclusively received the third generation implants. Holmich (2005) also provided the proportion of women receiving each of the three implant generations. Results of studies among women who received earlier generation of implants might not be generalized to the generation(s) currently used. One other limitation of the studies is the inclusion of self-selected symptomatic women who were requesting removal or replacement of the implants. The higher prevalence of rupture among these women would overestimate the accuracy of the tests, and limit generalization of the results to similar groups of patients. The overall results of the published studies show that the sensitivity of MRI in detecting an implant rupture among symptomatic women ranged from 64% to 90%. The specificity of the test ranged from 43% to 100%, the positive predictive value from 57% to 100% and the negative predictive values from 79% to 90%. Ultrasound came next in its accuracy with a sensitivity ranging from 30% to 69% and specificity ranging from 64% to 81%. Mammography was found to have the lowest sensitivity ranging from 20% to 69%, but with a specificity of 82% to 93%. Collis et al's study among asymptomatic who responded to the invitation for MRI testing showed a wide variations in sensitivity (71-86%) and specificity (48-95%) depending on the radiologist who interpreted the test. This assessment was based only on implants that were surgically removed. *Diagnostic impact:* There is insufficient evidence to determine that MRI may influence the management decisions for detected implant leak. *Therapeutic impact:* There are no published studies on the impact of MRI detection of implant leak on health outcomes.

##### **Conclusions:**

- MRI is moderately to highly sensitive, and more specific in detecting implant rupture among self-selected groups of symptomatic women. i.e. in confirming ruptures when suspected.
- There is insufficient evidence on the accuracy of MRI as a screening tool for detecting leak or rupture among asymptomatic women.
- There is insufficient evidence to determine that MRI may influence the management decisions for detected implant leak.
- There is insufficient evidence on the impact of MRI detection of implant leak on health outcomes.

**Articles:** The literature search revealed over 120 articles. Many were review articles or studies on and safety and durability of the silicone gel implants. The following questions were considered in screening the published articles:

1. What is the diagnostic accuracy of MRI in detecting silicone gel breast implant leak/rupture in asymptomatic and symptomatic women?
2. Would the detection of the implant rupture using MRI influence management decisions?
3. Does the detection of the implant rupture using MRI have an impact on health outcome?

##### **1. Diagnostic accuracy**

The literature search revealed several studies dating back to the early 1990s. There were 2 meta-analyses, and a systematic review on the diagnostic accuracy of MRI for detecting implant rupture among symptomatic women. The more recent meta-analysis, as well as studies that were not included in the analysis and that verified MRI findings with visual inspection of implant after surgical removal were critically appraised. Two studies that included asymptomatic women with a breast implant were identified (Brown 2000, and Collis 2007). In Brown and colleagues' (2000), study, the majority (92%) of the implants was second generation implants, and in Collis et al's study all were 3<sup>rd</sup> generation implant type. Collis' study was selected for critical appraisal as the second generation implants are known to be more prone to rupture, and the results of Brown's study may not be generalized to the other generations that are more commonly used.

## 2. Diagnostic impact

A small study on the clinical impact of MRI was identified and critically appraised.

## 3. Therapeutic impact

No studies on the impact of technology on patient outcomes were identified by the search.

*The following studies were critically appraised:*

Cher DJ, Conwell JA, Mandel JS. MRI for detecting silicone breast implant rupture: Meta-analysis and implications. *Ann Plast Surg* 2001;47:367-380. See [Evidence Table](#). Reynolds HE, Buckwalter KA, Jackson VP, et al. Comparison of mammography, sonography, and magnetic resonance imaging in the detection of silicone-gel breast implant rupture. *Ann Plast Surg*.1994;33:247-257. See [Evidence Table](#). Beekman WH, Hage JJ, van Amerongen AHM, et al. Accuracy of ultrasonography, and magnetic resonance imaging in detecting failure of breast implants filled with silicone gel. *Scand J Plast Reconstr Hand Surg* 1999;33:415-418. See [Evidence Table](#). Scaranelo AM, Marques AF, Smialowski EB, et al. Evaluation of the rupture of silicone breast implants by mammography, ultrasonography, and magnetic resonance imaging in asymptomatic patients: correlation with surgical findings. *Sao Paulo Med J* 2004;122:41-47. See [Evidence Table](#). Holmich LB, Vejborg I, Conrad C, et al. The diagnosis of breast rupture: MRI findings compared with findings of explantation. *Europ J Radiol*. 2005:213-225. Magnetic resonance imaging and explantation investigation of long-term silicone gel implant integrity. *Plast Reconstr Surg* 2007;120:1401-1406. See [Evidence Table](#). Dobke MK, Middleton MS. Clinical impact of breast implant magnetic resonance imaging. *Ann Plast Surg*.1994;33:241-246. See [Evidence Table](#)

The use of MRI in the detecting leakage from silicone implants does not meet the *Group Health Medical Technology Assessment Criteria*.

## 08/03/2009: MTAC REVIEW

### MRI in the Diagnosis of Breast Cancer and Breast Lesion

**Evidence Conclusion:** Published studies by two research groups comparing the specificity of breast MRI with and without CAD assistance for distinguishing between benign and malignant lesions were reviewed. Williams et al. (2007) evaluated 155 breast lesions detected by MRI and found a statistically significant reduction in the false-positive rate (reduced 23%) with CAD enhancement at 100%. Meinel et al. (2006) evaluated 80 lesions and found a statistically significant increase in specificity (from 51% to 81%) when human readers were aided by CAD. A higher specificity (and corresponding low false-positive rate) would contribute to improved diagnosis since fewer women would be subject to unnecessary follow-up tests or procedures. No published studies, however, evaluated whether there was a reduction in the number of biopsies or other procedures, or whether use of CAD contributed to a change in diagnosis. The above findings are insufficient to draw conclusions about the use of CAD systems with breast MRI and its impact on health outcomes. The quantity of published studies is low, and sample sizes of individual studies are small. Only one research group, Williams et al. (2007) did a comparative analysis with a commercially available CAD system. Moreover, no studies are available on the impact of CAD-enhanced MRI on follow-up procedures or diagnosis.

**Articles:** The Pubmed search yielded 79 articles. One additional article was identified on the CADStream website (Lehman et al., 2006). BCBSA TEC conducted an assessment in 2006; their search in March of that year identified the same articles as the PubMed search. Most of the articles in the PubMed search were either review articles, dealt with related topics such as other types of cancer, or addressed CAD development of other technical aspects of CAD systems or MRI. Three empirical studies were identified that compared breast MR imaging with and without a CAD system. Two of the articles were published by the same research group (T. Lehman, W DeMartini, S Peacock and others) and the later article (2007) appears to also include lesions included in the earlier article (2006). The 2007 article by this group and the other comparative study were both critically appraised. References are as follows: Williams TC, DeMartini WB, Partridge SC et al. Breast MR imaging: Computer-aided evaluation program for discriminating benign from malignant lesions. *Radiol* 2007; 244: 94-103. See [Evidence Table](#). Meinel LA, Stolpen AH, Berbaum KS et al. Breast MRI lesion classification: Improved performance of human readers with a backpropagation neural network computer-aided diagnosis (CAD) system. *J Magn Reson Imaging* 2007; 25: 89-95. See [Evidence Table](#).

The use of computer-aided detection (CAD) applied to breast MRI does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Weight-Bearing MRI

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Magnetic Resonance Imaging (MRI) (220.2)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Magnetic resonance imaging (MRI) uses magnetic fields and radiofrequency waves to provide images of internal organs and tissues. Among other applications, MRI is widely used to diagnose joint and musculoskeletal disorders especially injuries affecting the knee, shoulder, hip, elbow and wrist.

Conventional MRI may have limits for diagnosing certain conditions such as degenerative cervical spinal disorders in which symptoms are aggravated when patients are standing and relieved when patients are lying down. The closed cylindrical design of standard MRI systems requires patients to be imaged in a supine position. Thus, with conventional non-weight-bearing MRI, the conditions under which symptoms arise are often not reproduced. Biomechanical studies have found a decrease in spinal canal cross-sectional area (or dural sac) and spinal foraminal dimensions with weight-bearing (axial loading) and with flexion and extension. In some cases, MRI findings correlate with patient symptoms. Disk extrusion, disk sequestration and nerve root compression are infrequently seen in asymptomatic patients, leading to the common belief that nerve root compression seen on MRI is clinically relevant. MRI of patients in the supine position may not identify clinically relevant spinal canal and foraminal stenosis, or the degree of nerve root compression (Kumura et al., 2005; Weishaupt & Boxheimer, 2003).

Weight-bearing MRI is proposed as an alternative to conventional MRI imaging. There are two ways to image the weight-bearing spine. One approach is to simulate weight bearing using a special device with conventional MRI machines. A study of patients with symptoms of spinal stenosis (Hiwatashi et al., 2004) found that imaging with axially loaded MR imaging can yield information that results in different treatment decisions than standard MRI. The Hiwatashi study used a device, consisting of a harness/jacket with straps connected to a footplate that applies an axial load to the patient's spine during imaging in the supine position.

The other approach is to use a vertically open-configuration MRI that allows the patient to be imaged in a weight-bearing position. There are two FDA-approved devices:

- The Indomitable MRI scanner (Fonar) was approved by the FDA in October 2000 for imaging multiple planes of the head and body. It has an open design and the patient-scanning table can be moved to a variety of positions with the patient on it. Scanning positions include a vertical (upright) position, a horizontal (supine) position and an angled position (angles between -20o and 90o). Fonar, the manufacturer, claims that this is the only MRI system that can scan patients in flexion, extension, rotation and lateral bending (Fonar website; FDA website).

- The G-scan (Esaote) was approved by the FDA in August, 2004; its use is limited to imaging the ankle, knee, hip, shoulder joint and spine. The scanning table can also be moved to a variety of positions with the patient on it. The table can be rotated to angles between supine (0o) to fully upright (90o). The system also includes specialized knee, hand/wrist, ankle/foot and shoulder coils (Esaote website; FDA website).

Weight-bearing MRI has not been previously reviewed by MTAC.

Assessment questions:

- Diagnostic accuracy: What is the evidence on the ability of upright MRI to accurately detect problems/pathology compared to conventional MRI?
- Diagnostic impact: What is evidence on whether findings from weight-bearing MRI contribute substantially to improved diagnosis compared to conventional MRI?
- Therapeutic impact: What is the evidence that more appropriate therapy is used after weight-bearing MRI compared to conventional MRI?

## Medical Technology Assessment Committee (MTAC)

### Weight-Bearing MRI

#### 06/04/2007: MTAC REVIEW

**Evidence Conclusion:** There are no published studies on the diagnostic accuracy (sensitivity/specificity), diagnostic impact or therapeutic impact of upright MRI compared to conventional MRI. One study with the Fonar Upright MRI system (Perez et al., 2007 in press) compared the diagnostic yield of the new device compared to conventional MRI. There was no gold standard comparison; rather, weight-bearing MRI was compared to conventional MRI. 68 pathologies were identified in 89 symptomatic patients by one or both methods. The authors considered a technology to be “superior” if it identified a pathology not detected by the other method, or indicated a herniation or spondylolisthesis that was larger in size. Upright MRI was found to be superior to recumbent MRI in 52 out of 68 pathologies identified, and recumbent MRI was found to be superior to upright MRI in 11 cases. The reports by the Washington State Labor and Industries Department and the Washington State Department of Health both also concluded that there was insufficient evidence on the diagnostic accuracy or utility of weight-bearing MRI.

**Articles:** Diagnostic accuracy: No studies were identified evaluated the sensitivity and specificity of weight-bearing MRI compared to conventional MRI, using an objective comparison. The empirical articles identified in the search generally involved obtaining spinal measurements with patients in various positions. For example, Hirasawa et al. (2007) examined 20 asymptomatic volunteers with the Fonar Indomitable MRI scanner in supine, sitting and standing positions. The primary outcome measures were differences in spinal measurements, specifically mean dural sac cross-sectional area and diameter. One study was identified that compared clinical diagnoses of patients imaged with weight-bearing MRI versus conventional MRI. This study (Ferreiro Perez et al., in press 2007) was critically appraised. See [Evidence Table](#). Diagnostic accuracy: No studies were identified evaluated the sensitivity and specificity of weight-bearing MRI compared to conventional MRI, using an objective comparison. The empirical articles identified in the search generally involved obtaining spinal measurements with patients in various positions. For example, Hirasawa et al. (2007) examined 20 asymptomatic volunteers with the Fonar Indomitable MRI scanner in supine, sitting and standing positions. The primary outcome measures were differences in spinal measurements, specifically mean dural sac cross-sectional area and diameter. One study was identified that compared clinical diagnoses of patients imaged with weight-bearing MRI versus conventional MRI. This study (Ferreiro Perez et al., in press 2007) was critically appraised. See [Evidence Table](#). Diagnostic impact: No studies were identified that evaluated whether findings from weight-bearing MRI contribute substantially to improved diagnosis compared to conventional MRI. Therapeutic impact: No studies were identified that reported quantitative data on whether more appropriate therapy was used after weight-bearing MRI than conventional MRI.

The use of weight-bearing MRI does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Magnetic Resonance Spectroscopy (MRS)

- ADHD
- Autism
- Cerebral Tumors
- Differentiating Tumors from Non-Tumors
- Epilepsy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Magnetic Resonance Spectroscopy (220.2.1)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

Group Health has elected to use the Magnetic Resonance Spectroscopy (A-0482) MCG\* for medical necessity determinations. This service is not covered per MCG guidelines.

**\*MCG manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Magnetic resonance spectroscopy (MRS) is a non-invasive technique that provides chemical information on metabolites in tissues. It uses strong magnetic fields to generate an exchange of energy between external magnetic fields and protons within tissues. The energy exchange is transmitted back to the machine as a radiofrequency signal which is decoded by computer software. The software produces a waveform with peaks corresponding to the relative concentration of various chemicals. In addition, the specific chemicals that are present are identified--they appear at different locations on a horizontal axis. MRS utilizes the magnetic property of atomic nuclei. The proton is the most commonly studied nucleus. Proton ( $^1\text{H}$ ) MRS defines approximately 15 brain metabolites. These include lipids, lactate, N-acetylaspartate (NAA), glutamate/glutamine (Glx), creatine (Cr), choline (Cho) and myoinositol (ml) (Gulati et al., 2003; Lin et al., 2005; BlueCross BlueShield Association, 2005).

A potential use of MRS is to diagnose conditions when other tests have been negative or inconclusive, or to refine existing diagnoses. For example, an increased Cho signal is believed to indicate the presence of cancerous cells. MRS can be used alone or in combination with magnetic resonance imaging (MRI) which produces anatomic images. In addition, MRS can be used to monitor metabolites to evaluate the effectiveness of therapy by seeing if levels change from elevated back to normal (Lin et al., 2005).

MRS has been used to study various neurologic diseases, including epilepsy, multiple sclerosis, HIV-related neurologic disorders and brain tumors, as well as cerebrovascular and metabolic diseases. One review article stated that MRS's most important use in neurology is quantifying neuronal loss and demonstrating reversible neuronal damage. (Rudkin & Arnold, 1999).

Other imaging tests used for epilepsy include EEG, MRI, FDG PET and CT scanning. ADHD and autism are diagnosed mainly by clinical evaluation. EEG and MRI are sometimes used to provide additional information on autism.

### Cerebral Tumors

More than 190,000 people in the United States are diagnosed with primary or metastatic cerebral tumors annually. It is challenging to diagnose and treat cerebral tumors due to the similarity of these lesions to other types of pathologies on conventional imaging, the inaccessibility of the lesions and their proximity to complex brain structures. An accurate non-invasive method for diagnosing cerebral tumors is desirable, especially one that could replace biopsy which has a reported morbidity of 3-4% (AHRQ, 2003, Sibtain et al., 2007; National Brain Tumor Foundation).

Imaging procedures for diagnosing cerebral tumors include CT, MRI, SPECT and PET. CT uses x-rays and MRI uses non-ionizing radio frequency to acquire images. Both methods can generate multiple two-dimensional cross-sections of tissue as well as three-dimensional reconstructions, and are generally used in conjunction with stereotactic biopsy. PET scans measure glucose activity which can be translated to a moving picture of the brain. SPECT imaging uses gamma rays to acquire multiple two-dimensional images from multiple angles, which can produce true three-dimensional information.

Magnetic resonance spectroscopy (MRS), a technique related to MRI, is also proposed for imaging cerebral tumors. MRS is a non-invasive technique that provides chemical information on metabolites in tissues. It uses strong magnetic fields to generate an exchange of energy between external magnetic fields and protons within tissues. The energy exchange is transmitted back to the machine as a radiofrequency signal which is decoded by computer software. The software produces a waveform with peaks corresponding to the relative concentration of various chemicals. In addition, the specific chemicals that are present are identified--they appear at different locations on a horizontal axis. MRS utilizes the magnetic property of atomic nuclei. The proton is the most commonly studied nucleus. Proton (1H) MRS defines approximately 15 brain metabolites. These include lipids, lactate, N-acetylaspartate (NAA), glutamate/glutamine (Glx), creatine (Cr), choline (Cho) and myoinositol (mI). A chemical profile that may be characteristic of brain tumors includes an increase in Cho, and a reduction in Cr and NAA (Sibtain et al., 2007; Lin et al., 2005; BlueCross BlueShield Association, 2005).

Potential areas in which MRS may contribute diagnostic information include distinguishing abscesses from tumors, providing a more accurate way to determine the grade of primary tumors than conventional MRI, distinguishing single metastatic brain lesions from primary tumors, providing guidance for biopsy and gamma knife therapy, determining tumor recurrence and differentiating between radiation necrosis and tumor recurrence. MRS can be used alone, or in combination with MRI (AHRQ, 2003; Sibtain et al., 2007).

Several factors may limit the performance of MRS in identifying cerebral tumors. Sudden dramatic changes in the composition of tissue can cause inaccuracies in the magnetic fields. This is relevant for lesions adjacent to bone or air-filled structures such as the sinuses. Moreover, lesions that lie near areas of old infarcts or ischemic changes, or concurrent demyelinating disease, can distort the chemical ratios used in interpretation. In addition, visual interpretation of spectra is difficult and requires special training (AHRQ, 2003; Sibtain et al., 2007).

## **Medical Technology Assessment Committee (MTAC)**

### ***Magnetic Resonance Spectroscopy (MRS)***

#### **12/05/2005: MTAC REVIEW**

**Evidence Conclusion:** No published studies were identified on the accuracy of magnetic resonance spectroscopy for diagnosing ADHD or autism. One study was identified on the accuracy of MRS for lateralization of patients with medically refractory temporal lobe epilepsy. This study (Cendes et al., 1997) included 100 patients and used EEG as the gold standard. Lateralization based on MRS agreed with EEG findings in 87% of cases. Lateralization based on the results of MRS and MRI combined agreed with EEG findings in 86% of cases.

**Articles:** The ideal study of diagnostic accuracy would report the sensitivity and specificity of MRS, and compare this to an independent blinded comparison to a "gold standard" diagnosis.

**ADHD and autism** None of the studies on ADHD, or ADHD and autism reported the sensitivity and specificity of MRS diagnosis compared to a "gold standard" such as clinical evaluation. The empirical studies reported on preliminary research using MRS to measure the concentrations of various chemicals in the brains of children with ADHD compared to healthy children. One of the articles included children with autism, in addition to children with ADHD and healthy controls. **Epilepsy** None of the studies on epilepsy reported the sensitivity and specificity of MRS diagnosis compared to a "gold standard". There were several studies examining the correlations between concentrations of chemicals identified by MRS and seizure duration, seizure severity or surgical outcome. One

study compared chemical concentrations in patients with epilepsy and normal controls. These were all descriptive studies and were not evaluated further. One study was identified that compared the performance of MRI, MRS and the combination of the two in the lateralization of temporal lobe epilepsy (TLE). This article (Cendes et al., 1997) was critically appraised. No other studies on the diagnostic accuracy of MRS in patients with epilepsy were identified and no studies were identified on diagnostic or therapeutic impact.

*The study critically appraised was:* Cendes F, Caramanos Z, Andermann F et al. Proton magnetic resonance spectroscopic imaging and magnetic resonance imaging volumetry in the lateralization of temporal lobe epilepsy: A series of 100 patients. *Ann Neurol* 1997; 42: 737-746. See [Evidence Table](#).

The use of Magnetic resonance spectroscopy (MRS) in diagnosing autism, ADHD and epilepsy does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **10/02/2006: MTAC REVIEW**

##### **Magnetic Resonance Spectroscopy (MRS)**

**Evidence Conclusion:** No new published studies were identified on the accuracy of magnetic resonance spectroscopy for diagnosing ADHD, epilepsy or autism. No new studies were identified that validate specific chemical profiles that are diagnostic of particular conditions.

**Articles:** The ideal study of diagnostic accuracy would report the sensitivity and specificity of MRS, and include an independent blinded comparison to a "gold standard" diagnosis. *ADHD and autism* - 2005 Review: None of the studies on ADHD, or ADHD and autism reported the sensitivity and specificity of MRS diagnosis compared to a "gold standard" such as clinical evaluation. The empirical studies reported on preliminary research using MRS to measure the concentrations of various chemicals in the brains of children with ADHD compared to healthy children. One of the articles included children with autism in addition to children with ADHD and healthy controls. 2006 Review: The newer studies were similar to those identified in the 2005 search. Studies reported on use of MRS to measure the concentrations of chemicals (i.e. Cho, CR and NAA) in children with autism or ADHD compared to healthy children. None of the studies reported the ability of MRS to diagnose autism or ADHD (i.e. sensitivity and specificity of MRS findings). *Epilepsy* - 2005 Review: None of the studies on epilepsy reported the sensitivity and specificity of MRS diagnosis compared to a "gold standard". Several studies examined the correlations between concentrations of chemicals identified by MRS and seizure duration, seizure severity or surgical outcome. One study compared chemical concentrations in patients with epilepsy and normal controls. These were all descriptive studies and were not evaluated further. One study compared the performance of MRI, MRS and the combination of the two in the lateralization of temporal lobe epilepsy (TLE). This article (Cendes et al., 1997) was critically appraised. 2006 Review: One meta-analysis was identified. This study (Willmann et al., in press, 2006) assessed the pre-operative value of MRS in identifying the epileptogenic zone (EZ) for epilepsy surgery. Preoperative evaluation of epilepsy patients is outside the scope of the current review and the study was thus not evaluated further.

The use of Magnetic resonance spectroscopy (MRS) in diagnosing autism, ADHD and epilepsy does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **12/03/2007: MTAC REVIEW**

##### **Magnetic Resonance Spectroscopy (MRS)**

**Evidence Conclusion:** Three studies were reviewed that reported the sensitivity and specificity of MRS for distinguishing brain tumors from non-tumors, compared to a reference standard. All had relatively small sample sizes, especially as regards the number of patients without tumors, so estimates may not be reliable. One of the studies used combined MRS/MRI findings. Sensitivity ranged from 81% to 90% and specificity from 86% to 100%. The size of the studies were too small to draw conclusions about the accuracy of MRS for differentiating between brain tumors and any specific alternate condition such as radiation necrosis or abscess. There is a lack of evidence on the diagnostic accuracy of MRS alone compared to conventional imaging, or on MRS plus conventional imaging versus conventional imaging alone. Thus, it is difficult to draw conclusions about the ability of MRS to replace other diagnostic tests. Two studies addressed the impact of MRS on clinical decision-making. Both were case series; Lin et al., 1999 was limited in that it had only 15 patients, and Adamson et al. was retrospective. In the Adamson et al., study, MRS was seen as having a potential positive impact on treatment in 23/78 (29%) of cases. In 2 cases, MRS was seen as having a potential negative impact on treatment. For the remainder of the cases, MRS was viewed as neutral, or patients were lost to follow-up. In the Lin study, which only included 15 patients, MRS was used in place of biopsy in 7 cases, and MRS was correlated with clinical course in 6 cases. MRS did not correlate with clinical course in only 1 patient.

**Articles:** *Accuracy of MRS* The ideal study of diagnostic accuracy would report the sensitivity and specificity of MRS and include an independent blinded comparison to a "gold standard" diagnosis. Several studies met these criteria and were critically appraised. All had relatively small sample sizes. Rand et al., 1997 and McKnight et al.,

2002 evaluated MRS alone and Gajewicz et al., 2003 evaluated MRS in combination with MRI. Rand SD, Prost P, Haughton V et al. Accuracy of single-voxel proton MR spectroscopy in distinguishing neoplastic from nonneoplastic brain lesions. AJRN 1997; 18: 1685-1704. See [Evidence Table](#). McKnight TR, von dem Bussche BS, Vigneron DB. et al., Histopathological validation of a three-dimensional magnetic resonance spectroscopy index as a predictor of tumor presence. J Neurosurg 2002; 97: 794-802. See [Evidence Table](#). Gajewicz W, Papierz W, Szymczak W et al. The use of proton MRS in the differential diagnosis of brain tumors and tumor-like processes. Med Sci Monit 2003; 9: MT97-105. See [Evidence Table](#). Diagnostic impact (does MRS contribute substantially to improved diagnosis and/or replace other diagnostic tests or procedures). There were no studies comparing diagnosis with MRS to diagnosis with conventional imaging. Therapeutic impact of MRS (is more appropriate therapy used after application of MRS than would be used if the test were not available). Two studies that evaluated the impact of MRS on clinical decision-making were identified and critically appraised: Adamson AJ, Rand SD, Prost RW et al. Focal brain lesions: Effect of single-voxel proton MR spectroscopic findings on treatment decisions. Radiol 1998; 209: 73-78. See [Evidence Table](#). Lin A, Blum s, Mamelak AN. Efficacy of proton magnetic resonance spectroscopy in clinical decision making for patients with suspected malignant brain tumors. J Neuro-Oncol 1999; 45: 69-81. See [Evidence Table](#).

The use of Magnetic resonance spectroscopy (MRS) in diagnosing cerebral tumors and differentiating tumors from non-tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Naturopathy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Naturopathy is not covered by Medicare and is considered a supplemental benefit. Please check member contract for specific coverage language.

##### For Non-Medicare Members

- I. Authorizations for covered naturopathic treatments beyond three visits require prior approval by the health plan for those plans with alternative medicine benefits.
- II. Clinical review criteria for naturopathy are as follows:
  - A. The patient has an established, documented diagnosis of one of the following:
    - Fibromyalgia (The patient has an established, documented diagnosis of fibromyalgia consistent with the 1990 American College of Rheumatology Criteria.)
    - Chronic arthritis
    - Chronic fatigue syndrome
    - Premenstrual syndrome
    - Irritable bowel syndrome
    - Menopausal symptoms
    - Headaches (persistent sinus, muscle tension, migraine)
    - Chronic sinusitis, defined as persistent sinusitis
    - Chronic serious otitis media, defined as persistent middle ear fluid for greater than three months
    - Atopic dermatitis/chronic eczema
    - Asthma that is mild to moderate in severity and not dependent on oral steroids
  - B. Treatment progress reports submitted to the health plan after the second visit, or at intervals as specified in the referral, must demonstrate the benefit of treatment for continuation of care to be approved.

Review Services will consider each referral request on a case-by-case basis and will consider requests outside the above criteria based on, among other things, clear documentation of objective improvement by the licensed naturopathic physician or the patient's personal physician, as well as a detailed treatment plan.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Naturopathic medicine is a distinct profession of health care that has been in existence since the late nineteenth century. The philosophical approach includes the following principles:

- Utilization of therapies that first do no harm.
- Prevention of disease through healthy lifestyle and control of risk factors.
- Recognition and encouragement of the body's inherent healing abilities.
- Treatment of the whole person – physical, emotional, mental, and spiritual.
- Patient education and cultivation of an attitude of personal responsibility for one's health.

Education standards for naturopathic medicine require at least three years of college level work followed by a four-year curriculum with over 4,000 hours of instruction at an accredited training institution (such as Bastyr University). In addition to conventional basic science courses, students receive training in botanical medicine, therapeutic

nutrition, and various physical medicine modalities. Naturopathic physicians are licensed in the state of Washington and in ten other states.

## Evidence and Source Documents

There is a small body of literature that supports some of the interventions that naturopaths provide.

## Clinical Review Criteria

### Neuropsychiatric EEG-Based Assessment Aid (NEBA)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

No Policy Found

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Attention deficit hyperactivity disorder (ADHD) is one of the most common neurodevelopmental disorders of childhood. It is reported that it affects 3-7% of school aged children in the USA, and that 30-65% will continue to have symptoms through adulthood. The combined form of ADHD is characterized by inattention, hyperactivity and impulsivity. ADHD can substantially affect the individual's normal cognitive and behavioral functions and create significant impairment in school and home environment, and in social relations (Altunel 2013, Mayer 2013, Nazari 2011, Ogrim 2012).

ADHD is increasingly considered as a heterogeneous disorder involving multiple pathways and neurophysiological subtypes. The disorder has multiple etiologies ranging from genetics to mild head trauma, but the specific etiology is unknown. Currently there is no single diagnostic or objective laboratory test for ADHD. A proper diagnostic evaluation for the disorder generally involves a multistep process that includes a comprehensive history, complete medical and psychiatric examination with clinical interviews, parents and teachers rating questionnaires, and behavior rating scales. The diagnosis is based on the DSM-IV criteria (modified in DSM-V) or on the ICD-10 criteria. ADHD symptoms may overlap with other diagnoses that makes it hard to determine whether ADHD is the primary cause. It may also be difficult for clinicians to distinguish between ADHD and other disorders that may have similar presentations e.g. autism spectrum disorders, learning disabilities, anxiety, or mood disorders. A biologically-based diagnostic test or biomarker that is objective, reliable, sensitive and specific for ADHD would provide a valuable addition in making a diagnosis (Arns 2013, Liechti 2013, Loo 2012).

In the last three decades many studies compared brain activity using electro-encephalography (EEG) among children with ADHD versus the brain activity of normal controls in an attempt to study the underlying neurophysiology of ADHD; and to investigate subtypes of the disorder and their response to treatment. The EEG frequency bands of most interest in ADHD research are the theta, beta, and alpha bands either alone or in relation to one another such as the theta/beta power or amplitude ratio. Alpha band activity is typically observed during rest when the eyes are closed, and is negatively associated with central nervous system arousal. Beta band activity on the contrary, generally accompanies mental activity and concentration. Cortical theta is observed frequently in young children, but in older children and adults, it tends to appear during meditative, drowsy, or sleeping states. Researchers suggest that most children with ADHD display EEG differences in their brain electrical activity as compared to normal children, particularly with respect to their increased frontocentral theta activity primarily during the resting state. This indicates decreased cortical activity that may be associated with underarousal. A theta /beta ratio (TBR) due to increased theta is reported by many investigators as a consistent characteristic of ADHD. Some groups recommend using the TBR during eyes-opened or eye-closed resting condition as an add-on for the diagnosis and monitoring of ADHD. However, it is reported that the true functional significance of this measure is still unknown, and an elevated theta activity may be a nonspecific marker of cortical dysfunction common to other disorders such as epilepsy, bipolar disorder, and polysubstance abuse (Arns 2013, Liechti 2013, Loo 2012).

A number of studies examined the accuracy and diagnostic value of the theta power and TBR in discriminating normal children from children with learning disorders, ADD, and ADHD. In 2005, Boutros and colleagues performed a review and meta-analysis to estimate the strength and effect size of increased theta activity in ADHD patients. Based on their findings they concluded that the increased EEG theta activity in ADHD is promising, and should be further developed as a diagnostic test for ADHD. Around the same time another group of investigators (Synder and Hall, 2006) also conducted a meta-analysis to investigate the theta and beta powers and their ration (TBR), and concluded that the pooled results support the finding that an increase in the theta/beta ratio is a commonly observed trait in ADHD relative to normal controls. They however, cautioned that theta/beta ratio trait may arise with other conditions, and that a prospective study covering differential diagnosis would be required to determine generalizability to clinical applications (Arns 2013, Boutros 2005, Loo 2012 Snyder 2006).

Based on this EEG technology, the Neuropsychiatric EEG-Based Assessment Aid (NEBA) System (NEBA Health, Augusta, GA) was developed and recently received Food and Drug Administration (FDA), in July 2013, to help assess ADHD in children and adolescents 6-17 years of age. It is not to be used as a stand-alone diagnostic test, but as a conjunctive tool for diagnosing ADHD. NEBA is a non-invasive test that calculates the ratio of theta and beta waves frequencies in 15-20 minutes (FDA and NEBA websites accessed January 15, 2014).

According to the FDA, the use of the device together with the complete medical and psychological examination, can help confirm an ADHD diagnosis or a clinician's decision that further diagnostic testing should focus on ADHD or other medical or behavioral conditions that lead to symptoms similar to ADHD. The FDA reviewed the NEBA System through a de novo classification process, a regulatory pathway for some low- to moderate-risk medical devices that are not substantially equivalent to an already legally marketed device (FDA website accessed January 15, 2014).

## Medical Technology Assessment Committee (MTAC)

### 02/10/2014: MTAC REVIEW

#### Neuropsychiatric EEG-Based Assessment Aid (NEBA)

**Evidence Conclusion:** There is no published evidence to date to determine the safety, accuracy, or clinical utility of NEBA system in discriminating between children with or without ADHD. The FDA approval was based on a clinical study of 275 children and adolescents with attention and/or behavioral concerns. The study was conducted by the manufacturer of the NEBA system and has not been published in a peer reviewed journal to date. The observational studies on the correlation between the theta/beta ratios (TBR) had their limitations, and their results were inconclusive. In addition (according to Loo, 2012) there are wide variation in EEG instrumentation that can make it very hard to compare or generalize results of studies using different EEG hardware and software.

**Articles:** The literature search did not reveal any published study on the NEBA system; it only identified several observational studies that investigated brain activity using EEG in children with ADHD compared with normal controls, as well as three meta-analyses that pooled the results of a number of these studies.

The use of NEBA does not meet the *Group Health Medical Technology Assessment Criteria*.

Negative Pressure Wound Therapy Pumps (NPWT)

##### Initial Coverage:

An NPWT pump and supplies are covered for wound edema, exudate management and stimulation of granulation for an initial 14 day course when the following main criteria are met:

- 1) Must complete the [Group Health initial coverage request form](#) and fax it to the DME staff at 877-290-4632.
- 2) Ulcers and Wounds in the Home Setting:
  - A. The patient has a Stage III or IV pressure ulcer, neuropathic/diabetic ulcer, venous insufficiency or arterial ulcer, or a chronic ulcer of mixed etiology. These wounds should have exudate, size and depth to require this specialized therapy. A complete wound therapy program described by criterion 1 and criteria 2, 3, or 4, as applicable depending on the type of wound, should have been tried for 30 days unless edema and/or exudate mandates NPWT.
    1. For all ulcers or wounds, the following components of a wound therapy program must include a minimum of all of the following general measures prior to application of NPWT:
      - i. Documentation in the patient's medical record of evaluation, care, and wound measurements by a licensed medical professional.
      - ii. Consideration of the following risk factors is addressed in the documentation
        - (a) Risk for bleeding and hemorrhage
        - (b) Active treatment with anticoagulants or platelet aggregation inhibitors
        - (c) Presence of:
          - Friable vessels and infected blood vessels
          - Vascular anastomosis
          - Infected wounds
          - Osteomyelitis
          - Exposed organs, vessels, nerves, tendons, and ligaments
          - Sharp edges in the wound (i.e. bone fragments)
          - Spinal cord injury (stimulation of sympathetic nervous system)
          - Enteric fistulas
        - (d) Requirement for:
          - MRI
          - Hyperbaric chamber
          - Defibrillation

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

- (e) Size and weight
- (f) Use of device near the vagus nerve
- (g) Use of circumferential dressing application
- (h) Mode of therapy – intermittent versus continuous negative pressure
- iii. Application of dressings to maintain a moist wound environment.
- iv. Debridement of necrotic tissue if present.
- v. Evaluation of and provision for adequate nutritional status.
- 2. For Stage III or IV pressure ulcers:
  - i. The patient has been appropriately turned and positioned.
  - ii. The patient's moisture and incontinence have been appropriately managed.
- 3. For neuropathic/diabetic ulcers:
  - i. The patient with diabetes has been on a comprehensive diabetic management program, **and**
  - ii. A foot ulcer has been appropriately off-loaded.
- 4. For venous insufficiency ulcers:
  - i. Compression bandages and/or garments have been consistently applied only after Ankle-Brachial Index has been done per guidelines, and
  - ii. Leg elevation with alternating ambulation has been encouraged.
- 3) Goal of therapy is clearly stated
- 4) Ulcers and Wounds Encountered in an Inpatient Setting:
  - A. An ulcer or wound (described in section A above) is encountered in the inpatient setting and, after wound treatments described under sections A-a through A-d have been tried or considered and ruled out, NPWT may be initiated.
  - B. The patient has complications of a surgically created wound (for example, dehiscence) or a traumatic wound (for example, pre-operative flap or graft) where there is documentation of the medical necessity for accelerated formation of granulation tissue which cannot be achieved by other available topical wound treatments (for example, other conditions of the patient that will not allow for healing times achievable with other topical wound treatments).  
*In either of the above situations, NPWT will be covered when treatment continuation is ordered beyond discharge to the home setting.*
  - C. Skin-flaps or grafts approved as covered by the health plan in advance of the procedure.
- 5) Contraindications for use:
  - A. The presence in the wound of necrotic tissue with eschar, if debridement has not been carried out
  - B. Untreated osteomyelitis within the vicinity of the wound
  - C. Possibility of malignant cells present in the wound
  - D. The presence of a fistula to an organ or body cavity within the vicinity of the wound
  - E. Exposed vascular in the wound
  - F. Exposed nerves in the wound
  - G. Exposed anastomotic site
  - H. Exposed organs
  - I. Recent lab values for albumin equal to or less than 2.5, hemoglobin less than 10, or hematocrit less than 30
  - J. Pediatric patients ( newborns, infants and children)

Continued Coverage:

- 1) For wounds and ulcers described under sections A and B of Initial Coverage, once placed on an NPWT pump with supplies, in order for coverage to continue a licensed medical professional must do the following:
- 2) Must complete the [Group Health continued coverage request form](#) and fax it to the DME staff at 877-290-4632.
- 3) On a regular basis:
  - A. Directly assess the wound(s) being treated with the NPWT pump
  - B. Supervise or directly perform the NPWT dressing changes
- 4) On at least a weekly basis, document changes in the ulcer's dimensions and characteristics and the degree of granulation and management of exudate
- 5) Laboratory values at monthly intervals to show a contraindication does not exist
- 6) If these criteria are not fulfilled, continued coverage of the NPWT pump and supplies will be denied as not medically necessary

When Coverage Ends:

- 1) For wounds and ulcers described under sections A and B of Initial Coverage, an NPWT pump and supplies will be denied as not medically necessary with any of the following, whichever occurs earliest:
  - A. Criteria for Continued Coverage cease to occur.

- B. In the judgment of the treating physician, adequate wound granulation has occurred to the degree that NPWT may be discontinued.
- C. Progressive wound healing has failed to occur over the prior 14 days. There must be documented in the patient's medical records quantitative measurements of wound characteristics including wound length and width (surface area), or depth, serially observed and documented, over a specified time interval. The recorded wound measurements must be consistently and regularly updated and must have demonstrated progressive wound healing from week to week.
- D. NPWT should be ordered for a 2 week period of time as wounds are expected to change with this therapy. Once equipment or supplies are no longer being used for the patient, whether or not by the physician's order, the provider should be directly contacted and the delivery of further supplies stopped. Pumps must be returned to the provider for billing purposes and cleaning.

**Supplies:**

- 1) Coverage is provided up to a maximum of 6 dressing kits (A6550) per wound per 14 day period unless there is documentation that the wound size requires more than one dressing kit for each dressing change. Dressings should be changed based on the patient's condition and the condition of the wound but normally not more frequently than 3 times a week.
- 2) Coverage is provided up to a maximum of 2 canister sets (A7000) per 14 day period unless there is documentation evidencing a large volume of drainage (greater than 90 ml of exudate per day). For high volume exudative wounds, a stationary pump with the largest capacity canister must be used. Excess utilization of canisters related to equipment failure (as opposed to excessive volume drainage) will be denied as not medically necessary.

Service	Criteria Used
Negative Pressure Wound Therapy: non-powered <ul style="list-style-type: none"> <li>• SNAP</li> <li>• PICO</li> </ul>	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

**Background**

Negative pressure wound therapy (NPWT) is a wound dressing system that was designed to promote wound healing through the use of subatmospheric pressure to the wound surface. NPWT systems include a vacuum pump, drainage tubing, and a dressing set. To place the device, the wound is covered or packed with a foam or gauze dressing and then secured using an adhesive film drape. A vacuum pump connected to the draining tube(s) in the wound dressing is used to apply pressure to the wound surface in the range of -50 to -125 mmHg. The precise mechanism through which NPWT aids the healing process is not fully understood; however, it has been suggested that NPWT may aid in the healing process through increasing local blood flow, increasing granulation tissue, reducing bacterial contamination, reducing wound area, reducing edema and exudate, and changes to the microenvironment (AHRQ 2009, Webster 2011).

Negative pressure therapy has been used in clinical applications for over five decades. The concept of applying topical negative pressure in the management of wounds emerged in the late 1980s and is increasingly used for a wide variety of wounds. The technique is also known as vacuum assisted closure (VAC), negative pressure wound therapy (NPWT), vacuum sealing technique (VST), sealed surface wound suction (SSS), subatmospheric pressure therapy or dressing, foam suction dressing, and vacuum pack technique (VPT). The technology generally involves putting a dressing (foam or gauze) into the wound cavity, connecting it to a vacuum pump, and sealing the area with an adhesive film. The vacuum pump creates and maintains a subatmospheric pressure (intermittent or continuous) in the range of -50 to -125 mmHg. The default setting is -125 mmHg, and the pressure may be titrated up by 25 mmHg increments when there is excessive drainage or a large wound volume, or titrated down when the patient is elderly, nutritionally compromised, or has a risk of excessive bleeding. Dressings are usually changed every 48 hours, or every 12-24 hours if the wound is infected. The mechanism by which NPWT is believed to promote wound healing is unclear. In theory it may increase dermal perfusion, stimulate granulation tissue formation, reduce the edema and interstitial tissue fluid, reverse tissue

expansion, and/or reduce bacterial colonization. It is also thought that the vacuum pressure may act as an effective skin graft splint over irregular surfaces. The therapy cannot be used as a replacement for surgical debridement, but as a complementary treatment. It is contraindicated for use in wounds with necrotic tissue, exposed vital structures, untreated osteomyelitis, unexplored fistulae and malignant wounds. Adverse effects include pain and damage to the skin around the wound (Braakenburg 2006, Bovill 2008, Wild 2008, Preston 2008).

Acute and chronic wounds and are a major cause of morbidity and impaired quality of life. They affect at least 1% of the population and represent a significant risk factor for hospitalization, amputation, sepsis, and even death. Wound healing is a complex series of events, broadly classified into inflammatory, proliferative, and remodeling phases. The healing process may be compromised by arterial or venous insufficiency which can prevent or delay healing and/or increase the risk of recurrent wound infections. The treatment of difficult-to-manage and chronic wounds remains a significant challenge to practitioners, a cause of pain and discomfort to the patients, and costly (Gregor 2008, Sadat 2008).

For centuries, gauze has been used in local wound care, mainly due to its low price and simplicity. In 1950s, a new concept, that wound healing is optimal when it is kept in a moist environment rather than air dried, was introduced. Since then, a large variety of occlusive or semi-occlusive dressings, topical applications, and other products were developed for the treatment of all kinds of wounds. Modern wound-healing agents include hydrocolloidal, alginates, hydrogels, hydrofiber, paraffin gauze dressings, as well as many others types of moist dressings and topical agents. The choice of the ideal regimen remains controversial due to the lack of good evidence from well conducted RCTs, and depends mainly on the clinicians' preference (Chaby 2007, Gregor 2008, Ubbink 2009).

Skin grafts are used to promote healing in complex wounds with tissue loss. Successful skin grafting relies on the ability of the skin graft to integrate with the recipient wound bed. Bolstering the graft to the wound bed by applying a dressing along with positive pressure is used to improve integration with the wound bed and minimize seroma formation. NPWT is an alternative to standard bolstering techniques. It has been suggested that NPWT offers all of the advantage of standard bolstering in addition to other advantages such as active fluid removal and easier patient mobilization (Runkel 2011).

NPWT systems are FDA approved for use in patients with chronic, acute, traumatic, subacute and dehisced wounds, partial thickness burns, ulcers, flaps, and grafts. The device is contraindicated for use in wounds with exposed vital structures, devitalized tissue, malignant tissue, untreated osteomyelitis, or in patients with untreated coagulopathy or allergy to any component required for the procedure (AHRQ 2009). NPWT was reviewed by MTAC in 1999, 2003, and 2008 for the management of chronic wounds and did not meet MTAC evaluation criteria. It is being re-reviewed for a new indication.

### *Vacuum Assisted Closure for the Treatment of Wounds*

**02/10/1999: MTAC REVIEW**

**Evidence Conclusion:** The efficacy of the VST cannot be determined from the combination of these widely disparate studies/case series because of the widely heterogeneous samples, varying methods and application of the technique; small sample sizes, possible selection and observation bias, and the absence of comparison groups. In addition, there are a number of unresolved issues surrounding this technique, including but not limited to:

- which wounds are ideally suited for the application of this technique;
- the optimal conditions in which the technique can/should be applied;
- the ideal pressure required;
- ideal delivery of the negative pressure, e.g., by vacuum pump or bottle;
- when the wound dressing should be applied.

Further studies, preferably blinded, randomized control trials are warranted to determine the efficacy of this technique/device.

**Articles:** Articles were selected based on study type. There was one prospective clinical trial (Mullner et al, 1997), no meta-analyses or cohort studies, and a few case series. An evidence table for the clinical trial. No evidence

tables were created for the case series, as the sample sizes were either too small, or the not described in sufficient detail. Case series were reviewed by abstract, and a brief summary of their findings is included. Mullner T, Mrkonjic L, Kwasny O, Vecsei V. The use of negative pressure to promote the healing of tissue defects: a clinical trial using the vacuum sealing technique. *British Journal of Plastic Surgery* 1997 Apr;50(3):194-9. See [Evidence Table](#).

The use of Vacuum Assisted Closure for the treatment of wounds to promote healing does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Vacuum Assisted Closure in the Treatment of Non-Healing Wounds**

#### **08/13/2003: MTAC REVIEW**

**Evidence Conclusion:** The best evidence on VAC consists of two RCTs, each with fewer than 30 patients. Both are limited by their small sample sizes which makes selection bias likely and results in low statistical power. The two studies had different findings. Ford found no significant differences in wound healing between VAC and gel. Joseph found a statistically significant greater reduction in wound volume, width and depth with VAC compared to traditional saline wet-to-moist (WM) dressings. Joseph had the stronger methodology—more complete follow-up and consistency between the unit of randomization and the unit of analysis. Although the Joseph RCT suggests that VAC may be superior to traditional WM dressings, additional research is needed with larger sample sizes and consideration of potential selection bias/confounding.

**Articles:** The search yielded 144 articles. Many of these were review articles, opinion pieces, dealt with technical aspects of wound closure techniques or were on related procedures. There were two small randomized controlled trials using the VAC system. No non-randomized comparative studies were identified. The two RCTs were critically appraised. Ford CN, Reinhard ER, Yeh D. et al. Interim analysis of a prospective, randomized trial of Vacuum-Assisted Closure versus the Healthpoint System in the management of pressure ulcers. *Ann Plast Surg* 2002; 49: 55-61. See [Evidence Table](#). Joseph E, Hamori CA, Bergman S. A prospective, randomized trial of vacuum-assisted closure versus standard therapy of chronic non-healing wounds. *Wounds* 2000; 12: 60-67. See [Evidence Table](#).

The use of vacuum assisted closure in the treatment of non-healing wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **04/06/2009: MTAC REVIEW**

### **Vacuum Assisted Closure in the treatment of Non-Healing Wounds**

**Evidence Conclusion:** There is a lack of high quality randomized controlled trials on the use of negative pressure therapy for wound healing. The best published clinical evidence consists of few RCTs with flawed methodology. The majority of the studies were small, had inadequate power to detect differences between treatment groups, were unblinded, and had little or no information on the baseline characteristics of the participants, or causes of dropouts. The trials mainly used surrogate outcomes as reduction in wound size and formation of granulation tissue, rather than complete healing of the ulcer. The largest published trial to date (Blume et al, 2008) randomized 341 patients with diabetic foot ulcers to receive negative pressure wound therapy (NPWT) or advanced moist wound therapy (AMWT). All participants in the two groups also underwent wound debridement and off-loading. The results of the trial showed a significantly higher rate of complete ulcer closure in the patients receiving NPWT vs. AMWTs. The study was randomized and controlled, however, it had several limitations including unblinding of the patients and physicians which is a potential source of bias as it could influence the patient motivation and the care provided. Patients were treated at home or in a hospital setting and there is no indication whether they were given the same care and therapy e.g. equal pressure relief, intermittent or continuous negative atmospheric pressure, debridement, antibiotics, and other potentially confounding factors. Moreover, the study had a high drop-out rate and was financially supported by the manufacturer of the device. **Conclusions:** There is insufficient published evidence to date to determine whether topical negative pressure therapy is more effective than alternative wound dressings as regards rate of healing, pain management and quality of life. There is insufficient published evidence to date to determine that topical negative pressure therapy is safe to use in patients with acute or chronic wounds.

**Articles:** The search yielded over 300 articles on negative pressure wound therapy. Many were review articles, opinion pieces, dealt with technical aspects of wound closure techniques, or were unrelated to the current review. There were four systematic reviews with or without meta-analyses, four RCTs, and a number of case series published after the last MTAC review of the technology. Gregor et al's 2008 review included both randomized and non-randomized trials but pooled the results of each group of studies for only one surrogate outcome. In two Cochrane reviews (Ubbink 2008, Wasiaik 2007), the authors could not pool the results in meta-analyses due to the small number of studies, poor reporting, heterogeneity in endpoints and comparator treatments. Another published meta-analysis (Sadat et al, 2008) included two small negative trials (total of 70 participants) on the use of VAC for various types of ulcers, and one positive larger trial (N= 162) on its use after diabetic foot amputation,

which skewed the results of the meta-analysis. Only one RCT (Blume 2008) had clinically important outcomes, relatively large sample size, and generally valid methodology. Both the review with a meta-analysis as well as the RCT with generally valid methodology were selected for critical appraisal: Gregor S, Maegele M, Sauerland S, et al. Negative pressure wound therapy. A vacuum of evidence? *Arch Surg* 2008;143:189-196. See [Evidence Table](#). Blume PA, Ayala J, Walters J, et al. Comparison of negative pressure wound therapy using vacuum-assisted closure with advanced moist wound therapy in the treatment of diabetic foot ulcers. A multicenter randomized controlled trial. *Diabetes Care* 2008;31: 631-636. See [Evidence Table](#).

The use of vacuum assisted closure in the treatment of non-healing wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Negative Pressure Wound Therapy in the Treatment of Skin Grafts and Flaps**

#### **12/19/2011: MTAC REVIEW**

**Evidence Conclusion:** A RCT that included 60 subjects with acute traumatic injuries and skin loss evaluated the effectiveness of NPWT compared to dressings without NPWT. Results from this study suggest that NPWT may lead to less graft loss, less frequent regrafting, and reduced time from patient intervention to discharge compared to with dressings without NPWT (Llanos 2006).

	NPWT	Control	P-value
	Median (range)		
Loss of grafted area (cm <sup>2</sup> )	0.0 (0-12)	4.5 (0-53)	0.001
Percentage of graft loss	0.0 (0-62)	12.8 (0-76)	<0.001
Days from grafting to discharge	8 (7-13)	12 (7-23)	0.001
	Number (%)		
Need for 2 <sup>nd</sup> coverage procedure	5 (16.7)	12 (40.0)	0.045

**Conclusion:** There is some evidence to support the use of NPWT as a splint or bolster for skin grafts.

**Articles:** NPWT for skin grafts or skin substitutes was reviewed in 2010 by NHS Quality Improvement Scotland (NHS QIS). This review found some evidence to support the use of NPWT for wounds caused by burns or trauma that require a skin graft as treatment and certain types of venous leg ulcers with split-thickness pinch skin graft. The recommendations from NHS QIS were based on evidence from two high-quality and two low-quality randomized controlled trials (RCTs) as well as several observational studies (NHS QIS 2010). Since the NHS QIS review, the literature search revealed two additional RCTs that evaluated the safety and efficacy of NPWT for skin grafts or skin substitutes. These studies were not selected for review due to methodological limitations (i.e., small sample size, high loss to follow-up, etc.) (Chio 2010, Petkar 2011). One of the high quality trials evaluating the use of NPWT was not used for bolstering and therefore was not selected for review (Vuerstaek 2006). The other high quality trial included in the NIH QIS was selected for review. The following study was selected for critical appraisal: Llanos S, Danilla S, Barraza C, et al. Effectiveness of negative pressure closure in the integration of split thickness skin grafts. *Ann Surg*. 2006; 244:700-705. See [Evidence Table](#).

The use of negative pressure wound therapy in the treatment of skin grafts and flaps does meet the *Group Health Medical Technology Assessment Criteria*.

### **SNAP & PICO Device**

#### **02/09/2015: MTAC REVIEW**

**Evidence Conclusion:** First and foremost, it should be established that there is a lack of evidence to support the general use of NPWT. Previous MTAC critical appraisals have cited a lack of high-quality RCTs evaluating the use of NPWT for wound healing. To date, the best published clinical evidence consists of a few RCTs with flawed methodology due to limitations such as small sample size and inadequate power. Generally speaking, NPWT has been applied to a wide variety of wounds in varying locations, complexity and underlying pathology limiting the ability to make comparisons across studies. This limitation is demonstrated in a various systematic reviews with attempted meta-analyses that have failed to reach any definitive conclusions due to variable endpoints (Mendonca, Papini et al. 2006; Pham, Middleton et al. 2006; Sjögren, Malmsjö et al. 2006; Kanakaris, Thanasis et al. 2007; Wasiak and Cleland 2007; Bovill, Banwell et al. 2008; Group 2008; Noble-Bell and Forbes 2008; Ubbink, Westerbos et al. 2008; Ubbink, Westerbos et al. 2008; Dumville, Hinchliffe et al. 2013). **Effectiveness:** In 2011 and 2012, Armstrong and colleagues published an interim and final analysis with the overall aim of comparing NPWT with an ultraportable mechanically powered device with a traditional electrically powered device. Overall, the study enrolled 132 patients with lower-extremity diabetic and venous wounds. The primary outcome measurement was wound size reduction, however, data assessing the time for dressing change and user experience was also collected. The primary end point results indicated that the SNaP treated subjects were non-inferior to the VAC-

treated patients at all follow-up points 4, 8, 12 and 16 weeks (p-value of 0.0054, 0.0047, <0.0001, and <0.0001, respectively). Exit surveys addressing quality of life (QoL) and activity were completed by 105 patients (79.5%) with the SNaP group consistently reporting less impact on activities such as sleep, mobility and socializing. Patient reporting of pain and discomfort associated with treatment, however, was similar in both groups with no statistical difference (Armstrong, Marston et al. 2011; Armstrong, Marston et al. 2012). [Evidence Table 1] **Safety:** In terms of safety, device related adverse events (AE) were similar in both groups with maceration being the most commonly reported complication. The investigators ultimately concluded that the treatment of wounds with a mechanically powered NPWT device resulted in similar wound healing outcomes as treatment with a traditional, electrically powered, NPWT device with less impact on the patient's quality of life. The evidence is limited by a variety of factors most notably, the use of an inadequate comparator. While NPWT is widely used, the current body of evidence is limited in supporting its effectiveness in promoting wound healing. Beyond that, limitations of the study's methodology include small sample size, as well as significant differences between groups in terms of wound size and age prior to treatment. Finally, it should be noted that the study was sponsored by Spiracur, Inc. the manufacturers of the SNaP® device. In addition, two of the investigators, Armstrong and Marston, have received research funding from both Spiracur and K.C.I. **Conclusions:** There is insufficient evidence to support the safety of the non-powered NPWT devices for treatment of patients with wounds. There is insufficient evidence to support the effectiveness of the non-powered NPWT devices for treatment of patients with wounds.

**Articles:** The literature search revealed a variety of articles relating to the general use of NPWT. Only a few articles were directly related to the use of non-powered or non-electrically powered NPWT devices including a small pilot trial (n=30) of the effect of the PICO device on surgical wound healing in patients with Crohn's disease (Pellino, Sciaudone et al. 2014), a small case series (n=20) describing experience with the PICO device (Hudson, Adams et al. 2013), and a small retrospective case-control study (n=78) comparing the SNaP™ device to a variety of other wound therapies (Lerman, Oldenbrook et al. 2010). There were no randomized control trials (RCTs) identified that compared non-powered/electrical NPWT to conventional wound care. Two publications were revealed that presented the interim and final results of a small RCT comparing the SNaP device with a standard powered VAC (Armstrong, Marston et al. 2011; Armstrong, Marston et al. 2012). The following articles were selected for critical appraisal: Armstrong DG, Marston WA, Reyzelman AM et al. Comparison of negative pressure wound therapy with an ultraportable mechanically powered device vs. traditional electrically powered device for the treatment of chronic lower extremity ulcers: A multicenter randomized-controlled trial. *Wound Rep Reg.* 2011; 19(2):173-180. [Evidence Table 1](#). Armstrong DG, Marston WA, Reyzelman AM et al. Comparative effectiveness of mechanically and electrically powered negative pressure wound therapy devices: a multicenter randomized controlled trial. 2012;20(3):332-341. [Evidence Table 1](#)

The use of SNAP & PICO device in the treatment of negative wound pressure therapy does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Neurofeedback (EEG Biofeedback) and Neuropsychiatric EEG-Based Assessment Aid (NEBA) – ADHD

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None
GHC Medical Policy	In the absence of a NCD or a LCD use GHC Medical Policy Electroencephalography (EEG) for Attention Deficit Hyperactivity Disorder (ADHD) for medical necessity. see below

##### For Non-Medicare Members

Service	Criteria used
Neurofeedback for ADHD (biofeedback)  Neuropsychiatric EEG-Based Assessment Aid (NEBA)	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.  <i>See also MCG* 20<sup>th</sup> Edition (A-0330) for Inconclusive or Non-Support Evidence.</i>

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Attention Deficit Hyperactivity Disorder (ADHD) is a common chronic neurobehavioral condition affecting approximately 5% of children worldwide. A child with ADHD may present as: 1) predominantly hyperactive, 2) predominantly inattentive, or 3) both hyperactive and inattentive. ADHD is often accompanied by impaired social adjustment, academic problems, and lower adaptive functioning in major life activities which may persist to adolescence and adulthood (Benner-Davis 2007, Gevensleben 2009, Lansbergen 2011).

Medication, particularly psychostimulants, is the primary treatment for ADHD. Psychostimulants work quickly, improve attention, and reduce hyperactivity and impulsivity in about 70% of all children. However, their effect on academic achievement, family relation, and social skills is small. There are also some concerns regarding their side effects, and their long-term benefits have not been established. Behavioral therapy has been shown to reduce ADHD symptoms, but may not be sufficiently effective especially in terms of generalization and long-term effects (Leins 2007, Gevensleben 2009, Lansbergen 2011).

In searching for additional or alternative treatments for children with ADHD, neurofeedback (NF) emerged as a promising option. NF is a type of biofeedback that uses electroencephalography (EEG) to provide a signal that can be used by a person to receive feedback about brain activity. It is based on the rationale that there is a relationship between surface EEG and the underlying thalamocortical mechanism responsible for its rhythms and frequency modulations. Lubar was the first to report on EEG and behavioral changes in a hyperkinetic child. He explained that ADHD children differ from others in that their brain waves tend to be of larger amplitude. Specifically, the EEG

shows excess theta activity along with lower amounts of beta activity. This pattern of brain wave activity usually indicates a sleep or day dreaming state, rather than an alert and focused state. The goal of EEG biofeedback training is to alter these abnormal brain waves by decreasing theta waves, while simultaneously increasing beta waves (i.e. theta suppression/beta enhancement). This would potentially help the child acquire self-control over certain brain activity patterns, derive self-regulation strategies, and apply the gained self-regulation skills in daily life (Lubar 1976, Lubar 1991, Bakhshayesh 2011).

In EEG biofeedback training, the therapist explains to the child the connection between what is happening in his/her cortex and what is recorded on the EEG, and helps him/her learn how to gain control over the brain activity patterns. The EEG biofeedback equipment is connected to the individual with sensors that are placed on the scalp and ears. Once connected, the brainwave activity can be observed on a computer monitor. Individuals are then taught to play computerized games using their brainwave activity. Changes in the individual's brainwave activity are then fed back to the individual through visual and/or auditory information by the computer. During a typical 45-minute session, the child is seated in front of a computer, electrodes are connected to his head, and then a therapist starts up a videogame or movie on the child's screen and monitors his brain waves on another screen. The child then locks his eyes on the action, concentrating on sending the kind of brain waves that will keep a virtual airplane flying, or perhaps a favorite movie rolling. If his attention wanders or he begins to fidget, the plane slows or the movie screen darkens, and the therapist encourages him to regain focus using techniques such as slow, deep breathing. Children may also practice maintaining learned brainwave states when engaged in school- or work-related tasks (Gevensleben 2009).

In the last three decades many studies compared brain activity using electro-encephalography (EEG) among children with ADHD versus the brain activity of normal controls in an attempt to study the underlying neurophysiology of ADHD; and to investigate subtypes of the disorder and their response to treatment. The EEG frequency bands of most interest in ADHD research are the theta, beta, and alpha bands either alone or in relation to one another such as the theta/beta power or amplitude ratio. Alpha band activity is typically observed during rest when the eyes are closed, and is negatively associated with central nervous system arousal. Beta band activity on the contrary, generally accompanies mental activity and concentration. Cortical theta is observed frequently in young children, but in older children and adults, it tends to appear during meditative, drowsy, or sleeping states. Researchers suggest that most children with ADHD display EEG differences in their brain electrical activity as compared to normal children, particularly with respect to their increased frontocentral theta activity primarily during the resting state. This indicates decreased cortical activity that may be associated with underarousal. A theta /beta ratio (TBR) due to increased theta is reported by many investigators as a consistent characteristic of ADHD. Some groups recommend using the TBR during eyes-opened or eye-closed resting condition as an add-on for the diagnosis and monitoring of ADHD. However, it is reported that the true functional significance of this measure is still unknown, and an elevated theta activity may be a nonspecific marker of cortical dysfunction common to other disorders such as epilepsy, bipolar disorder, and polysubstance abuse (Arns 2013, Liechti 2013, Loo 2012).

A number of studies examined the accuracy and diagnostic value of the theta power and TBR in discriminating normal children from children with learning disorders, ADD, and ADHD. In 2005, Boutros and colleagues performed a review and meta-analysis to estimate the strength and effect size of increased theta activity in ADHD patients. Based on their findings they concluded that the increased EEG theta activity in ADHD is promising, and should be further developed as a diagnostic test for ADHD. Around the same time another group of investigators (Synder and Hall, 2006) also conducted a meta-analysis to investigate the theta and beta powers and their ration (TBR), and concluded that the pooled results support the finding that an increase in the theta/beta ratio is a commonly observed trait in ADHD relative to normal controls. They however, cautioned that theta/beta ratio trait may arise with other conditions, and that a prospective study covering differential diagnosis would be required to determine generalizability to clinical applications (Arns 2013, Boutros 2005, Loo 2012 Snyder 2006).

Based on this EEG technology, the Neuropsychiatric EEG-Based Assessment Aid (NEBA) System (NEBA Health, Augusta, GA) was developed and recently received Food and Drug Administration (FDA), in July 2013, to help assess ADHD in children and adolescents 6-17 years of age. It is not to be used as a stand-alone diagnostic test, but as a conjunctive tool for diagnosing ADHD. NEBA is a non-invasive test that calculates the ratio of theta and beta waves frequencies in 15-20 minutes (FDA and NEBA websites accessed January 15, 2014).

According to the FDA, the use of the device together with the complete medical and psychological examination, can help confirm an ADHD diagnosis or a clinician's decision that further diagnostic testing should focus on ADHD or other medical or behavioral conditions that lead to symptoms similar to ADHD. The FDA reviewed the NEBA System through a de novo classification process, a regulatory pathway for some low- to moderate-risk medical devices that are not substantially equivalent to an already legally marketed device (FDA website accessed January 15, 2014).

## Medical Technology Assessment Committee (MTAC)

### Neurofeedback for ADHD

#### 10/17/2011: MTAC REVIEW

**Evidence Conclusion:** A number of small randomized and nonrandomized controlled trials included in Arns and colleagues' meta-analysis (evidence table 1) and the pooled results of available data indicate that NF may have some beneficial effects on a number of ADHD measures. However, when compared with stimulant therapy, NF did not prove to have an equivalent or superior effect on ADHD core symptoms. None of the studies monitored potential adverse effects of NF. The small study sizes, their short duration, lack of a valid control group, mixed and multiple interventions used, lack of double-blinding, additional time spent with the therapists for NF, as well as other study methodological limitations make it hard to determine the efficacy of the neurofeedback used alone or in addition to other interventions for the treatment of children with ADHD. Gevensleben and colleagues' trial (evidence table 2) conducted by a group of researchers in a university hospital in Germany, compared NF training to computerized attention skills training. This may be considered as a more valid comparison as it controls for therapist time and attention training. The primary endpoint was improvement in attention and reduced hyperactivity as rated by the parents. No measures of children's academic functioning or classroom performance were collected. The results of the trial showed that symptoms improved in both groups; however, the score of the primary outcome measure (parents' rating of FBB-HKS [a German rating scale]) was significantly higher in children in the NF group. The trial was randomized and controlled, but was not blinded, and the NF training program was developed by the study group. After the training period 18% of the children were started on a medication. Six months follow-up data, available for only two thirds of the participants, showed that the behavioral improvements were maintained at 6 months, but the difference between the two interventions did not reach a statistically significant level. The investigators attributed the lack of significant difference to insufficient statistical power due to the smaller number of children with follow-up data. They authors concluded that NF training may help some children, but more research is needed to replicate the findings and identify which children with ADHD are more likely to benefit from NF training. Well conducted randomized trials with a sham neurofeedback control, double-blinding, and long term follow-up are needed to establish the efficacy and safety of neurofeedback in improving the core symptoms of ADHD.

**Articles:** The search revealed one meta-analysis on the efficacy of neurofeedback treatment in ADHD and a number of RCTs that were included in the meta-analysis. Three small RCTs published after the meta-analysis, as well as a report on 6 months follow-up of an earlier RCT were also identified. The meta-analysis as well as the largest trial, which had a more valid design and longer follow-up, were selected for critical appraisal. Arns M, de Ridder S, Strehl U, et al. Efficacy of neurofeedback treatment in ADHD: the effects on inattention, impulsivity and hyperactivity; a meta-analysis. *Clin EEG Neurosci* 2009;40:180-189. See [Evidence Table](#). Gevensleben H, Holl B, Albrecht B, et al. Is neurofeedback an efficacious treatment for ADHD? A randomized controlled trial. *J Child Psychol Psychiatry*. 2009;50:780-789. See [Evidence Table](#). Gevensleben H, Holl B, Albrecht B, et al. Neurofeedback training in children with ADHD: 6-month follow-up of a randomized controlled trial. *Eur Child Adolesc Psychiatry* 2010;19:715-724. See [Evidence Table](#).

The use of Neurofeedback for ADHD does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 06/20/2016: MTAC REVIEW

### Electroencephalography (EEG) Neurofeedback (NF) for Attention deficit hyperactivity disorder (ADHD)

**Evidence Conclusion:** EEG-NF versus placebo, sham: EEG neurofeedback (EEG-NF) treatments in children with ADHD: an updated meta-analysis of randomized controlled trials: (Micoulaud-Franchi et al., 2014) (Evidence table 1) On parent assessment (probably unblinded assessment), the overall ADHD scores (-0.49 [-0.74, -0.24],  $p < 0.001$ ) as well as the inattention and hyperactivity/impulsivity scores were significantly improved (-0.46 [-0.76, -0.15],  $p = 0.003$ ); -0.34 [-0.59, -0.09],  $p = 0.007$ ) in patients receiving EEG NF compared to controls. On teacher assessment (probably blinded assessment), only the inattention score was significantly improved (Effect size of -0.30 [-0.58,-0.03] with  $p=0.03$ ). Based on the findings, EEG-NF may improve core ADHD symptoms. However, the major limitation lie in the heterogeneity of EEG-NF protocols across individual studies. Other limitations include: 1) the small number of studies, 2) small size of individuals RCTs, 3) the exclusion of relevant RCTs in the meta-analysis, 4) the lack of blinded parent assessment and 5) the lack of evaluation of study quality. These result in low quality of evidence. Due to the aforementioned limitations, result should be interpreted with caution. A randomized placebo-controlled trial of electroencephalographic (EEG) neurofeedback in children with attention-deficit/hyperactivity disorder (van Dongen-Boomsma et al., 2013) (Evidence table 2) In both groups, and based on investigator assessment, ADHD symptoms decreased over time ( $F= 26.56$ ,  $p < .001$ ) to a similar degree. According to teacher assessment, significant improvement of symptoms over time ( $F= 13.54$ ,  $p = .001$ ) was reported, without a difference between groups ( $F= 0.45$ ,  $p = .509$ ). On the CGI-I scale, symptoms did not worsen. On CGAS, score increased similarly in both groups ( $F= 1.96$ ,  $p = .169$ ).

On PSERS, the total number of adverse events decreased significantly over time ( $F= 6.30, p = .016$ ) and decreased similarly in the two groups ( $F= 0.10, p = .754$ ). The SDQ assessment showed that sleep problems decreased significantly over time ( $F= 5.42, p = .025$ ) in both groups. Overall, no differences in improvements between the groups were reported. However, several limitations are worth noted: 1) the small sample size limiting statistical power; 2) the therapist was not blinded; 3) the use of medications by some participants could have biased the outcomes of NF; 4) no follow-up data was available to assess the short or long term effects of NF; 5) generalizability might have been compromised since the sample is composed of white children. Studies with larger sample size and long follow-up are warranted to confirm these findings.

**Neurofeedback versus stimulant Medication: Effects of Neurofeedback versus stimulant Medication in Attention-Deficit/Hyperactivity Disorder: A Randomized pilot study (Meisel et al., 2014) (Evidence table 3)** Regarding pre-post comparison, ADHD symptoms and functional impairment improved in general in both groups. Academic performance was only improved (except for math and oral expression) in NF group. Concerning pre-follow-up comparisons, similar results were observed. NF group maintained symptoms achievement at 2 & 6 months after treatment completion. Inattention improved more than hyperactivity/impulsivity across evaluators, time & treatment. The major limitations are the small sample size and lack of longer follow-ups. In addition, patients were not blinded and allocation concealment was not discussed. The risk of bias is therefore high. However, no major differences in symptom improvement were observed.

**Effects of Neurofeedback versus stimulant Medication in Attention-Deficit/Hyperactivity Disorder: A Randomized pilot study (Ogrim & Hestad, 2013) (Evidence table 4)** After treatment, there was a significant difference between the two groups with improvement observed in the medication groups. There were significant differences after treatment between the groups on inattention, Visual Continuous Performance Test (VCPT) & reaction time measures on patient assessment. All were in favor of the medication groups. Similar findings were observed on teacher assessment. In addition, higher positive changes were observed with the medication groups. The results indicate that medication led to better symptoms control on both parent and teacher assessment, particularly on inattention, VCPT & reaction time measures and that NF did not produce positive changes. However, this pilot study has several limitations: 1) generalizability of the findings may have been compromised because of the non-use of standard protocols, 2) small sample size 3) blinding was not discussed, 4) 59% of patients had learning disabilities making harder to achieve a positive outcome. Overall, the risk of bias is high and results should be interpreted with caution.

**A randomised controlled trial of combined EEG feedback and methylphenidate therapy for the treatment of ADHD (Li et al., 2013) (Evidence table 5)** In terms of Core symptoms and behavioral problems, significant improvement was noted for combination group compared to the control group. For social function assessments, the combination group performance was significantly better than that of the control group after 40 sessions of treatment ( $p < 0.001$ ). Regarding brain function assessment, the dominant probability of 8 Hz wave decreased significantly in the combination group. Adverse events correlate with methylphenidate dosage. The authors conclude that the combination of neurofeedback and methylphenidate is effective in improving the symptoms of ADHD in children. They also demonstrated that this combination is superior in enhancing core symptoms, behavioral issues, and brain function. However, limitations reside in small sample size limiting statistical power; the lack of long term follow-up. One of the authors had financial tie with the Janssen Pharmaceutical. Therefore, results should be interpreted with caution.

**Additional study:** A placebo controlled neurofeedback study (Arnold et al., 2012) did not demonstrate superiority of NF on ADHD core symptoms.

**Conclusion:**

- The body of evidence is of low quality.
- Variations in the characteristics of EEG-NF protocols, the use of medications while receiving NF treatment, the small sample size, the lack of blinding in a number of studies and the short follow-up periods may have biased the findings.
- Neurofeedback may improve the core symptoms of ADHD in children but did not demonstrate superiority or was not equivalent to pharmacological therapy in reducing ADHD symptoms in children.
- There is insufficient evidence to determine whether Neurofeedback in combination with methylphenidate is effective in reducing the core symptoms of ADHD in children.

**Articles:** The literature revealed a number of articles, but the following articles were selected for critical appraisal: EEG neurofeedback treatments in children with ADHD: an updated meta-analysis of randomized controlled trials (Micoulaud-Franchi et al., 2014) [See Evidence table 1](#). A randomized placebo-controlled trial of electroencephalographic (EEG) neurofeedback in children with attention-deficit/hyperactivity disorder (van Dongen-Boomsma, Vollebregt, Slaats-Willemse, & Buitelaar, 2013) [See Evidence table 2](#). Effects of Neurofeedback versus stimulant Medication in Attention-Deficit/Hyperactivity Disorder: A Randomized pilot study (Meisel, Servera, Garcia-Banda, Cardo, & Moreno, 2014) [See Evidence table 3](#). Effects of Neurofeedback versus stimulant Medication in Attention-Deficit/Hyperactivity Disorder: A Randomized pilot study (Ogrim & Hestad, 2013) [See Evidence table 4](#). A randomised controlled trial of combined EEG feedback and methylphenidate therapy for the treatment of ADHD (Li, Yang, Zhuo, & Wang, 2013) [See Evidence table 5](#).

The use of Electroencephalography (EEG) Neurofeedback (NF) for Attention deficit hyperactivity disorder (ADHD) does not meet the *Group Health Medical Technology Assessment Criteria*.

**Neuropsychiatric EEG-Based Assessment Aid (NEBA)**

**02/10/2014: MTAC REVIEW**

**Evidence Conclusion:** There is no published evidence to date to determine the safety, accuracy, or clinical utility of NEBA system in discriminating between children with or without ADHD. The FDA approval was based on a clinical study of 275 children and adolescents with attention and/or behavioral concerns. The study was conducted by the manufacturer of the NEBA system and has not been published in a peer reviewed journal to date. The observational studies on the correlation between the theta/beta ratios (TBR) had their limitations, and their results were inconclusive. In addition (according to Loo, 2012) there are wide variation in EEG instrumentation that can make it very hard to compare or generalize results of studies using different EEG hardware and software.

**Articles:** The literature search did not reveal any published study on the NEBA system; it only identified several observational studies that investigated brain activity using EEG in children with ADHD compared with normal controls, as well as three meta-analyses that pooled the results of a number of these studies.

The use of NEBA does not meet the *Group Health Medical Technology Assessment Criteria*.

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or will provide better long term outcomes than current standard services/therapies. Requests will be reviewed on a case-by-case basis.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Neutron radiotherapy is an alternative to conventional photon radiotherapy. Photon radiation is a type of low linear-energy-transfer (LET) radiation. After LET radiation, there is a relatively high chance that damaged tumor cells can repair themselves and continue to grow. In contrast, with neutrons, which are high LET radiation, damaged tumor cells are much less likely to resume growth. Because of the higher biological effectiveness of neutron radiotherapy, the required tumor dose with neutrons is about one-third the dose needed with photons and a lower total number of treatments is needed.

Neutrons were first used to treat patient tumors in 1938 using an early cyclotron. Research was discontinued due to World War II and began again in the 1960s in England. In the late 1970s, the National Cancer Institute awarded contracts for four modern cyclotrons in the U.S. According to a recent review article (Laramore, 1997), of the four centers, only the one at the University of Washington (UW) is still in operation. There are currently two other operating neutron radiotherapy centers in the country; the others are located at Harper-Grace Hospital in Detroit and the Fermi National Laboratory in Illinois. The UW built a new control system for its cyclotron, completed in July 1999. The UW materials state that the UW has the only facility with a computer-controlled, multi-leaf collimator for field shaping.

Neutron radiotherapy is believed to be most beneficial for malignant salivary gland tumors. The modern neutron facilities can deliver neutron radiation doses of approximately 20 Gy to the head and neck which corresponds to a proton dose of about 60-70 Gy-equivalent for normal tissues and approximately 160 Gy-equivalent for the tumor. In his review article, Laramore (1997) states that other than for salivary gland tumors, neutron radiotherapy has been shown to be most promising for sarcomas of soft tissue, bone and cartilage and locally advanced prostate cancer.

### **Neutron Beam Radiotherapy for Soft Tissue Sarcoma**

#### **06/12/2002: MTAC REVIEW**

**Evidence Conclusion:** There were only two case series that had sample sizes greater than n=10. The Schwartz study had n=73 (n=42 was treatment with curative intent) and was conducted at UW, where patients from Group Health would be sent. The Schonekaes study, which was conducted in Germany, reports on two independent series of patients. Schwartz found a 68% local relapse-free 4-year survival rate and 66% overall 4-year survival rate in the 42 curative patients. Schonekaes found a 52% 5-year local recurrence-free survival rate and a 42.5% overall 5-year survival rate. In both studies, patients varied greatly in clinical characteristics, there was a lack of clear eligibility criteria, the intervention received was not consistent (e.g., dose of radiation). The Schwartz article did not have a control or comparison group. The efficacy of neutron radiotherapy for the treatment of soft-tissue sarcoma cannot be determined from these descriptive reports.

**Articles:** The search yielded 13 articles, many of which were review articles or opinion pieces. There were no randomized controlled trials or meta-analyses. There were four case series, two of which had sample sizes of ten or less. The two largest case series (n=73 and n=161) were critically appraised. Schwartz DL, Einck J, Bellon J, Laramore GE. Fast neutron radiotherapy for soft tissue and cartilaginous sarcomas at high risk for local recurrence. *Int J Radiation Oncology Biol Phys* 2001; 50: 449-456. See [Evidence Table](#). Schonekaes K-G, Prott F-J, Micke O et al. Radiotherapy on adult patients with soft tissue sarcoma with fast neutrons or photons. *Anticancer Res* 1999; 19: 2355-2360. See [Evidence Table](#).

The use of neutron beam radiotherapy in the treatment of soft tissue sarcoma does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Neutron Beam Radiotherapy for Salivary Gland Tumors**

#### **06/12/2002: MTAC REVIEW**

**Evidence Conclusion:** There was one small RCT (n=32 randomized, n=25 analyzed) comparing neutron radiotherapy to photon radiotherapy. This study (Griffin, 1988; Laramore, 1993) had methodological limitations but dramatic findings. At ten years, there was a statistically significant 39% absolute risk reduction for local/regional control favoring the neutron group. For survival, there was an absolute risk reduction of 37% at two years and 10% at ten years. Differences in survival rates were not statistically significant and the study may have been under powered. A case series from the UW with 128 patients was also reviewed. Actuarial local/regional control at five years was 59% and the 5-year survival rate was 39%. The evidence suggests that neutron radiotherapy is superior to traditional photon radiotherapy, but case series and one small, compromised RCT do not provide conclusive evidence.

**Articles:** The search yielded 34 articles, most of which were review articles, opinion pieces, dealt with technical aspects of the procedures or addressed other, similar treatments. There was one randomized controlled trial, published in 1993 and five newer case series with more than 50 patients. Some of the case series were from the same institution and there was overlap in the patients included in the articles. The RCT and the largest, most recent case series from the UW were reviewed. Laramore GE, Krall JM, Griffin TQ et al. Neutron versus photon irradiation for unresectable salivary gland tumors: Final report of an RTOG-MRC randomized clinical trial. *Int J Radiat Oncol Biol Phys* 1993; 27: 235-240. See [Evidence Table](#). Douglas JG, Lee S, Laramore GE et al. Neutron radiotherapy for the treatment of locally advanced major salivary gland tumors. *Head Neck* 1999; 21: 255-263. See [Evidence Table](#).

The use of neutron beam radiotherapy in the treatment of salivary gland tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Neutron Beam Radiotherapy for Locally Advanced Prostate Cancer**

#### **06/12/2002: MTAC REVIEW**

**Evidence Conclusion:** There were two RCTs; Laramore compared photon radiation to mixed photon-neutron radiotherapy and Russell compared photon radiation to neutron radiotherapy alone. Laramore found higher local/regional control and higher 5-year and 10-year survival rates in the neutron radiotherapy group. Russell found greater local/regional control but no difference in 5-year survival rates. It is possible that there could be a

difference in effectiveness between mixed-beam and neutron-only radiotherapy, but this has not been studied. Neither study presented baseline demographic or clinical information, so the possibility of selection bias cannot be ruled out. The Laramore study has been criticized in the literature for the low rates of local/regional control and survival in the photon-treated group. The final reports on each of these RCTs were published in the early 1990s. No more recent studies were identified.

**Articles:** The search yielded 15 articles, many of which were review articles, dealt with technical aspects of the procedures or addressed other, similar treatments. There were two randomized controlled trials and one small case series on mixed-beam (mixed photon-neutron) treatment. The two RCTs were reviewed. Laramore GE, Krall JM, Thomas FJ et al. Fast neutron radiotherapy for locally advanced prostate cancer: Final report of Radiation Therapy Oncology Group Randomized Clinical Trial. *Am J Clin Oncol* 1993; 16: 164-67. See [Evidence Table](#). Russell KJ, Caplan RJ, Laramore GE et al. Photon versus fast neutron external beam radiotherapy in the treatment of locally advanced prostate cancer: Results of a randomized prospective trial. *Int J Radiat Oncol Biol Phys* 1993; 28: 47-54. See [Evidence Table](#).

The use of neutron beam radiotherapy in the treatment of locally advanced prostate cancer does not meet the *Group Health Medical Technology Assessment Criteria*

## Clinical Review Criteria

### Recombinant Activated Factor VII (NovoSeven®)

- Glanzmann's Disease
- Hemophilia
- Post-Partum Hemorrhage
- Cardiac Surgery Hemorrhage

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Non-Medicare Members

Group Health has elected to use the Coagulation Factor VIIa – (Novoseven) (GHC-0452) MCG\* for medical necessity determinations.

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 12 months of clinical notes from requesting provider &/or specialist (hematology, primary care physician)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Glanzmann's disease (a.k.a Glanzmann's thrombasthenia) is a platelet disorder characterized by a deficiency in the platelet membrane glycoproteins (GP) IIb-IIIa. It is one of several hereditary platelet disorders typified by normal platelet numbers and a prolonged bleeding time. NovoSeven® may also be appropriate for use with patients who have other bleeding disorders such as Glanzmann's thrombasthenia or Bernard-Soulier's thrombasthenia.

NovoSeven® (manufactured by Novo Nordisk, Denmark) is a product containing recombinant coagulation Factor VII. It has been used to prevent bleeding and treat hemorrhage during surgery in patients with hemophilia A with a Factor VIII inhibitor, hemophilia B with a Factor IX inhibitor and acquired deficiencies in Factors VIII or IX.

NovoSeven® has been approved by the FDA as a biological product.

People with hemophilia A (approximately 85% of hemophilia patients) lack the blood clotting protein, factor VIII and people with hemophilia B lack factor IX. The severity of the condition varies, depending on the amount of clotting factor in the blood. About 70% of individuals with hemophilia A have less than 1 percent of the normal amount of clotting factor and are considered to have severe disease. Treatment of hemophilia A or B consists of replacement of the deficient factor.

Approximately 20-50% of severe hemophilia A patients and 1.5-3% of hemophilia B patients (Kulkarni, 2001) develop antibodies called inhibitors that block the activity of the replacement clotting factor. Management of hemophilia patients with inhibitors is challenging. Injection of high quantities of clotting factors is sometimes effective at neutralizing the inhibitors and allowing sufficient quantities of the factors to circulate. Another treatment is injection of porcine factor VIII, which is often sufficiently different from human factor VIII to go unrecognized by inhibitors. However, many patients have cross-reactive antibodies to Porcine FVIII concentrates. Removing the antibody from the plasma (plasmapheresis), in combination with injections of clotting factor, is sometimes used.

Another approach to treatment is the use of bypassing agents, treatments that induce hemostasis independent of the presence of factors VIII and IX. Prothrombin complex concentrates (PCCs) and activated prothrombin complex

concentrates (aPCC) were developed in the 1970s. They are derived from human plasma and contain the vitamin K-dependent coagulation proteins.

Recombinant activated Factor VII (rFVIIa) or NovoSeven is also a bypassing agent. This product is derived from cultured baby hamster kidney cells using recombinant DNA technology. Because it does not contain any human serum or proteins, NovoSeven has a low risk of infecting patients with human viruses that could be present in plasma-derived products. NovoSeven has a relatively short half-life and injections must be given frequently. The initial recommended dose is 90 ug/kg every two hours until cessation of bleeding. PCCs and aPCCs have been associated with thromboembolic side effects and it is also possible that there is a risk of thrombosis with NovoSeven (Kulkarni, 2001).

NovoSeven (manufactured by Novo Nordisk, Denmark) has been available in the European Union since 1996. In 1999, NovoSeven was approved by the FDA for the treatment of bleeding episodes in hemophilia A or B patients with inhibitors to factors VIII or IX. It is available in the US through Novo Nordisk Pharmaceuticals, New Jersey.

Major bleeding is a common and potentially serious complication in high-risk **cardiovascular surgeries**, and is a well-known risk factor for postoperative morbidity and mortality. Excessive blood loss frequently requires the transfusion of allogenic blood, blood products, and surgical re-exploration when appropriate. Re-exploration may not reveal a surgically repairable source of bleeding in up to 50% of cases. Both massive blood transfusion and re-exploration are associated with longer intensive care and hospital stay, wound infection, higher morbidity, and reduced survival rates. The high risk of bleeding and its consequences have prompted cardiac surgeons to explore the off-label use of recombinant factor VIIa as an alternative haemostatic agent for postoperative bleeding (Murphy 2007, Zangrillo 2009, Goksedef 2010, Chapman 2011).

Recombinant factor VIIa (rFVIIa; NovoSeven®, NovoNordisk, Copenhagen, Denmark) is a recombinant DNA preparation of activated blood coagulation factor VII. It is an engineered preparation of factor VIIa produced in cultured baby hamster kidney cells and is nearly identical to plasma-derived factor VIIa in structure and function. At the pharmacological level, it is to some degree different from the natural FVIIa (nFVIIa). Its pharmacologic action induces thrombin generation on locally activated platelets and contributes to the formation of a stabilized clot at the site of vessel injury. NovoSeven received market approval by the US Food and Drug Administration (FDA) in 1999 for the treatment of bleeding episodes in hemophilia A or B patients with inhibitors to Factor VIII or Factor IX respectively. In 2005, it was further approved by the FDA for the treatment of bleeding episodes and for the prevention of bleeding in surgical interventions or invasive procedures in patients with acquired hemophilia. NovoSeven is licensed in Europe for the treatment of congenital factor VII deficiency and Glanzmann's thrombasthenia refractory to platelet administration (Ratko 2004, Al-Ruzzeh 2008, Gill 2009, Zangrillo 2009, Logan 2011, Goksedef 2012, Guzette 2012).

Over the last decade, rFVIIa (NovoSeven) has been increasingly used off-label for a wide range of disorders including life threatening bleeding after body and brain trauma, intracranial hemorrhage, major abdominal surgeries, drug-induced coagulopathy, platelet disorders, intraoperative or postoperative hemorrhage, and a number of other conditions. The vast majority of adults and pediatric patients who have received rFVIIa received it for an off-label indication. It is also being used off-label for pediatric and adult cardiac surgery. However, its use in these patients is controversial and widely debated due to the concern about its safety especially for the potential increase the risk of thromboembolic events. Cardiac surgery patients are already at high risk of myocardial ischemia, arterial and venous thrombosis before, during, and after the surgery due to either or both the underlying pathology and the surgery performed with cardiopulmonary bypass or cross clamping. The reported mortality and complication rate among cardiac surgery patients receiving rFVIIa ranged from 19-40%. The issue of the appropriate dosing is also a major concern (Ratko 2004, Al-Ruzzeh 2008, Gelsomino 2008, Gill 2009, Zangrillo 2009, Logan 2011, Goksedef 2012, Guzette 2012).

## Medical Technology Assessment Committee (MTAC)

### NovoSeven®

#### 10/10/2001: MTAC REVIEW

**Evidence Conclusion:** There is insufficient published scientific evidence on which to base conclusions about the effect of NovoSeven® on health outcomes in people with Glanzmann's disease.

**Articles:** The search yielded 7 articles. Two were review articles, two were case studies (report on only one patient) and three were case series, each of which included five or fewer patients with Glanzmann's disease. Due to the small sizes of the case series, no evidence tables created.

The use of NovoSeven® in the treatment of Glanzmann's disease does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **NovoSeven®**

##### **12/10/2003: MTAC REVIEW**

**Evidence Conclusion:** There are no studies comparing NovoSeven to another treatment for hemophilia patients with inhibitors. A comparison to the alternative bypass agents, prothrombin complex concentrates (PCCs) or activated prothrombin complex concentrates (aPCC), might be feasible. In the Scharrer study, 7 (25%) of the patients had failed PCCs/aPCCs, but neither of the other two studies attempted to select patients who had failed treatment with another bypass agent. Non-comparative clinical data suggests that NovoSeven is effective at achieving hemostasis in 80-90% of bleeding episodes. There are data on both in-home and surgical use of NovoSeven. There was a low rate of thrombosis associated with treatment in the published data.

**Articles:** The search yielded 71 articles, many of which were reviews, opinion pieces, overviews or dealt with technical aspects of the treatment. There were no randomized or non-randomized studies with hemophilia patients with inhibitors that compared NovoSeven to an alternate treatment. One randomized controlled trial was identified with hemophilia patients, but this compared two doses of NovoSeven. The remaining empirical studies were case series. The RCT was critically appraised, not for comparative data, but because it was a reasonably well-designed study with the target population. In addition, two of the largest case series using NovoSeven to treat hemophilia patients with inhibitors were critically appraised. The articles reviewed are as follows: Shapiro AD, Gilchrist S, Hoots WK. Prospective, randomized trial of two doses of rFVIIa (NovoSeven) in hemophilia patients with inhibitors undergoing surgery. *Thromb Haemost* 1998; 80: 773-778. See [Evidence Table](#). Key NS Aledort LM, Beardsley D. Home treatment of mild to moderate bleeding episodes using recombinant factor VIIa (NovoSeven) in hemophiliacs with inhibitors. *Thromb Haemost* 1998; 80: 912-918. See [Evidence Table](#). Scharrer I et al. Recombinant factor VIIa for patients with inhibitors to factor VIII or IX or factor II deficiency. *Hemophilia* 1999; 5: 253-259. See [Evidence Table](#).

The use of NovoSeven® in the treatment of Hemophilia does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **NovoSeven®**

##### **02/11/2013: MTAC REVIEW**

**Evidence Conclusion:** There is a lack of published high quality studies on the off-label use of rFVIIa in cardiac surgery. To date only two RCTs evaluated the use of rFVIIa in adult cardiac surgery; one was a very small pilot study with 20 patients that assessed the prophylactic use of the therapy, and the other was conducted among 172 patients (Gill 2009, evidence table 3) to evaluate the effectiveness and safety of rFVIIa in 172 patients bleeding after cardiac surgery requiring cardiopulmonary bypass. Both trials lacked statistical power to detect significant differences between the study groups. The rest of the published studies were observational with or without matched comparison groups. A number of these observational studies compared outcomes of patients receiving rFVIIa to matched groups using propensity score (PS) analysis. This method is used to adjust for selection bias in observational studies of causal effect, when RCTs are unfeasible, unethical, or too costly to conduct. PS matching adjusts for observed variables and can only decrease but not eliminate the selection bias. It may also reduce the study's external validity as only a subset of the treated patients is used in the analysis. The majority of the published studies were conducted over a long period of time; the administration of rFVIIa was based on the guidelines of each institution, but was ultimately made by at the discretion of the operating team, and may have evolved throughout the study period as the experience with using the therapy increased (Anderson 2012). There were no consistent well-defined and measurable endpoints to evaluate the efficacy of the therapy. In addition, the published studies followed different protocols for the threshold for using rFVIIa and its dose. This ranged from prophylactic use as a haemostatic agent in the operating room, to a rescue therapy for patients with refractory bleeding. Rescue therapy is defined as situations in which rFVII is used when patients continue to bleed excessively despite having received maximal standard haemostatic therapy, the definition of which varied between institutions (Guzette 2012). The dosage of rFVIIa ranged between studies from 9-192 µg/kg, and was used either repeatedly or in a single dose. The results of the RCTs and the four comparative observational studies on the use of rFVIIa in adult cardiac surgery were pooled in three meta-analyses (Zangrillo 2009, Ponschab 2011, and Yank 2011). The pooled results of the two more recent meta-analyses comprising a total 470 patients, showed no significant effect of rFVIIa on reducing mortality compared to usual care, but a statistically significant increase in the occurrence of stroke (calculated number needed to harm of 26). The meta-analyses showed a lower but statistically insignificant rate of re-exploration and a trend towards the lower blood loss and need for transfusion with the use of rFVIIa. Gill and colleagues' RCT found a statistically significant lower rate of re-operation rates and need for blood transfusion, and a statistically insignificant increase in serious adverse events in the adult cardiac

surgery patients who received rFVIIa. In conclusion, the available evidence suggests that rFVIIa use in adult cardiac surgery patients may result in an increased risk of stroke and lower re-exploration rate without a significant mortality benefit. Larger randomized controlled trials with sufficient power are needed to verify the results of the meta-analyses and clearly assess the benefits and risks of the off-label use of rFVIIa in cardiac surgery patients.

**Articles:** The literature search for studies on the use of rFVIIa (NovoSeven) for adults undergoing cardiac surgery revealed two meta-analyses, two randomized controlled trials, and a number of observational prospective and retrospective studies with or without comparison groups. The search also identified an updated Cochrane review and other meta-analyses and systematic reviews that included trials on the use of rFVII for any off-label indication including cardiac surgery. Among these, there was one review (Yank 2011) prepared for the agency for Healthcare Research and Quality (AHRQ) that included a meta-analysis of studies on the use of the rFVIIa for adult cardiac surgery. The two meta-analyses on the use of rFVIIa or cardiac surgery patients were conducted by the same group of authors, but the more recent analysis included an additional RCT and focused on the rates of thromboembolic events associated with the use of rFVIIa. Two meta-analyses of trials using rFVII for adult patients undergoing cardiac surgery as well as the most recent RCT among cardiac surgery patients were selected for critical appraisal. Zangrillo A, Mizzi A, Biondi-Zoccai G, et al. Recombinant activated factor VII in cardiac surgery: a meta-analysis. *J Cardiothoracic Vasc Anesth.* 2009.23:34-40. [Evidence Table](#). Ponschab M, Landoni G, Biondi-Zoccai G, et al. Recombinant activated factor VII increases stroke in cardiac surgery: a meta-analysis. *J Cardiothoracic Vasc Anesth.* 2011.25:804-810. [Evidence Table](#). Gill Ravi, Herbertson M, Vuylsteke A, et al. Safety and efficacy of recombinant activated factor VII A randomized placebo-controlled trial in the setting of bleeding after cardiac surgery. *Circulation* 2009;120:21-27. [Evidence Table](#).

The use of NovoSeven® in the prevention of cardiac surgery bleeding does not meet the *Group Health Medical Technology Assessment Criteria*.

Local Coverage Article	None

##### For Non-Medicare Members

GroupHealth has elected to use the MCG\* Occipital Nerve Stimulation (A-0716) for medical necessity determinations. This service is not covered per MCG guidelines.

See [Deep Brain Stimulation for Primary Headache](#).

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Headache is a major worldwide health problem disabling millions of people and resulting in considerable economic burden. Up to 40% of patients seen in major headache clinics suffer from chronic daily headache. Chronic headache disorders include migraine, cluster headache, cervicogenic headache, occipital neuralgia, and others types of primary headache (Maizels 1998, Jasper 2008).

Cluster headache (CH), an excruciating headache syndrome, is the most common type of trigeminal autonomic cephalalgias, and is thought to be the most severe primary headache disorder. 10-20% of CH patients develop a chronic form in which the attacks persist for more than one year without remissions, or with remissions lasting less than a month. Acute treatment for the attacks includes injectable or intranasal triptans or oxygen inhalation. About one percent will become refractory to medical treatment and fulfill the criteria of intractable headaches. These patients may get some relief with attack treatments, but the disorder could be disabling and may be associated with depression and suicidality (Magis 2007, Leroux 2008).

Migraine headache is a chronic headache that affects about 15% of the population and is one of the most common problems seen in emergency departments and doctors' offices. Migraine is believed to result from changes in the brain and surrounding blood vessels. The attacks typically last from 4-72 hours and vary in frequency from daily to less than one per year. Transformed migraines are chronic daily or almost daily headaches (>15/month) that lasts more than 4 hours. There is no cure for migraine, and medications can only help reduce the frequency and severity of disorder (Bigal 2008).

Cervicogenic headache is a chronic hemicranial pain that usually occurs daily. It usually begins at the suboccipital region and spreads anteriorly to the ipsilateral orbital, frontal, and temporal areas. It is typically unilateral but occasionally affects the two sides. It is believed to be due to convergence of upper cervical and trigeminal sensory pathways allowing pain signals to refer from the neck to the trigeminal sensory fields of the head and face. Treatments with pain medication, physical therapy, manipulative treatment, and surgical interventions may provide only some inconsistent temporary relief of pain (Naja 2006).

Various ablative surgical procedures targeting the trigeminal nerve or the cranial parasympathetic outflow have been tried to treat these patients with intractable headaches. These include gamma knife surgery or root section of the trigeminal nerve, trigeminal tractotomy, microvascular decompression of the trigeminal nerve, glycerol injection of the Gasserian ganglion, and others. However, none of these procedures has a consistent effect, and many are associated with serious complications (Magis 2007).

Electrical stimulation of the brain was first attempted late in the 19th century, but its application for pain control began in the 1960s with spinal cord stimulation. The neurostimulation technique for ablating pain is based on the theory that peripheral nerve stimulation can produce specific focal analgesia and anesthesia. In addition, the technique may alter perception of pain by blocking cell membrane depolarization and axonal conduction with directly applied current (Shealy 1967, Lim 2007, Trentman 2008).

In the early 2000s, neurostimulation therapy emerged as a potential treatment option for a variety of different intractable primary headache disorders. This is an invasive device-based approach that has two broad types:

1. Peripheral therapy that involves branches of the occipital nerve: occipital nerve stimulation (ONS), and supraorbital nerve stimulation.
2. Central which refers to deep-brain stimulation (DBS) approaches e.g. hypothalamic deep brain stimulation used for chronic cluster headache (Schwedt 2009).

The occipital nerve stimulators (ONS) are implanted surgically in a 3 phase procedure: Phase 1. An incision is made over the occipital region at the level of the first cervical vertebra for the subcutaneous implantation of bilateral electrodes. These are tunneled in a cephalad direction so that they come to lie across the path of the greater occipital nerve on each side of the head. Phase 2. Confirmation of the electrode position by testing each separately by an external stimulator. The operator gradually increases the amplitude delivered to the electrodes from 0 to 4 v, and the patient is asked to locate and describe any sensation he /she feels. Correct placement is confirmed by the patient describing a vibrating sensation that radiates at least 4 cm cephalad from the base of the skull, on the side of the tested electrode, and Phase 3. Implantation of the stimulator battery in the pectoral, abdominal, or gluteal region, and connecting it to the electrodes via subcutaneously tunneled leads. The procedure is performed under sedation or general anesthesia, however during the second phase the patients are required to be awake and to be able to identify the position of the occipital electrodes when the electric stimulus is applied. Potential complications of the procedure include lead migration, infection, localized pain, muscle spasm, and lack or loss of effect (Lim 2007, Trentman 2008).

The deep brain stimulation (DBS) of the posterior hypothalamus has been investigated in patients with chronic cluster headaches or SUNCT (short-lasting, unilateral, neuralgiform headache attacks with conjunctival injection and tearing). DBS involves MRI guided stereotactic placement of an electrode into the brain (e.g. thalamus, globus pallidus, or subthalamic nucleus). It is typically implanted unilaterally on the side corresponding to the most severe symptoms. The use of bilateral stimulation using two electrodes has been investigated in patients with bilateral, severe symptoms. Initially, the electrode(s) is/are attached to a temporary transcutaneous cable to validate treatment effectiveness and, if effective, the patient returns to surgery several days later for permanent subcutaneous implantation of the cable and a radiofrequency-coupled or battery-powered programmable stimulator. After implantation, noninvasive programming of the neurostimulation can be adjusted to control the patient's symptoms. The procedures can be performed only by a highly experienced neurosurgeon and may be associated with a small risk of mortality due to intra-cerebral hemorrhage. Before implantation, all patients must undergo complete preoperative neuro-imaging to exclude disorders associated with increased hemorrhagic risk (Leon 2006, Bartsch 2008).

Neither the occipital nerve stimulation nor the deep brain stimulators are approved to date by the U.S. Food and Drug Administration for the treatment or prevention of primary headaches.

## Medical Technology Assessment Committee (MTAC)

### Occipital Nerve Stimulation (ONS)

08/03/2009: MTAC REVIEW

**Evidence Conclusion:** The literature on brain stimulation for the treatment of chronic primary headache is limited and does not provide sufficient evidence to determine the efficacy or safety of either occipital or deep brain stimulation therapy for the prevention or treatment of chronic headache. There are no published randomized or nonrandomized controlled trials on the intervention to date. The empirical studies consist of a few very small case series with no comparison groups and a number of case reports. The outcome measures varied between studies as some reported change in pain and others reported on headache frequency intensity, disability and/or medication use. Popeney and Alo's (2003), the largest series on ONS studied the response to occipital nerve stimulation in a series 25 consecutive patients with transformed migraine. A comparison between pre- and post-

implant measurements, showed significant reductions in headache frequency, severity, and disability after the implant. The study was only an observational case series with potential biases, and with no control or comparison group to rule out the placebo effect of the implant.

**Articles:** The search yielded almost four hundred articles. The majority was review articles, opinion pieces, or dealt with technical aspects the procedure. ONS: There were around 15 small prospective and retrospective case series with patient sizes ranging from 3-25, and a number of case reports on peripheral nerve stimulation. Popeney CA, Alo KM. Peripheral neurostimulator for the treatment of chronic disabling transformed migraine. Headache 2003,43:369-375. See [Evidence Table](#).

The use of Occipital Nerve Stimulation (ONS) for the treatment of primary headache does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Low back pain is believed to be the most common cause of disability for people under 45 years of age in the United States. Conservative treatment usually starts with physical therapy and traction, and may progress to more invasive measures from epidural steroid injections to surgery. Various devices have been introduced to provide spinal decompression, and stabilization while keeping the patient ambulatory. These include abdominal binders, corsets, rigid braces, and others.

The Orthotrac™ Pneumatic Vest, manufactured by Kinesis Medical Inc, is a traction inducing spinal orthotic. It is a device that applies decompressive forces to the spine, transferring body weight from the upper torso to the hips to prevent compression and aggravation of the lower back. It uses pneumatic lifter coils, built in the front and back of the vest. The patient controls the amount of force generated by a manual inflation technique. The force required for offloading weight from the spine varies from one patient to another, and is prescribed by the physician. The design of the vest allows the patient to be ambulatory and participate in his/her normal daily activities. To be effective, the device should be worn 2 to 3 times a day for 20-30 minutes each time.

The Orthotrac technology and product application is patented and registered with the FDA.

#### Medical Technology Assessment Committee (MTAC)

##### Orthotrac™ Pneumatic Vest

##### 02/11/2004: MTAC REVIEW

**Evidence Conclusion:** Due to lack of scientific data, there is no evidence to determine the effectiveness of Orthotrac™ pneumatic vest in relieving low back pain.

**Articles:** The search did not yield any peer-reviewed published clinical study on the effectiveness of the Orthotrac™ pneumatic vest in relieving low back pain.

The use of Orthotrac™ Pneumatic Vest in the treatment of chronic low back pain does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

- I. Pancreas Transplant Alone (PTA) without kidney transplant is considered medically necessary when **All of the following** general and disease specific criteria are met:
  - A. General Criteria:
    1. Absence of ongoing or recurrent active infections that are not effectively treated; and
    2. Absence of uncontrolled HIV/AIDS infection, defined as:
      - a. CD4 count greater than 200 cells/mm<sup>3</sup> for more than 6 months; *and*
      - b. HIV-1 RNA (viral load) undetectable; *and*
      - c. No other complications from AIDS, such as opportunistic infection (e.g., aspergillus, coccidioidomycosis, resistant fungal infections, tuberculosis) or neoplasm (e.g., Kaposi's sarcoma, non-Hodgkin's lymphoma); *and*
      - d. On stable anti-viral therapy more than 3 months; and
    3. Documentation of compliance with medical management; *and*
    4. Member has adequate cardiac status (e.g., no angiographic evidence of significant coronary artery disease, ejection fraction greater than or equal to 40 %, no myocardial infarction in last 6 months, negative stress test); *and*
    5. Member has satisfactory kidney function (creatinine clearance greater than 40 ml/min); *and*
    6. No malignancy (except for non-melanomatous skin cancers) or malignancy has been completely resected OR (upon medical review) malignancy has been adequately treated such that the risk of recurrence is small.
  - B. Disease Specific Criteria:
    1. Member has a history of labile (brittle) insulin-dependent diabetes mellitus (IDDM); *and*
    2. Member has recurrent, acute and severe metabolic and potentially life-threatening complications requiring medical attention, as documented by chart notes, frequent emergency room visits and/or hospitalizations. They may include:
      - a. Hyperglycemia; *or*
      - b. Hypoglycemia; *or*
      - c. Hypoglycemic unawareness associated with high risk of injury; *or*
      - d. Ketoacidosis; *and*
    3. Member has consistent failure of exogenous insulin-based management, defined as inability to achieve sufficient glycemic control (HbA1c of greater than 8.0) or recurrent hypoglycemic unawareness, despite aggressive conventional therapy including all of the following:
      - a. Adjusting frequencies and amounts of insulin injected; *and*
      - b. Measuring multiple blood glucose levels on a daily basis; *and*
      - c. Modifying diet and exercise; *and*
      - d. Monitoring HgbA1c levels.
- II. Pancreas retransplantation after a failed primary pancreas transplant is considered medically necessary when member meets the selection criteria stated above.

- III. Pancreas retransplantation after 2 or more prior failed pancreas transplants may be considered medically necessary upon individual case review.
- IV. Contraindications:
- A. Contraindications: PTA is considered not medically necessary in members with prohibitive cardiovascular risk because the risks of PTA exceed the benefits. Examples of prohibitive cardiovascular risk include, but are not limited to:
1. Angiographic evidence of significant non-correctable coronary artery disease; *or*
  2. Ejection fraction less than 35 %; *or*
  3. Myocardial infarction within last 6 months; *or*
  4. Refractory uncontrolled hypertension
- B. Relative Contraindications: Pancreas transplant is may be considered medically necessary for members with the following relative contraindications to pancreas transplant only if the requesting physician documents that these relative contraindications were considered, and has determined that the benefits of pancreas transplant outweigh the risks in these members. Relative contraindications to PTA include the following:
1. Ejection fraction 35 % to 40 %; *or*
  2. Severe peripheral vascular disease.
- V. Islet cell autotransplantation (i.e., transplantation of the member's own islet cells) is considered medically necessary for members undergoing near-total or total pancreatic resection for severe, refractory chronic pancreatitis.
- Islet cell allotransplantation (i.e., transplantation of islet cells from a donor) is considered experimental and investigational.
- VI. Partial pancreas transplant is considered from a living donor an acceptable alternative to cadaveric transplant for persons who meet medical necessity criteria for pancreas transplant.
- VII. The following is considered experimental and investigational because their safety and effectiveness have not been established in the peer-reviewed published medical literature.
- A. Pancreatic islet xenotransplantation; *or*
- B. PTA for increased longevity; *or*
- C. PTA primarily indicated for life-style issues, i.e., a desire to no longer take insulin.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Pancreas transplantation is used in patients with type 1 diabetes. After a successful transplantation, many diabetic patients no longer require insulin. Due to the danger of organ rejection in the short- or long-term, pancreas transplant recipients need to take immunosuppressive drugs.

Most pancreas transplants are done in conjunction with (at the same time or following) a kidney transplant. A reason for this combination transplant is that the pancreas induces a strong immune response and therefore requires larger doses of immunosuppressive drugs that can jeopardize kidney function and the transplanted pancreas.

The first clinical pancreas transplant (of any type) was done in 1966. Initially there was a low success rate but clinical outcomes improved in the 1980s due to advances in surgical techniques and the introduction of cyclosporine for immunosuppression. Newer immunosuppressants, Tacrolimus and mycophenolate mofetil, were introduced in 1994 and 1995, respectively. Since 1994, there have been improved graft survival rates in patients receiving pancreas transplants alone (PTA).

## Medical Technology Assessment Committee (MTAC)

### **Pancreas Transplant**

#### **12/12/2001: MTAC REVIEW**

**Evidence Conclusion:** Only one article reported data on patients receiving pancreas transplants alone. The methodology was not well described and the intervention procedures varied dramatically over time. The article reported on the experience of the institution; it was primarily a review article rather than a research study. The

case series portion of this article had inadequately described methodology and is subject to selection and observation biases. Due to lack of quality scientific data, the evidence is insufficient to draw conclusions about the effect of this technology on health outcomes.

**Articles:** The search yielded 36 articles, many of which were review articles, opinion pieces or dealt with pancreas transplantation in conjunction with kidney transplantation. There were no empirical studies that presented separate data on the outcomes of PTA. There were several case series that included both pancreas transplantation in conjunction with kidney transplantation and PTA, but the data were not divided by type of procedure. Only one article presented some data separately for patients receiving PTA. This was primarily a review article, and included case series data. This study was critically appraised:

Sutherland DER, Gruessner RWG, Dunn DL, Matas AJ, Humar A, Kandaweamy R, Mauer M, Kennedy WR, Goetz FC, Robertson RP, Gruessner AC, Najarian JS. Lessons learned from more than 1,000 pancreas transplants at a single institution. *Ann Surg* 2001; 233: 463-501.

The use of Pancreas Transplant alone in the treatment of Juvenile Diabetes does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Loss-of-Heterozygosity Topographic Genotyping with Pathfinder TG®

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Cytogenetic Studies (190.3)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

Group Health has elected to use the Topographic Genotyping PathFinderTG (A-0632) MCG\* for medical necessity determinations.

**\*MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider
- Genetics consult if applicable & requesting provider is not a geneticist

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Pathologic analysis of tissue samples is central to the diagnosis of cancer; however, there are some instances when these results may be inconclusive. Pathfinder TG® is a molecular DNA-based cancer diagnostic test that can aid diagnosis when pathology results are inconclusive. The Pathfinder TG® test uses a method known as topographic genotyping that combines pathology and molecular analysis using specific genetic marker panels to identify acquired mutations in a variety of different types of cancer.

#### Medical Technology Assessment Committee (MTAC)

##### Pathfinder TG®

##### 06/18/2012: MTAC REVIEW

**Evidence Conclusion:** Analytic validity - No studies were identified that evaluated the analytic validity of loss-of-heterozygosity based topographic genotyping with Pathfinder TG® (AHRQ 2010). Clinical validity- Fifteen retrospective studies with methodological limitations were identified that evaluated the clinical validity of loss-of-heterozygosity based topographic genotyping with Pathfinder TG®. Details on patient characteristics, treatments, clinical definitions, and statistical methods were limited. Additionally, only 3 studies had more than 50 patients and it is possible that these publications analyzed the same patient population. There is insufficient high-quality evidence to determine the clinical validity of loss-of-heterozygosity based topographic genotyping with Pathfinder TG® (AHRQ 2010). Clinical utility - No studies were identified that evaluated the clinical utility of loss-of-heterozygosity based topographic genotyping with Pathfinder TG® (AHRQ 2010). Conclusion: There is insufficient evidence to determine the analytic validity, clinical validity, and clinical utility of loss-of-heterozygosity based topographic genotyping with Pathfinder TG®.

**Articles:** The literature search revealed a 2010 AHRQ technology assessment that evaluated the analytic validity, clinical validity, and clinical utility of loss-of-heterozygosity based topographic genotyping with Pathfinder TG®. Studies were excluded if they had less than 25 subjects. No relevant articles were identified after the 2010 ARHQ review. The following technology assessment was selected for review: Trikalinos TA, Terasawa T, Raman G et al. A systematic review of loss-of-heterozygosity based topographic genotyping with PathfinderTG®. AHRQ Technology Assessment Program (Project ID GEND0308). March 2010. See [Evidence Table](#).

The use of Pathfinder TG® does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Breast cancer is the most common non-skin cancer among women in the United States, and one of the leading causes of cancer death among women of all races. Although the incidence rate has increased, there has been a steady decline in the breast cancer death rate since the early 1990s, mostly due to screening, better awareness, and improved treatment. Early detection and accurate staging and restaging of recurrent breast cancer are important to define appropriate therapeutic strategies and increase the chance of a cure (Bartella 2006, CDC 2010, Pan 2010).

Mammography remains the gold standard screening method for women at average risk for breast cancer. It is relatively inexpensive, requires a low dose of radiation, and reliably identifies malignant tumors especially those that are too small to feel. It can also be used to investigate breast lumps and other symptoms. Although the benefit of mammographic screening is widely accepted, its limitations and failure to detect all breast cancers are also recognized. It is reported that the false negative rate of screening mammography ranges between 20-30%. It also has a low specificity resulting in a large number of unnecessary procedures. It is reported that only 25-45% of the biopsies done based on mammographic abnormalities result in a diagnosis of carcinoma. Diagnostic mammography is commonly used to identify possible breast cancers in women with signs and symptoms, and has a higher sensitivity (85-93%) compared with screening mammography (Bartella 2007).

Ultrasound (US) imaging may be used to evaluate abnormalities detected during a breast exam or mammogram and is useful in differentiating solid tumors from fluid filled cysts. It is considered the imaging technique of choice for evaluating palpable masses in women younger than 30 years as well as in pregnant and lactating women. It can also be used for the guidance of interventional procedures and treatment planning for radiation therapy. US is easily accessible, relatively low in cost, and does not involve the use of ionizing radiation. However it cannot detect microcalcifications, can be time consuming, and its performance is operator dependent (Ferrara 2010).

Breast MRI using a special receiver and injected contrast material is more sensitive and accurate than mammography and ultrasound in detecting invasive lobular cancer. MRI detects blood flow to lesions and does not expose the patient to radiation. The increased blood flow is indicative of vascularization frequently found in cancer. MRI however, has some disadvantages; it can lead to false positive results as both benign and malignant lesions can absorb the contrast, it is less sensitive in detecting in situ cancers, and its interpretation is challenged when

the breast is under estrogen modulation during menstrual cycle or HRT use, which affects the glandular tissue of the breast. In addition, MRI is not indicated and/or tolerated by many patients due to renal disease, metallic implants, claustrophobia, large body size, or general medical condition. It is a costly test to use for screening and is not a substitute for mammography. MRI is recommended for screening women at very high risk of breast cancer especially for the BRCA1 and BRCA2 subgroups. Other accepted indications include patients presenting with axillary adenopathy and an unknown primary, patients with equivocal mammograms, the differentiation of scar versus recurrence at lumpectomy site, as well as other indications (Tafreshi 2010, Philpotts 2011, Schilling 2011).

Nuclear breast imaging refers to functional imaging of the breast through the use of radiopharmaceuticals such as 18 F-fluorodeoxyglucose (18FDG) or 99mTc-sestamibi. It takes advantage of the differences in metabolic activity between tumor and normal tissue. Functional imaging can thus show changes in cell metabolism that are due to malignancies as the majority of primary and metastatic cancers take up more glucose than the adjacent normal tissues. Positron emission tomography (PET) with the radiotracer FDG may be able to detect cancer even before vascularization as cancer cell metabolism is usually heightened prior to the stimulation of new vessel growth. It has the potential of improving detection of cancer in dense breasts, illustrating the extent of the disease for surgical planning, and distinguishing between recurrent cancer and scar tissue (Schilling 2011).

The use of whole body PET (WB- PET) and PET/CT is limited due to the low sensitivity and positive predictive value in detecting early stage breast cancer, invasive lobular and ductal carcinoma in situ, as well regional lymphadenopathy. The reasons reported for this low sensitivity include low spatial resolution, and lower level of FDG tracer uptake in some breast malignancies compared to other cancers (Schilling 2011).

Positron emission mammography (PEM) is a modification of PET that allows for a much more spatial resolution by putting the photon detectors directly on the breast. PEM uses similar principles as PET but is a breast specific imaging tool. Both work through the introduction and detection of a positron-emitting glucose analog 18F-FDG as the imaging radiotracer. The 18F-FDG analog decays by emitting a positron that is annihilated within a few millimeters resulting in emission of two gamma rays that radiate in opposite directions and are detected by the PET instrument. The resolution of PEM is increased by allowing the detectors to be directly placed on the breast. Gentle compression provides the advantage of spreading out the breast tissue for imaging. PEM devices use 2 moving detector heads mounted on compression paddles, with a similar configuration and size as a traditional mammography system. This allows direct correlation of the initial and recurrence images obtained by both devices. PEM images can also be reconstructed into 3D for localization of abnormalities. It is reported that the technique used allows capturing sharp detailed images of breast lesions as small as 2 mm, and the detection of small foci of ductal carcinoma in situ without depending on the presence of calcification for its identification. The whole body radiation dose the patient receives from PEM is approximately three times higher than that of a mammogram, which may be a barrier to using it as a screening modality in the general population. PEM also cannot take the place of breast cancer staging performed with whole-body PET because PEM is limited to breast views only. It is reported that the same benign conditions that cause high FDG uptake in PET (e.g. infection, inflammation and fat necrosis) may cause false positive results in PEM. Glucose control is another problem with PEM as it is with PET; women with inadequately controlled diabetes cannot undergo either procedure (Tafreshi 2010, Ferrara 2010, Moadel 2011).

PEM 2400 PET scanner and PEM Flex devices have received FDA clearance to perform PET imaging of the breast under gentle compression for patients with confirmed breast cancer.

## Medical Technology Assessment Committee (MTAC)

### Positron Emission Mammography (PEM)

#### 08/15/2011: MTAC REVIEW

**Evidence Conclusion:** Berg et al (2006) study (Evidence table 1) evaluated PEM diagnostic performance in 77 women with 77 index and 15 incidentally discovered lesions, all histologically proven breast cancer. PEM identified 91% of DCIS, and had an overall sensitivity of 93% for the index cancers, and 90% when incidental cancers were included. Combined with conventional imaging (mammography and ultrasonography) the sensitivity of PEM improved to 98%, but with a reduced specificity. The study had its limitations and used nonstandard method for calculating the standardized uptake value (SUV). Berg et al, 2011 (Evidence table 2) examined the diagnostic performance of PEM and its impact on surgical management compared with MRI in 388 women with newly diagnosed, histologically proven breast cancer. The results of the study showed that PEM and MRI had an overall similar accuracy. MRI was more sensitive and less specific than PEM at the lesion level and in detecting incidental additional cancers. MRI was also more accurate than PEM in assessing disease extent and need for mastectomy. Still, as the authors indicate, "the combination of both MRI and PEM did not fully depict the disease extent, particularly in cases with extensive intraductal component, multifocal disease, or multicentric disease, the patient population that would benefit from accurate assessment of the disease extent". Schilling et al, 2011

(Evidence table 3) also compared the performance of FDG-PEM vs. MRI, including their effect on presurgical planning in 208 patients with newly diagnosed, biopsy proven breast cancer. Only 76% of the participants were included in the analysis. Overall, the results show that PEM and MRI had similar sensitivities of 92.8% in depiction of index cancerous lesions. Similar to the Berg's study, MRI was more sensitive and less specific than PEM in detecting additional unsuspected ipsilateral lesions but, the difference was statistically insignificant. However, the authors did not discuss if they performed any power analysis to determine the appropriate sample size. The study did not examine whether PEM results alone influenced surgical treatment as all imaging results were available to the surgeons prior to surgery treatment.

**Articles:** The literature search revealed around two hundred articles on PET exams for the breast. Many were review articles, technical reports, or studies on the diagnostic accuracy of FDG-PET rather than PEM which is the focus of the review. There were a limited number of studies that compared the accuracy of PEM with mammography or MRI, and most were conducted by one PEM working group. The following studies were selected for critical appraisal: Berg WA, Weinberg IN, Narayanan D, et al. High resolution fluorodeoxyglucose positron emission tomography with compression ("positron emission mammography") is highly accurate in depicting primary breast cancer. *Breast J.* 2006;12:309-323. See [Evidence Table](#). Berg WA, Madsen KS, Schilling K, et al. Breast cancer: comparative effectiveness of positron emission mammography and MR imaging in presurgical planning for the ipsilateral breast. *Radiology.* 2011;25:59-72. See [Evidence Table](#). Schilling K, Narayanan D, Kalinyak JE, et al. Positron emission mammography in breast cancer: presurgical planning f comparison with magnetic resonance imaging. *Eur J Nucl Med Mol Imaging* 2011;25:23-36. See [Evidence Table](#).

The use of Positron Emission Mammography (PEM) does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Vertebroplasty

[See Separate Criteria for Kyphoplasty](#)

- Percutaneous Vertebroplasty with Polymethylmethacrylate
- Radiofrequency Ablation with Vertebral Augmentation for Painful Spinal Metastases

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

See [LCD for Percutaneous Vertebral Augmentation \(L34106\)](#).

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Vertebral compression fractures (VCFs) occur when the bones of the spine become compressed and break. It is estimated that about five million new vertebral fractures occur worldwide each year. Most common in elderly populations and females, osteoporosis is responsible for more than 1.5 million fractures annually, the majority of which are vertebral. Other potential causes of VCFs include trauma, steroid use, malignancy in the vertebrae, and haemangioma. In any case, VCFs can be asymptomatic and resolve without treatment, however, they are frequently associated with pain, disability, and reduced quality of life (QoL). To add to this, VCFs are a risk factor for subsequent fractures which can lead to additional complications such as kyphosis, impairment of mobility or balance, and increased mortality to name a few (Chitale and Prasad 2013).

The majority of patients with VCFs are successfully treated with conservative management aimed to alleviate symptoms via external bracing, decreased activity and analgesics. Some patients, however, will experience persistent pain and symptoms refractory to medical therapy and may require additional intervention.

Percutaneous vertebroplasty is an interventional radiology technique developed to provide mechanical support and symptomatic relief in patients with VCFs. The minimally invasive procedure was first performed in France by Deramond and colleagues in 1984 and later, in 1993, was introduced to clinical practice in the US. The procedure was initially performed to strengthen vertebrae weakened by angiomas. Since then, however, indications for vertebroplasty have expanded to include metastatic vertebral cancer, multiple myeloma, as well as, osteoporotic VCFs that have not responded to conservative therapy. Performed under local anesthesia, the procedure involves injection of polymethylmethacrylate (PMMA) into a collapsed vertebral body under fluoroscopic guidance (Deramond, Depriester et al. 1998).

Vertebroplasty has been associated with serious complications such as infection, or more frequently cement leakage that can lead to pulmonary embolism, adjacent vertebral collapse, nerve root irritation, or spinal cord compression. Cement leakage was reported to occur in 20-65% of all cases. Other less serious complications may include allergic reactions, hypertension, and temporary pain (Majd, Farley et al. 2005).

As a surgical procedure, vertebroplasty is not subject to US Food and Drug Administration (FDA) regulation. The FDA does, however, regulate the injectable bone cement which is integral to the procedure. While various bone cements have been approved, the FDA issued several notifications to orthopedic specialists and other healthcare professionals about the complications related to the use of these products. The Medical Technology and

Assessment Committee (MTAC) has previously reviewed vertebroplasty in 2000 and 2005. In each case, the procedure failed MTAC criteria due to insufficient evidence to determine the efficacy of vertebroplasty in augmenting the collapsed vertebrae, and reducing pain in patients with osteoporotic compression fractures. Vertebroplasty is currently being re-reviewed to update the evidence.

## Evidence and Source Documents

## Medical Technology Assessment Committee (MTAC)

### ***Percutaneous Vertebroplasty of Low Back Pain***

#### **02/09/2000: MTAC REVIEW**

**Evidence Conclusion:** Efficacy of vertebroplasty in patients with osteoporotic compression fractures cannot be determined from these studies because of the likelihood of selection bias, observation bias, confounding and chance as explanations for some of, or all of, the studies' findings.

**Articles:** Articles were selected on the basis of study type. Because the literature revealed no randomized control trials or meta-analyses, the 14 cohort studies or case series were reviewed by abstract. The largest case series were selected for critical appraisal and evidence tables were created (Weill A, Chrias J, Simon J, et al. Spinal Metastases: Indications for Results of Percutaneous Injection of Acrylic Surgical Cement. *Radiology*. 1996; 199:241-247. Cortet B, Cotton A, Boutry N, et al. Percutaneous Vertebroplasty in the Treatment of Osteoporotic Vertebral Compression Fractures: An Open Prospective Study. *J Rheumatol*. 1999;26:2222-8.) Weill A, Chrias J, Simon J, et al. Spinal Metastases: Indications for and Results of Percutaneous Injection of Acrylic Surgical Cement. *Radiology* 1996; 199:241-247. See [Evidence Table](#). Cortet B, Cotten A, Boutry N, et al. Percutaneous vertebroplasty in the treatment of osteoporotic vertebral compression fractures: An open prospective study. *J Rheumatol*. 1999;26:2222-8. See [Evidence Table](#). Deramond H, Depriester C, Galibert P, et al. Percutaneous Vertebroplasty with Polymethylmethacrylate: Techniques, Indications, and Results. *Radiologic Clinics of North America*, Vol 36(3); May 1998:533-546. See [Evidence Table](#).

The use of percutaneous vertebroplasty of low back pain has been approved by the FDA and therefore meets *Group Health Medical Technology Assessment Criteria*.

### ***Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fracture***

#### **06/06/2005: MTAC REVIEW**

**Evidence Conclusion:** The studies reviewed do not provide sufficient evidence to determine the efficacy of the procedure, its long-term benefits, or late complications. No direct randomized studies comparing the intervention with standard, non-operative care are available.

Diamond et al's study had the advantage of comparing the intervention with conservative therapy. However, it was not randomized, and conservative therapy was offered to those who denied percutaneous vertebroplasty, which might be a potential source of selection bias. The study was also subject to observation bias as it was not blinded and all outcomes were subjective. Moreover, the follow-up duration might be insufficient to determine the long-term effects of the vertebroplasty. The Grohs' study compared kyphoplasty head to head with vertebroplasty. However, it was small, nonrandomized and unblinded. Postoperative comparison was made vs. baseline condition for each intervention with no direct comparison between the two techniques. The results of the study show that both procedures offered significant pain relief, which was maintained at a lower level with the kyphoplasty. The functional disability on the other hand was significantly improved only with kyphoplasty and not vertebroplasty. The results of the study also indicate that the rate of fracture of an adjacent vertebra seems to be higher with the kyphoplasty vs. vertebroplasty (21% vs. 4%). Gangi's study was a case series with potential selection and observation bias, with no control or comparison group, and the authors did not provide sufficient data on patient selection for the intervention, their characteristics, and follow-up, or long-term outcomes.

**Articles:** The search yielded 179 articles, most of which were review articles, discussion pieces and technical reports. A nonrandomized trial comparing percutaneous vertebroplasty with conservative therapy, and another comparing it to kyphoplasty were identified, as well as several case series. *The two studies with comparison groups, as well as the largest case series (N=868), were selected for critical appraisal:* Diamond T, Champion B, and Clark W. Management of acute osteoporotic vertebral fractures: A nonrandomized trial comparing percutaneous vertebroplasty with conservative therapy. *Am J Med*. 2003;114:257-265. See [Evidence Table](#).

Grohs JG, Matzner M, Trieb K, et al. Minimal invasive stabilization of osteoporotic vertebral fractures. A prospective nonrandomized comparison of vertebroplasty and balloon kyphoplasty. *J Spinal Disord Tech*

2005;18:238-242. See [Evidence Table](#). Gangi A, Guth S, Imbert JP, et al. Percutaneous vertebroplasty: Indications, technique, and results. *Radiographics*. 2003;23:e10-e10. See [Evidence Table](#).

The use of Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fractures does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 09/04/2009: MTAC REVIEW

##### **Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fracture**

**Evidence Conclusion:** There is fair evidence from two randomized controlled trials that vertebroplasty does not have a significant benefit over sham treatment in reducing pain and pain-related disability in patients with osteoporotic vertebral fractures. [Kallmes, et al 2009 trial](#): Kallmes and colleagues randomly assigned 131 patients with 1-3 painful osteoporotic compression vertebral fractures (between T4 and L5), that was <1 year old and not responding to standard medical therapy, to undergo vertebroplasty or a sham treatment that simulated the procedure but without PMMA infusion. The primary outcomes were scores on the modified Roland-Morris Disability Questionnaire (RDQ) and patient's rating of average pain intensity during the preceding 24 hours at 1 month. Patients were allowed to cross over to the other study group after one month. The results of the trial show no significant differences in the primary outcome between the two groups (difference in RDQ score 0.7; 95%CI, -1.3 to 2.8, p=0.49, and difference in pain rating 0.7; 95% CI, -0.3 to 1.7, p=0.19). One serious adverse event occurred in each of the 2 study groups (injury to the thecal sac in the vertebroplasty procedure, and tachycardia and rigors in the control group) At 3 months there was a higher rate of cross over in the control group (43%) than the vertebroplasty group (12%), p<0.001. The study had generally valid methodology, but not without limitations. It was randomized, controlled, blinded, multicenter, with well defined inclusion/ exclusion criteria, sufficient statistical power to detect differences between the study groups, and analysis was based on ITT. The limitations of the trial included allowing cross-over between the two treatment groups after 1 month which did not allow evaluating the long-term efficacy of the procedure. Moreover, no adjustments were made for other medical treatments received, or other causes of pain all of which are potential confounders. [Buchbinder, et al 2009](#): Buchbinder and colleagues randomized 78 patients with one or two painful MRI confirmed unhealed osteoporotic vertebral fractures. <12 months duration to undergo vertebroplasty or a sham procedure. Patients were followed up for 6 months, and the primary outcome was overall pain at 3 months. Secondary outcomes included functional status and QoL at 1 week, 1, 3, and 6 months after the procedures. The trial had generally valid methodology but was relatively small. It was randomized, controlled, blinded, multicenter, with sufficient statistical power to detect significant differences between the study groups, and analysis was based on ITT. The results show no significant difference between the vertebroplasty and sham treatment in any of the outcomes. The mean reduction in pain was 2.6 +2.9 and 1.9+3.3 respectively with an adjusted difference between the two groups of 0.6; 95% CI, -0.7 to 1.8. Both groups showed a significant reduction of pain at three months vs. baseline. 7 new of clinical vertebral fractures occurred during the 6-month follow-up (three in the vertebroplasty group and 4 in the control group. **Conclusion:** The published literature provides fair evidence that vertebroplasty has no significant benefit over a sham procedure in the treatment of patients with osteoporotic vertebral fractures.

Articles: Two trials on vertebroplasty for osteoporotic spinal fractures were recently published: Buchbinder R, Osborne RH, Ebeling PR, et al. A randomized trial of vertebroplasty for painful osteoporotic vertebral fractures. *N Engl J Med* 2009;36:557-568. Kallmes DF, Comstock BA, Heagerty PJ, et al. A randomized trial of vertebroplasty for osteoporotic spinal fractures. *N Engl J Med* 2009;36:569-579.

The use of Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fractures does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 02/09/2015: MTAC REVIEW

##### **Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fracture**

**Evidence Conclusion: Effectiveness:** In the first RCT, detailed in evidence table one, Buchbinder and colleagues included 78 subjects with back pain, ≤12 months in duration, who had up to two VCF evidenced by the presence of vertebral collapse, edema and/or a fracture line on MRI. Patients were randomized into either the vertebroplasty treatment group or a group that received sham procedure. Outcomes were measured at baseline and several points in time up to six months following the procedure. The primary endpoint was overall pain at three months, however, the study also included QoL measures and a survey specific to osteoporotic vertebral fractures. Ultimately the study found no beneficial effect of vertebroplasty over the sham procedure at any time. In fact, the only significant between-group difference was seen on the Quality of Life Questionnaire of the European Foundation for Osteoporosis (QUALEFFO) total score at one week, favoring the sham group [-4.0 (95%CI -7.8 to -0.2)] (Buchbinder, Osborne et al. 2009). [Evidence Table](#). The second study, by Kallmes and colleagues, also randomized osteoporotic patients with up to three painful VCFs (n=131) to vertebroplasty or sham procedures. After one month, if patients did not achieve adequate pain relief, the investigators allowed cross-over to the alternate therapy. The primary outcomes, pain and disability, were assessed at one month, however, investigators

also describe outcomes up to three months to assess the effects of cross-over. At one month, both the vertebroplasty and sham groups demonstrated substantial improvements, however, no significant differences were seen between groups in either of the primary outcomes. The mean Roland-Morris Disability Questionnaire (RDQ) in the vertebroplasty group was 12.0±6.3 and 13.0±6.4 in the sham group (adjusted treatment effect, 0.7; 95% CI, -1.3 to 2.8; P=0.49). Similarly, the mean pain-intensity rating was 3.9±2.9 in the vertebroplasty group and 4.6±3.0 in the sham group (adjusted treatment effect, 0.7; 95% CI, -0.3 to 1.7; P=0.19). The investigators note, however, that the control group saw a higher rate of cross-over than the vertebroplasty group (51% vs. 13%, P<0.001). Despite this significance, the investigators concluded that improvements in pain and pain-related disability associated with osteoporotic VCF in patients treated with vertebroplasty were similar to the improvements seen in the sham group (Kallmes, Comstock et al. 2009). [Evidence Table](#). **Safety:** Adverse events were documented in both studies and included hospitalizations from the procedure, as well as, subsequent fractures. Cement leakage was not reported by Kallmes and colleagues, however, Buchbinder et al. reported 37% cement leakage rate with no symptomatic events. Neither of the studies provided extended follow-up of safety and adverse events with the longest follow-up limited to six months following procedure. Previous reviews of vertebroplasty failed MTAC criteria with the available evidence offering little value due to methodological limitations such as a lack of randomization, inappropriate comparators and the likelihood of selection bias, observation bias, confounding and chance as explanations for study findings. Currently, however, the literature is more robust with two RCTs that compare vertebroplasty to sham procedures. The design of both studies was strengthened by the use of a sham procedure replicating verbal and visual cues allowing for the blinding of patients. With that said, an additional control group receiving no treatment would have benefited the outcome comparisons. Other limitations include sample size. Despite relatively lax inclusion criteria, both of the studies experienced difficulties recruiting patients resulting in a modification of sample size in the study by Kallmes et al. and the inability to assess two year follow-up in the Buchbinder study. Ultimately, the studies provide adequate evidence to suggest that vertebroplasty is no better than sham treatment for treating patients with VCF due to osteoporosis.

**Conclusions:** There is evidence to suggest that vertebroplasty is no more effective than sham therapy for the treatment of vertebral compression fractures in osteoporotic patients. There is insufficient evidence to assess the safety of vertebroplasty for the treatment of vertebral compression fractures in osteoporotic patients.

**Articles:** The search yielded a large quantity of publications relating to vertebroplasty. The majority of the literature was comprised of non-randomized, observational studies, many of which sought to compare vertebroplasty with kyphoplasty. A supplemental search of the clinical trials database revealed several studies relating to vertebroplasty that are currently recruiting or on-going. Since the last MTAC review, two randomized trials comparing percutaneous vertebroplasty with a sham procedure therapy were published and selected for critical appraisal. The following articles were selected for critical appraisal: Buchbinder R, Osborne RH, Ebeling PR, et al. A randomized trial of vertebroplasty for painful osteoporotic vertebral fractures. *NEJM*. 2009; 361(6):557-568. [Evidence Table 1](#). Kallmes DF, Cornstock BA, Heagerty PJ, et al. A randomized trial of vertebroplasty for osteoporotic spinal fractures. *NEJM*. 2009;261(6):569-571. [Evidence Table 2](#).

The use of Percutaneous Vertebroplasty in Treatment of Osteoporotic Vertebral Fractures does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Ablation with Vertebral Augmentation for Painful Metastases**

#### **BACKGROUND**

The number of patients living with cancer in the United States (US) is estimated to be 4.86 million. Virtually all cancers have the potential to spread, or metastasize, with bone being one of the more common sites of metastasis. Generally speaking, skeletal metastases are associated with debilitating symptoms such as intolerable pain and hypercalcemia compromising the quality of life. Occurrence in the vertebral column, as does with a third of all cancer patients, contributes the additional complexity of complications such as vertebral compression fractures (VCF) and spinal cord or nerve root compression that can cause potentially irreversible loss of neurologic function (Coleman 2000).

Depending on the primary tumor, prognosis is variable with five year survival ranging from 2% in patients with lung cancer to 44% in those with thyroid cancer. Treatment presents a challenge in that there is no currently available cure, nor has there been any established treatment proven to increase life expectancy. Instead, the goals of treatment aim to control pain, limit complications and preserve function. Depending on individual patient factors, management options range from medications and systemic therapy all the way to surgical resection (Dunning, Butler et al. 2012).

Due to the advanced nature of metastatic cancer and its accompanying comorbidities, populations with skeletal metastases are usually at a higher surgical risk, making minimally invasive techniques an attractive option. Vertebral augmentation (VA) techniques, aimed at stabilizing vertebral compression fractures (VCF), have been documented to provide immediate and sustained relief (Weill, Chiras et al. 1996). In the same way, radiofrequency

ablation (RFA), a technique that utilizes thermal energy to destroy cancer cells, has also been demonstrated to reduce pain (Goldberg and Dupuy 2001; Kassamali, Ganeshan et al. 2011). Most recently, RFA and VA, in combination, have been considered a promising treatment option for treating metastatic lesions of the spine (Grönemeyer, Schirp et al. 2002; Schaefer, Lohrmann et al. 2002; Schaefer, Lohrmann et al. 2003).

The STAR™ Tumor Ablation System was developed by DFINE, Inc. (San Jose, CA) specifically for metastatic spinal lesions. The system itself consists of the SpineSTAR™ Ablation Instrument and the corresponding MetaSTAR™ RF Generator which work in unison to deliver energy and provide access and navigation to the tumor within the vertebrae. Subsequent to tumor ablation, stabilization is carried out with the StabiliT® Vertebral Augmentation System, also developed by DFINE, Inc. Put simply, the StabiliT® System allows for the delivery of highly viscous bone cement to the tumor bed. In combination, the procedures require a small incision under local anesthesia with conscious sedation and offer the advantages of unipedicular access, and real-time monitoring of ablation zone allowing for the targeting of tumor cells and controlled cement delivery.

#### **04/20/2015: MTAC REVIEW**

##### **Radiofrequency Ablation with Vertebral Augmentation for Painful Metastases**

**Evidence Conclusion:** *Effectiveness:* In a small RCT, Orgera and colleagues, sought to compare the combined techniques of RFA and VA with VA alone. Following baseline assessment, the investigators randomized 36 patients into the two treatment groups and followed them up for six weeks. Outcomes of interest included surgery success, pain relief and the amount of analgesia administered. The investigators reported a 100% technical success rate in both groups with no significant differences noted between treatment groups with regard to pain as measured on a Visual Analogue Scale (VAS) or Roland Morris Questionnaire (RMQ). In addition, medication use decreased significantly in both groups but the investigators found no significant difference between groups. Ultimately, the results led the investigators to conclude that the addition of RFA did not offer any additional benefit (Orgera, Krokidis et al. 2014). [Evidence Table 1] A retrospective review of 128 metastatic lesions in 92 patients who underwent 96 procedures was carried out by Anchala and colleagues. The studies intent was to assess the safety and efficacy of RFA of malignant spinal lesions using the SpineSTAR ablation instrument. The investigators determined that RFA was 'technically successful' in all metastatic lesions. Post-operative pain rated on a Visual Analogue Scale (VAS) demonstrated significant changes at all time points when compared to baseline. The investigators also reported that within the largest institution, 54% of patients reported a decrease in pain medication. Ultimately, the investigators concluded that the STAR system was safely and effectively used in the treatment of spine metastatic osseous lesions (Anchala, Irving et al. 2014). [Evidence Table 2] *Safety* Although the follow-up period was limited, Orgera and colleagues reported several complications such as cement leakage (11%), death (5%) and opioid toxicity (8%). Anchala and colleagues, on the other hand, did not explicitly report safety details, but did note asymptomatic cement extravasation in two patients. Although Orgera's study was randomized and blinded, the population size was small and the follow-up period short. Limitations of Anchala's study include the lack of an adequate comparator and retrospective design. The investigators also highlight limitations such as a heterogeneous population and variable availability of data collected from each treatment center. Finally, it should be noted that at least two of the investigators from the retrospective review disclosed financial relationships with the device manufacturer. Collectively, the body of evidence is limited in nature and should be interpreted with caution.

**Conclusions:** There is insufficient evidence to support the effectiveness of the combination of RFA and VA, compared with VA alone, for the management of pain in metastatic spinal tumors. There is insufficient evidence to support the safety of RFA and VA, compared with VA alone, for the management of pain in metastatic spinal tumors.

**Articles:** A search of the literature returned a variety of publications relating to both RFA and VA, in general. The majority of publications returned were case studies/series. One study was identified comparing the combination of RFA and VA with balloon kyphoplasty, however, this study was performed in cadaveric models (Dalton, Kohm et al. 2012). A recent study identified in the search, by Song and colleagues, investigated the use of RFA and vertebral augmentation in 12 patients, however, this study was not selected for critical appraisal due to the small sample size and lack of a comparator (Song, Gu et al. 2014). The best evidence identified was a small randomized controlled trial (RCT) comparing RFA+VA with VA alone in patients with multiple myeloma (Orgera, Krokidis et al. 2014). In addition, a retrospective analysis, by Anchala and colleagues, evaluating the combination of RFA with VA for treating metastatic spinal lesions was also included (Anchala, Irving et al. 2014). An additional search of the clinical trials database identified a few prospective observational studies sponsored by DFINE, Inc. currently in the recruitment phase. The following articles were selected for critical appraisal: Orgera G, Krokidis M, Matteoli M, et al. Percutaneous vertebroplasty for pain management in patients with multiple myeloma: is radiofrequency necessary? 2014;37:203-210. See [Evidence Table](#). Anchala PR, Irving WD, Hillen TJ, et al. Treatment of metastatic lesions with a navigational bipolar radiofrequency ablation device: a multicenter retrospective study. Pain Physician. 2014;17:317-327. See [Evidence Table](#).

The use of Radiofrequency Ablation with Vertebral Augmentation for Painful Spinal Metastases does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Acute stroke is the third leading cause of death and the third most costly adult disease in the United States. Ischemic stroke is the more common type, and hemorrhagic stroke the more serious. Patients with acute ischemic stroke, who have intracranial arterial obstruction, have poorer prognosis and higher probability of deteriorating at 24 hours. When a cerebral artery is occluded, a core of the brain tissues dies rapidly. Surrounding this infarct core is an area of brain tissue that is hypoperfused but does not die quickly due of collateral blood flow. This area is called the ischemic penumbra, and its fate depends on the rapid reperfusion of the ischemic brain. The presence and extent of the ischemic penumbra is time dependent and may vary among patients. 90-100% of those with supratentorial arterial occlusion show an ischemic penumbra in the first 3 hours of a stroke, but only 75-80% may still have penumbral tissue at 6 hours after a stroke onset. Thus, the rapidity of diagnosis, distinction between types of stroke, and determining the extent and duration of ischemia are all critical in selecting the treatment strategy (Wintermark 2005, Muir 2005, Brunser 2009).

The ischemic penumbra is potentially salvageable with the administration of thrombolytic agents, but irreversibly damaged tissue will not benefit from reperfusion and may be at a higher risk of hemorrhage after thrombolytic therapy. Currently intravenous tissue plasminogen activator (tPA) administered within 3 hours of symptom onset is the only FDA approved drug for acute stroke in North America. Clinical trials showed that it can significantly reduce the effects of stroke and reduce permanent disability when administered within a limited time period. Thrombolytic drugs however, can also cause serious bleeding in the brain which could be fatal, and thus it is crucial to determine which patient would likely benefit from or likely to be harmed by the treatment. This narrow time window for using thrombolytic therapy in patients with acute nonhemorrhagic stroke intensified the need for an accurate, rapid, and accessible neuro-imaging technique that is able to identify and quantify ischemic penumbra. MR perfusion, xenon CT, PET and SPECT have been used but are limited by their availability, cost and/or patient tolerance. Clinical assessment scales that predict arterial occlusion have also been developed but are not highly accurate and their use is restricted to the middle cerebral artery (Lev 2001, Hoeffner 2004, Brunser 2009).

Conventional noncontrast CT (NCCT) is the standard initial imaging modality used to evaluate patients with acute stroke symptoms. It is widely available, convenient, and has a high sensitivity for the detection of intracranial hemorrhage which represents an absolute contra-indication to thrombolytic therapy. The Alberta Stroke Program

Early Computed Tomography Score (ASPECTS) was developed and validated in 1990 to quantify early ischemic changes on CT scans in the middle cerebral artery territory, before thrombolytic therapy. However, NCCT provides only anatomic and not physiologic information about the vessels. Researchers found that dynamic imaging after rapid injection of contrast material using CT or MRI allows assessing tissue hemodynamics from respective contrast curves, i.e. bolus tracking. MRI is currently the preferred imaging method for determining the core and penumbra tissue. It is the modality used in major clinical trials evaluating the use of tPA for stroke patients. However, MRI scanners may not be available or accessible in some hospitals and rapid imaging of acute stroke patients is of vital importance. CT scanners on the other hand are widely available in emergency rooms, and recent advances in CT and computer technology permit the calculation of contrast curves on a pixel-by-pixel basis providing high resolution perfusion CT (PCT) maps. Perfusion CT imaging has the potential of providing rapid assessment of the structural and functional status of cerebral vessels in patients who would have already undergone unenhanced head CT to exclude acute hemorrhage (Hoeffner 2004, Nabavi 2007).

PCT imaging, using standard nonionic iodinated contrasts can be performed as an adjunct to conventional CT imaging. It adds only a few minutes to the examination and does not require transferring the patient to another imaging device. PCT can be done with any spiral CT scanner and has the advantage of assessing both reversible and irreversible ischemia by generating parametric maps of cerebral blood volume (CBV), cerebral blood flow (CBF), and contrast mean transit time (MTT). The ultimate goal is to discriminate three types of tissues components: 1. The ischemic core that has the most severe ischemia and is the tissue at maximum risk of infarction, 2. Potentially salvageable tissue with mild to moderate ischemia, and 3. Tissue with normal hemodynamics. Unlike conventional CT which is normally assessed visually, perfusion imaging requires quantification of the enhancement in tissues and blood at certain time points following intravenous injection. By demonstrating a regional reduction in perfusion and prolongation of transit time, functional PCT can potentially make a positive diagnosis of acute cerebral ischemia and assess prognosis within the first few hours of stroke onset, when conventional CT images are typically normal. The perfusion maps can be generated in a short time at any workstation equipped by the appropriate software (Hoeffner 2004, Parsons 2005, Miles 2006, Nabavi 2007, Popiela 2008).

PCT however, has limited spatial coverage (20-48 mm thickness) and may not provide information on an ischemia located outside the scanning level. It also cannot detect small lacunae due to its limited spatial resolution. There is considerable variability in the protocols used for PCT scanning, perfusion postprocessing techniques, and in the threshold between scanners for CBV, CBF, and time to peak enhancement (TTP). Moreover, the reproducibility of PCT postprocessing has not been fully validated, the quantitative accuracy of the results is debated, and the quantitative analysis of the perfusion maps is still evolving, may be time consuming, and is less convenient in an emergency setting. It also has the disadvantage of exposure to ionizing radiation, and use of iodinated contrast which may be associated with contrast-induced nephropathy in high risk patients (Wintermark 2005, 2008, Miles 2006, Kohrmann 2007).

The FDA has cleared several software packages (CT perfusion 4, syngo Neuro PBV, syngo perfusion CT and others) for post processing images acquired with CT imaging systems for patients with suspected stroke.

## Medical Technology Assessment Committee (MTAC)

### *Perfusion computed tomography (PCT) for the Treatment of Acute Stroke*

**08/03/2009: MTAC REVIEW**

**Evidence Conclusion:** Several small studies assessed the accuracy of PCT in identifying the site of occlusion and characterizing the infarct. All had their advantages and limitations; the majority was multicenter, used MRI or follow-up MRI, CTA or clinical condition as gold standards, and had blind assessment of results. However, they were mainly retrospective, did not assess the time of recanalization and/or combined the results of those who received and did not receive thrombolytic therapy, all of which are potential sources of bias and confounding. In a small prospective study, Murphy and colleagues (2006) investigated whether PCT can be used to differentiate between penumbra and infarcted tissue. They used noncontrast CT at 5-7 days as a gold standard and showed that the pair of CBV and CBF derived from PCT had a sensitivity and specificity of 97.0% and 97.2% respectively, in differentiating an infarct from a penumbral tissue. Tan and colleagues 2007, retrospectively compared different CT modalities and found that decreased cerebral blood volume (CBV) derived from PCT was more accurate than CT angiography (CTA) in predicting of the anatomic distribution of final infarct core (sensitivity 80.4%, specificity 96.8%), while CTA was more accurate in determining the site of occlusion (sensitivity 94.6%, specificity 100.00%). Several other small studies including Schramm et al (2004, N=22, Schaeffer 2008, N=45, and Wintermark 2007, N=42) found that the PCT with or without and CTA correlate highly with MRI results in measuring the lesion volume in patients with acute stroke. In conclusion, the overall published evidence suggests that cerebral blood volume and cerebral blood flow values derived from a baseline PCT may have a potential use in differentiating an

infarct from penumbral tissue. However, there are no large randomized trials that examined the use of perfusion CT for selection of patients for thrombolysis. All published randomized controlled trials to date used MRI for the selection of the therapeutic strategy based on the presence or absence of tissues at risk. The use of PCT in acute stroke patients needs to be investigated further in large RCTs to determine whether it could be used to guide treatment decisions and improve outcomes.

**Articles:** The search yielded almost three hundred articles on brain CT in acute stroke patients. Many were review articles, opinion pieces, or dealt with technical aspects of the scan.

The search results were screened for the studies on: 1. Accuracy of PCT in determining the site of vessel occlusion, infarct core, salvageable brain tissue, or collateral flow, and in predicting final infarct volume in patients with suspected acute stroke: The literature search identified around thirty prospective and retrospective studies that evaluated the accuracy of PCT in identifying the site of occlusion and characterizing the infarct. PCT with or without noncontrast CT (NCCT) was compared with MRI, CT angiography, or follow-up NCCT. All studies were small with population sizes ranging from 22 to 44, except for one retrospective study that included 132 patients and evaluated both the accuracy and prognostic value of PCT compared to other CT imaging modalities. The studies presented the results in sensitivity and specificity, or just correlated the findings with those of MRI. Few small studies with sample sizes ranging from 19 to 44 patients, evaluated the accuracy of PCT in predicting prognosis of ischemic stroke. Predicting prognosis was based on comparison with delayed perfusion MRI, follow-up CT, or monitoring the evolution of each patient's clinical condition. The majority of the studies were retrospective, used earlier generations of multislice CT scanners with limited spatial coverage, and no adjustments were made for the potential confounding factors. 2. Impact of PCT in management decisions and patient outcomes: The literature search did not reveal any randomized controlled trials that examined the impact of perfusion CT on the management of ischemic stroke patients and /or clinical outcomes. There was one small case-control study that investigated whether the lesion volume on PCT maps within 3 hours of onset of symptoms would predict final infarct volume, and the effect of intravenous tPA on affected brain tissue. The study however, had several limitations and used the 8-section multidetector scanner. The following three studies on the accuracy of PCT in characterizing the cerebral infarct were selected for critical appraisal: Murphy BD, Fox AJ, Lee DH, et al. Identification of penumbra and infarct in acute ischemic stroke using computed tomography perfusion-derived blood flow and blood volume measurements. *Stroke* 2006;37:1771-1777. See [Evidence Table](#). Tan JC, Dillon WP, Liu S, et al. Systematic comparison of perfusion-CT and CT-angiography in acute stroke patients. *Ann Neuro*. 2007;61:533-543. See [Evidence Table](#). Shramm P, Schellinger PD, Klotz E, et al. Comparison of perfusion computed tomography and computed tomography angiography source images with perfusion-weighted imaging and diffusion-weighted imaging in patients with acute stroke of less than 6 hours duration. *Stroke* 2004;35:1652-1658. See [Evidence Table](#).

The use of Perfusion computed tomography (PCT) for the treatment of acute stroke does not meet the *Group Health Medical Technology Assessment Criteria*.

	2) The purpose of the scan is to determine likelihood of malignancy in order to plan management of care

### **Oncological Diagnosis Confirmed**

For patients with a biopsy proven or confirmed oncologic diagnosis (typically biopsy proven), PET scans may be medically necessary for any of the listed diagnoses below when standard staging/restaging diagnostic and imaging studies are inconclusive AND further characterization is needed to make management decisions. The expected change in clinical management must be documented in the clinical records. The grid below contains the letters TNM. T is for tumor and the number associated describes the tumor. N is for lymph node involvement. M is for extent of metastasis.

<b>Oncological Diagnosis</b>	<b>Indications</b>
<b>Anal</b>	1) New diagnosis – consider PET scan for staging of T3 – T4, N0; or with any T, node positive
<b>Breast Cancer</b>	1) Stage I, II: PET scan is not recommended 2) Stage III A or B: PET scan is not recommended for operable stage III. May be helpful in non operable stage III if equivocal findings on CT and bone scans 3) Stage IV: PET not routinely covered but may be indicated if conventional imaging is equivocal and results will change management 4) The following indications are not covered for PET scans <ol style="list-style-type: none"> <li>Routine surveillance</li> <li>Initial diagnosis of breast cancer and the staging of axillary lymph nodes</li> </ol>
<b>Cervical</b>	<u>Staging for Invasive Cervical Cancer as an Adjunct to Conventional Imaging:</u> An FDG PET scan is reasonable and necessary for the detection of metastases during the pre-treatment management phase (i.e., staging) in patients with newly diagnosed locally advanced cervical cancer with no extra-pelvic metastasis on conventional imaging tests, such as computed tomography (CT) or magnetic resonance imaging (MRI). Use of FDG PET as an adjunct may more accurately assist in the non-invasive detection of para-aortic, pelvic nodal involvement and other metastases in the pre-treatment phase of disease. The following conditions must be met: <ol style="list-style-type: none"> <li>If stage is less than or equal to IB1: PET not routinely recommended</li> <li>If stage is IB2 or greater: CT, PET scan or MRI as clinically indicated</li> </ol>
<b>Colorectal Cancer</b>	1) Initial staging Colon cancer appropriate for resection: Not routinely indicated and should not supplant contrast-enhanced CT. <ol style="list-style-type: none"> <li>PET may be indicated for metastatic adeno carcinoma of the large bowel when there is potentially surgically curable metastatic disease</li> </ol> 2) Restaging <ol style="list-style-type: none"> <li>When the post-operative carcinoembryonic antigen (CEA) or liver function tests (LFTs) remain elevated and other attempts at imaging are negative OR</li> <li>Evaluation of a potentially resectable metastatic lesion in order to confirm that it is resectable and to confirm absence of other sites of disease OR</li> <li>Differentiating local tumor recurrence from post-operative and/or post-radiation scarring</li> </ol> 3) Surveillance: not recommended 4) Monitoring therapy progress is not indicated
<b>Esophageal</b>	For staging and restaging <ol style="list-style-type: none"> <li>If no evidence of metastatic disease on chest/abdominal CT and</li> <li>Individual is a candidate for aggressive therapy</li> </ol>
<b>Gastric/GE Junction</b>	For staging and restaging (not necessary for T1 patients) <ol style="list-style-type: none"> <li>If no evidence of metastatic disease on chest/abdominal CT and</li> </ol>

Oncological Diagnosis	Indications
	2) Individual is a candidate for aggressive therapy
<b>Head and Neck Cancers</b>	<ol style="list-style-type: none"> <li>1) Staging indicated for: <ol style="list-style-type: none"> <li>a) Stage III-IV disease of oral cavity, oropharynx, glottic larynx and supraglottic larynx, hypopharynx, ethmoid sinus</li> <li>b) Nasopharynx: Imaging optional for evaluation of distant metastases (i.e. chest, liver, bone) for stage III-IV disease</li> <li>c) Maxillary sinus: Consult medical director</li> </ol> </li> <li>2) Restaging (only for stage III – IV cancers) <ol style="list-style-type: none"> <li>a) Post-treatment evaluation of cancers of head and neck ( minimum 12 weeks after radiation completed). If the study is negative, repeat PET not indicated for surveillance.</li> </ol> </li> <li>3) Lip: No PET is indicated</li> <li>4) Salivary: No PET is indicated; CT &amp; MRI as needed</li> </ol> <p><b>For thyroid see below.</b></p>
<b>Lung Cancer – Non-small cell</b>	<ol style="list-style-type: none"> <li>1) A positive PET scan finding can be caused by infection or inflammation, including absence of lung cancer with localized infection, presence of lung cancer with associated infection, and presence of lung cancer with related inflammation. A false negative PET scan can be caused by a small nodule, low cellular density, or low tumor activity for FDG. Serial PET scans are not recommended to follow response to therapy; conventional imaging is preferred. No need for bone scan if PET scan already done.</li> <li>2) Initial staging: Indicated for stages I-III A or B when active treatment is planned. Not typically recommended for known stage IV. Documentation must show how results will alter treatment for stage IV treatment</li> <li>3) Radiation planning in patients with significant atelectasis, IV contrast is contraindicated and when improved targeted is sought. ( if meets criteria 1 above)</li> </ol> <p><a href="#">See Solitary Pulmonary Nodule Above</a></p>
<b>Lung Cancer – Small Cell</b>  <b>Recommended clinical trials only</b>	<ol style="list-style-type: none"> <li>1) Initial staging small cell lung cancer (SCLC) when it has been determined to be of limited-stage (i.e. limited to the ipsilateral hemithorax and regional lymph nodes) after standard staging evaluation AND patient is a potential surgical candidate or for a combined modality approach with radiation and chemotherapy</li> <li>2) Restaging – not recommended for routine follow-up after initial therapy</li> </ol> <p><a href="#">See Solitary Pulmonary Nodule Above</a></p>
<b>Hodgkin Disease Lymphoma</b>	<ol style="list-style-type: none"> <li>1) Initial staging <ol style="list-style-type: none"> <li>a) Essential during initial work-up</li> </ol> </li> <li>2) Early/interim re-staging <ol style="list-style-type: none"> <li>a) Prognostic value is seen with a PET after 2-4 cycles of standard dose chemotherapy, if change in treatment is anticipated</li> </ol> </li> <li>3) Restaging <ol style="list-style-type: none"> <li>a) After completion of chemotherapy to assess treatment response and characterize residual mass at the end of treatment OR</li> <li>b) after radiation completion, typically at 3 months</li> </ol> </li> <li>4) Surveillance is not recommended due to risk of false positives</li> <li>5) Pet Scan – field determination for radiation therapy planning</li> </ol>
<b>Melanoma</b>	<ol style="list-style-type: none"> <li>1) Stage I &amp; II not for routine staging, only to evaluate specific signs or symptoms (CT, MRI also options)</li> <li>2) Stage III or IV; recommended for baseline staging and/or to address specific signs and symptoms (CT, MRI also options)</li> </ol>
<b>Multiple Myeloma</b>	<ol style="list-style-type: none"> <li>1) Skeletal survey with plain films is initial imaging of choice</li> <li>2) Staging and restaging if standard imaging and lab tests cannot define extent of disease and results will change management</li> </ol>
<b>Non-Hodgkin's Lymphoma</b>	<p><u>Low grade lymphoma</u>: PET scan may be indicated for Stage I &amp; II but not routinely for Stage III and IV unless management would be changed</p> <p><a href="#">See Lymphoma Grade Table below</a></p> <p><u>Intermediate &amp; High Grade Lymphoma</u>: PET scan is indicated for restaging</p>

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Oncological Diagnosis	Indications
	<p>after completion of therapy (chemotherapy or radiation); not for surveillance  <a href="#">See Lymphoma Grade Table below</a></p> <ol style="list-style-type: none"> <li>1) Diffuse large B-cell lymphoma (intermediate)               <ol style="list-style-type: none"> <li>a) Initial staging is essential</li> <li>b) Restaging                   <ol style="list-style-type: none"> <li>i) at completion of treatment ( wait 8 weeks minimum)</li> </ol> </li> <li>c) Early/interim restaging following 2-4 cycles of chemotherapy is controversial and should be done only if a planned change in management is documented. Biopsy of PET positive sites should be considered</li> </ol> </li> <li>2) AIDS-related B-cell lymphoma               <ol style="list-style-type: none"> <li>a) Initial staging is essential</li> </ol> </li> <li>3) Peripheral T-cell Lymphoma               <ol style="list-style-type: none"> <li>a) Initial staging is essential</li> <li>b) Interim restaging for all ALCL and ALK+                   <ol style="list-style-type: none"> <li>i) Repeat studies for all positive studies</li> </ol> </li> <li>c) Restaging                   <ol style="list-style-type: none"> <li>i) at completion of treatment</li> <li>ii) Repeat studies for all positive studies</li> </ol> </li> </ol> </li> <li>4) Extranodal NK/T-cell lymphoma nasal type               <ol style="list-style-type: none"> <li>a) Initial staging is essential</li> <li>b) Post-radiation therapy the role remains uncertain</li> </ol> </li> <li>5) Pet Scan – field determination for radiation therapy planning</li> </ol>
<b>Occult Primary</b>	<ol style="list-style-type: none"> <li>1) Not routinely recommended. Documentation must clearly identify the clinical reason for such testing.</li> </ol>
<b>Ovarian</b>	<ol style="list-style-type: none"> <li>1) PET scan not routinely indicated for initial staging</li> <li>2) Restaging: may be covered if conventional imaging (CT, MRI) give indeterminate results and PET will alter management</li> <li>3) May be approved if there is a solitary lymph node that is a possible candidate for surgical resection</li> </ol>
<b>Prostate</b>	<ol style="list-style-type: none"> <li>1) Use is unproven and should be provided within a clinical trial setting</li> </ol>
<b>Soft Tissue Sarcoma</b>	<ol style="list-style-type: none"> <li>1) Not routinely recommended</li> <li>2) Baseline staging, for cases when grade is uncertain or when conventional imaging has not conclusively evaluated the possibility of distant metastasis</li> <li>3) Differentiation of suspected tumor from radiation or surgical fibrosis</li> </ol>
<b>Thyroid</b>	<ol style="list-style-type: none"> <li>1) Localization to plan treatment for papillary or follicular thyroid carcinoma with the following:               <ol style="list-style-type: none"> <li>a) Previously treated with thyroidectomy and radioiodine ablation AND</li> <li>b) Thyroid Globulin (TG-antibody) positive (stimulated or on suppression) greater than 10 AND</li> <li>c) Negative structural imaging i.e. ultrasound and CT negative</li> </ol> </li> <li>2) Initial staging OR follow-up for localization to monitor response to prior treatment (surgery, I131, radiation therapy, or tyrosine kinase inhibitor), for treatment planning or to predict prognosis for the following:               <ol style="list-style-type: none"> <li>a) Aggressive tumors confirmed by histology (Hurthle cell, poorly differentiated, anaplastic) OR</li> <li>b) Aggressive behavior i.e. any tumor with confirmed metastasis showing progression on structural imaging or by rising TG level despite prior treatment</li> </ol> </li> </ol>
<b>All other cancers not listed above</b>	<ol style="list-style-type: none"> <li>1) Evaluated on a case by case basis, in conjunction with consultants and national guidelines</li> </ol>

### [Positron Emission Mammography \(PEM\)](#)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Positron Emission Tomography has been studied over the past few years at the University of Washington as well as other academic centers. The efficacy of this scan is still being evaluated. Because medical staff members have asked to have this study covered for cancer detection, a criteria set for medical necessity has been developed which involves review by the Medical Director of the radiology department and maintenance of a request log with determination outcomes.

Positron emission tomography (PET) also known as positron emission transverse tomography (PETT), or positron emission coincident imaging (PECI), is a noninvasive imaging procedure that assesses perfusion and the level of metabolic activity in various organ systems of the human body. A positron camera (tomograph) is used to produce cross-sectional tomographic images by detecting radioactivity from a radioactive tracer substance (radiopharmaceutical) that is injected into the patient.

Positron Emission Tomography (PET) is a non-invasive nuclear medicine scanning technique that provides unique diagnostic information that cannot be obtained by other imaging modalities. While CT and MRI provide detailed images of the patient's anatomy; PET scanning reveals vital information concerning cellular function. This functional information can be critical in the evaluation of a variety of common and serious diseases. PET has shown utility in the management of a wide range of malignancies including lung cancer, colon cancer, lymphoma and melanoma. PET scanning also plays an important role in the evaluation of certain neurologic and cardiac diseases and the applications of this unique imaging modality continue to expand.

Recent developments in the field of PET scanning are certain to lead to a rapid expansion in the utilization of this powerful technique. There have been improvements in the resolution of the cameras allowing for higher diagnostic yield. Reimbursement issues are being worked out and HCFA has approved payment for several indications in the area of oncology. Additional indications may be approved in the near future. The problems surrounding the delivery of the radioisotopes are also being solved. This is particularly true for the Puget Sound area where a production facility (cyclotron) has recently been built in Kent.

Several careful studies have shown that there is a cost benefit associated with PET. In many cases PET will reveal findings not identified by CT or MRI, resulting in a more appropriate and timely diagnostic evaluation. Costs for unnecessary procedures are avoided. This results in an overall cost saving, despite the initial cost of performing the PET study.

Interest in PET scanning continues to grow rapidly in both the national and local medical community. Several local hospitals already have PET capability and the number of facilities offering this important diagnostic capability is certain to expand quickly. Many facilities are beginning their PET program by utilizing a mobile service. There are a number of mobile PET companies that are already providing or will soon be providing service to our area. This approach would allow for a minimal initial investment with low risk and could provide the opportunity to provide PET scanning at a number of different GH facilities on a rotating basis. In the future, depending on patient volume, consideration may be given to installing a permanent facility.

## Medical Technology Assessment Committee (MTAC)

### ***Alzheimer's Disease and Dementia***

#### BACKGROUND

Dementia is a general decline in multiple cognitive abilities including language, memory, and logical thinking. It is a common disorder in the elderly, and has many potential causes. Alzheimer's disease (AD), a degenerative neurological condition, is the most common form of dementia in the elderly and accounts for approximately two thirds the cases in the USA. Other causes of dementia include vascular dementia, dementia with Lewy bodies, dementia due to Parkinson's disease, frontotemporal dementia and others. These have to be considered in the differential diagnosis and ruled out before a diagnosis of AD is made. Alzheimer's disease is mainly characterized by progressive memory impairment and other cognitive dysfunctions that can interfere with the patient's normal daily activities and social life. Its onset is gradual and involves continuing cognitive decline. The milder forms are classified as "possible" and the more advanced forms as "probable" AD. The standard evaluation of dementia and potential AD is extensive and include medical and psychiatric history, physical examination, neuropsychologic mental status testing, lab tests and structural imaging. MRI and CT scans are used to detect structural changes late in the disease, and in ruling out tumors or other abnormalities in the brain that may cause dementia symptoms. Early and accurate diagnosis of dementia has become of greater concern lately because of the availability of more effective drug therapies to treat the symptoms of the disease. These medications would have a greater impact when used in the earlier stages of the disease (Silverman 1999). The most widely used diagnostic criteria for dementia in North America are based on definitions in the National Institute of Neurological and Communicative Disorders and Stroke-Alzheimer's Disease and related Disorders Association (NINCDS-ADRDA) Work Group. Diagnostic criteria for AD have also been grouped by the American Psychiatric Association in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV). The clinical evaluation based on these criteria is relatively accurate in ruling out dementia due to causes other than AD, and in identifying probable AD when the level of dementia is moderate to severe. The clinical criteria that define AD are not the ideal gold standard because the clinical diagnosis does not always conform with the pathological diagnosis. The perfect gold standard

for the definitive diagnosis of AD or other specific forms of dementia is the histopathological examination of brain tissue, which is very rarely done during the patient's lifetime. Specific histopathologic findings of AD include gliosis, plaques, tangle formation, and neuronal loss (Hoffman 2000). Numerous studies have found that Alzheimer's disease and other neurodegenerative diseases could produce significant alterations in brain metabolism. AD was found to be associated with focal reduction of the cerebral metabolic rate of glucose (CMR-G1c) mainly in the temporoparietal, and frontolateral regions of the brain. Bilateral temporoparietal hypometabolism were found to be the characteristic patterns seen in AD but are not specific to it. Gamma camera imaging and single photon emission computed tomography (SPECT) have been used to measure the cerebral blood flow in the brain. However, they may not be very effective in identifying localized metabolic defects. Positron emission tomography (PET) is another technique proposed as a means for the diagnosis of dementia. PET is a functional nuclear imaging modality that uses biochemical rather than structural information to produce images. It involves using positron-emitting radioisotopes to generate radioactivity. The levels of radioactivity originating from a given point are recorded using certain camera-like devices. Different radiopharmaceuticals can be used in PET imaging. The most commonly used in brain imaging is  $^{18}\text{F}$ -fluorodeoxyglucose (FDG) which has the ability to compete with glucose for absorption and metabolism in a variety of cell types, including neurons. In AD and some other forms of dementias the ability of the cells to take up glucose and FDG is impaired. Theoretically, FDG PET may help in the early diagnosis of AD and other forms of dementia by highlighting these regions of decreased FDG uptake before any structural damage can be detected by MRI or CT scans. FDG PET is usually done under resting conditions, but can be also performed under activation conditions to study the extent of neuronal stimulation. Brain PET scans can be interpreted by visual, quantitative and semi quantitative methods. The visual method, the most commonly used, greatly depends on the observer's experience, and lacks a clear cutoff between normal and pathological findings. PET scanners are approved by the Food and Drug Administration (FDA) for general use. The FDA does not approve imaging devices as PET scanners for specific indications. FDG PET is FDA approved for evaluating seizures, and was determined to be safe and effective in detecting malignancy. However, to date no PET radiotracers have been approved by the FDA for evaluating AD or other forms of dementia.

#### **04/09/2003: MTAC REVIEW**

##### **Alzheimer's Disease and Dementia**

**Evidence Conclusion:** There is insufficient evidence to allow us to draw conclusions about the value of PET in the diagnosis of AD and non-AD dementias, or in the assessment of treatment response. There was also no evidence on the impact of PET on the disease management and clinical outcome for patients with AD. The review focused on the use of FDG PET in the diagnosis of Alzheimer's disease. It also focused on studies with histopathological confirmation, which provides a definitive diagnosis of AD because many forms of dementia have overlapping clinical presentations. The two studies reviewed had this advantage of histopathologic confirmation, but each had some validity threats that limit generalization of their results. Both studies were conducted among selected groups of patients who do not generally represent those who undergo dementia evaluation. In addition, neither study evaluated the impact of PET scanning on the disease management or the health outcome of the patients. Among the other limitations of the studies, is the small sample size in Hoffman's study, and the inclusion of two different cohorts with different protocols in Silverman's study. In these studies, Hoffman et al reported that FDG PET scans had a sensitivity of 92.9% and 87.5% in diagnosing AD alone, or with concurrent non AD dementias, and a specificity of only 62.2% and 66.7% respectively. Silverman reported a similar sensitivity of 93.8%, but a higher specificity of 73.2% for patient with neuropathologic confirmation of their AD diagnosis. In conclusion, the available studies do not provide sufficient evidence to support the addition of PET to the standard clinical evaluation of patients with Alzheimer's disease/dementia, and further prospective studies are needed to establish its diagnostic and prognostic values. An ideal study would include a large representative sample of patients, who would be followed up from the development of symptoms until death when histopathologic confirmation can be made. Ideally also the patients would be randomly assigned to different management groups to assess the value of PET scanning on the outcome of the disease.

**Articles:** *Diagnosis of Alzheimer's disease dementias:* The search revealed 24 studies. All were prospective with the exception of 2 studies. The inclusion/exclusion criteria were not specific in all of the studies, and the blinding of PET interpreters was not always discussed. In 22 of these studies clinical evaluation was the gold standard, and in only 2 studies FDG PET performance was compared to histopathological findings. The use of clinical criteria for the diagnosis of AD does not give an accurate assessment of sensitivity and specificity of PET, and the true accuracy of the test needs histopathologic confirmation. The following two studies with pathological confirmation were selected for critical appraisal: Hoffman JM, Welsh-Bohmer KA, Hanson M, et al. FDG PET in patients with pathologically verified dementia. *J Nucl Med* 2000;41:1920-1928. See [Evidence Table](#). Silverman DH, Small GW, Chang CY, et al. Positron Emission Tomography in Evaluation of Dementia. *JAMA* 2001;286:2120-2127. See [Evidence Table](#). *Diagnosis of non- Alzheimer's disease dementias:* The search revealed 7 studies on the diagnosis of vascular dementia, dementia with Lewy bodies, or frontotemporal dementia using FDG PET. All studies had very small sample sizes (7 to 21 patients), and various methodological issues including nonblinding of PET interpreters, nonspecific inclusion/exclusion criteria, and lack of histological confirmation of the diagnosis.

None was selected for critical appraisal. *Assessment of AD treatment response:* The search revealed 5 studies evaluating the role of FDG PET in assessing the treatment response. All had very small sample sizes (10 to 30 patients), and various methodological issues including nonblinding of PET interpreters, nonspecific inclusion/exclusion criteria, and lack of histological confirmation of the diagnosis. Two of these studies were conducted to evaluate the effect of passive audiovisual stimulation on the cerebral metabolic response, and another to study the effect of a therapeutic agent (propentofylline) in enhancing the metabolic response to auditory memory stimulation. None of these studies was selected for critical appraisal.

The use of FDG PET in the evaluation of Alzheimer’s Disease or Dementia does not meet the *Group Health Medical Technology Assessment Criteria*.

**12/20/2010: MTAC REVIEW**

**Alzheimer’s Disease and Dementia**

**Evidence Conclusion:** The first retrospective cohort study included 45 patients with dementia and assessed whether the addition of FDG-PET to clinical history and examination improves accuracy in distinguishing frontotemporal dementia (FTD) and Alzheimer’s disease (AD). Findings from this study suggest that the addition of FDG-PET to clinical diagnosis improves diagnostic accuracy, sensitivity, and specificity in distinguishing FTD from AD. However, because of the characteristics of this analysis (results were reviewed by six experts who were aware that the entire population had dementia) the result of this study may not be applicable to clinical practice. Additionally, the effect on disease management and health outcomes cannot be determined from this study (Foster 2007).

	Diagnostic accuracy, sensitivity, and specificity	
	Clinical scenario	Clinical scenario + FDG-PET
	Mean (95% CI)	
Accuracy Alzheimer’s disease	78.8% (73-87)	89.2% (87-91)
Sensitivity	86% (74-100)	97.6% (94-100)
Specificity	63% (36-79)	73.2% (57-82)

The second retrospective cohort study included 44 patients with and without dementia and evaluated the potential ability of both clinical and imaging diagnoses to detect AD. The results of this study suggest that the addition of FDG-PET to the initial clinical diagnosis of AD increased the sensitivity and specificity of the diagnosis; however, it is unknown whether these results will translate into clinical practice as two reviews rated each PET scan and the diagnosis of AD was determined at a multidisciplinary conference after review of all clinical data. Additionally, confidence intervals were not reported and there was a delay between initial examination and PET examination. PET imaging was performed an average of 1.3 years after initial examination (Jagust 2007).

	Sensitivity and specificity	
	Initial	Initial + PET
Sensitivity	76%	84%
Specificity	58%	74%

**Conclusion:**

There is insufficient information to determine whether the addition of FDG-PET to clinical diagnosis will lead to a more accurate diagnosis of AD.

**Articles:** Several articles were identified that evaluated whether the addition of a FDG-PET scan to clinical diagnosis would lead to a more accurate diagnosis of AD. The majority of these studies compared the addition of FDG-PET to a clinical diagnosis, which may be inaccurate and therefore not an ideal gold standard. Two small retrospective cohort studies that compared the addition of FDG-PET to a clinical diagnosis to a postmortem pathologic diagnosis of AD were selected for review. The following studies were critically appraised: Foster NL, Heidebrink JL, Clark CM, et al. FDG-PET improves accuracy in distinguishing frontotemporal dementia and Alzheimer’s disease. *Brain* 2007; 130:2616-2635. See [Evidence Table](#). Jagust W, Reed B, Mungas D, et al. What does fluorodeoxyglucose PET imaging add to a clinical diagnosis of dementia? *Neurology* 2007; 69:871-877. See [Evidence Table](#)

The use of FDG PET in the evaluation of Alzheimer’s Disease or Dementia does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Breast Cancer: Diagnosis, Staging and Restaging**

### BACKGROUND

Positron emission tomography (PET) with  $^{18}\text{F}$ -fluorodeoxyglucose (FDG) has the potential for demonstrating tumor metabolic activity before structural changes can be shown by other methods such as computed tomographic (CT) imaging. FDG is a biological tracer that allows the evaluation of glucose metabolism. Tumor cells have increased glucose metabolism compared to benign cells and PET imaging with FDG takes advantage of this metabolic difference. Elevated uptake of FDG has been shown in several types of malignant primary tumors. FDG PET is potentially useful for diagnosis, staging and restaging of breast cancer. Diagnosis: While mammography remains the main imaging technique for screening breast lesions, it may be nondiagnostic in women with dense breasts and fibrocystic disease. Staging: Detection of tumor-involved lymph nodes is important. If PET can accurately detect axillary node involvement, patients may be able to avoid surgical morbidity from axillary dissection. Restaging: Another potential use of PET is to detect metastatic breast cancer outside of the breast and axillary nodal basins. This can help identify patients who are most likely to benefit from chemotherapy or radiation therapy. Monitoring response to chemotherapy: The response to chemotherapy could be monitored by PET because FDG uptake may decrease more in tumors that respond to chemotherapy than those that do not respond (Hoh & Schiepers, 1999).

### **06/07/2001: MTAC REVIEW**

#### **Breast Cancer: Diagnosis, Staging and Restaging**

Evidence Conclusion: Diagnosis - The one study reviewed, Avril, found that FDG PET was insufficiently sensitive and specific at diagnosing breast tumors. Using the more conservative image interpretation, the negative predictive value was only 61%. This was a reasonably well-done study with a sample size of 144.

Staging (staging of axilla) - The three studies had sensitivities varying from 79-90% and specificities varying from 91-97%. FDG PET seemed to perform better than clinical examination. False-negative results do occur with FDG PET.

Restaging - The one study reviewed (Moon) suggests that FDG PET may not have sufficiently high sensitivity and specificity to forgo biopsy. This was a reasonably well-done study with n=57 patients. Replication of this study and comparisons with other diagnostic tests would provide stronger evidence about whether or not FDG PET and other non-invasive procedures can be used to restage breast cancer. Monitoring response to chemotherapy - The Smith study, which had a small sample size, found that primary breast cancers that improved clinically had a greater reduction in the rate of FDG uptake after one pulse of chemotherapy than cancers that did not respond to chemotherapy. As the authors conclude, these findings need to be replicated in larger studies with strong methodologies. In addition, more work needs to be done on determining the appropriate amount in decrease of FDG uptake to indicate a clinical response to chemotherapy.

Articles: The search yielded 120 articles. Articles that were opinion pieces, basic science, dealt with technical aspects of the FDG PET procedure or had very small numbers of patients (i.e. <30) were excluded. Articles on diagnosis, staging and restaging were considered separately. There was one empirical study on the use of FDG PET for initial diagnosis of breast cancer. Four articles were identified on the use of PET for staging of the axilla. One of these did not have well described methodology and results; a summary evidence table was created for the other three articles which were similar methodologically. One article focused on the use of FDG PET for restaging breast cancer (detecting recurrent or metastatic disease). There were two articles that addressed the use of FDG PET for monitoring patients' response to chemotherapy. The study with the stronger methodology was reviewed. Evidence tables were created for: Diagnosis: Avril N, Rose M, Schelling J, Dose W, Kuhn S, Weber W. et al. Breast imaging with Positron Emission Tomography and fluorine-18 fluorodeoxyglucose: Use and limitations. J Clin Oncol 2000; 18: 3495-3502. See [Evidence Table](#). Staging: Smith IC, Ogston KN, Whitford P, Smith FW, Sharp P, Norton M et al. Staging of the axilla in breast cancer: accurate in vivo assessment using positron emission tomography with 2-(fluorine-18)-fluoro-2-deoxy-d-glucose. Ann Surg 1998; 228: 220-227. See [Evidence Table](#). Avril N, Dose J, Janicke F, Ziegler S, Romer W, Weber W et al. Assessment of axillary lymph node involvement in breast cancer patients with positron emission tomography using radiolabeled 2-(fluorine-18)-fluoro-2-deoxy-D-glucose. J Natl Cancer Inst 1996; 88: 1204-9. See [Evidence Table](#). Crippa F, Agresti R, Seregini E, Greco M, Pascali C, Bogni A et al. Prospective staging of fluorine-18-FDG PET in presurgical staging of the axilla in breast cancer. J Nucl Med 1998; 39: 4-8. See [Evidence Table](#). Restaging: Moon DS, Maddahi J, Silverman DHS, Glapsy JA, Phelps ME, Hoh CK. Accuracy of whole-body fluorine-18-FDG PET for the detection of recurrent or metastatic breast carcinoma. Positron emission tomography using 18-F-Fluorodeoxy-D-glucose to predict the pathologic response of breast cancer to primary chemotherapy. J Clin Oncol 2000; 18: 1676-1688. See [Evidence Table](#)

FDG PET for diagnosis, staging and restaging breast cancer did not pass the *Group Health Medical Technology Assessment Diagnostic Test Evaluation Criteria*.

## **Cervical Cancer, Staging and Re-Staging**

### **BACKGROUND**

Cervical cancer is the second most frequently diagnosed gynecological malignancy in women worldwide (Chung et al., 2006). An analysis by the Centers for Disease Control and Prevention (Saraiya et al., 2007) identified about 60,000 cases of incident cervical cancer in the United States between 1998 and 2002. Rates were substantially higher among African-American and Hispanic women than other groups. If detected early, there is a high rate of treatment success with initial cervical cancer. However, the prognosis for women with recurrent cervical cancer is poor. There are limited treatment options, and treatment is often of a palliative nature (Dreyer et al., 2005). There is no generally accepted surveillance approach to detect recurrence in women with a history of cervical cancer. 80-90% of patients with recurrence will have signs or symptoms of disease, leading to investigations to confirm the diagnosis. Biopsy is routinely performed in symptomatic patients to confirm diagnosis. CT and MRI scanning, anatomic imaging techniques, are commonly used for cervical cancer imaging. In particular, CT-scan-directed biopsy is believed to be useful for obtaining histological confirmation of recurrence. There are concerns, however, that these techniques may result in false-positives due to the inability to distinguish between tumor masses and masses of necrotic or scar tissue, and false-negatives due to the inability to identify small tumors (Dreyer et al., 2005; Havrilesky et al., 2005). Positron emission tomography (PET) with 18F-fluorodeoxyglucose (FDG) is proposed as an alternative to CT and MRI to confirm cervical cancer recurrence in symptomatic patients. In addition, it is proposed as a method for early detection of cervical cancer recurrence in asymptomatic women. Unlike CT and MRI, PET is a functional imaging method and examines cellular function. PET is commonly used with the biological tracer FDG, a glucose analog, which allows the evaluation of glucose metabolism. This is useful for detecting cancer since FDG is preferentially taken up by and retained within malignant cells. PET has shown utility in the management of a wide range of malignancies including lung cancer, colon cancer, lymphoma and melanoma.

### **08/04/2007: MTAC REVIEW**

#### **Cervical Cancer, Staging and Re-Staging**

**Evidence Conclusion:** Diagnostic accuracy - The best available evidence on diagnostic accuracy of PET for cervical cancer recurrence is from a meta-analysis of observational studies (Havrilesky et al., 2005). To be included in the meta-analysis, diagnostic accuracy studies needed to include a reference standard (histology or clinical follow-up) for all participants. The Havrilesky analysis is limited, however, because all of the available studies were observational, retrospective and with small sample sizes (most had fewer than 40 patients). A pooled analysis of 3 studies in patients with a clinical suspicion of recurrence found a pooled sensitivity for PET of 0.96 (0.87-0.99) and specificity of 0.81 (0.58-0.94). A pooled analysis of 2 studies in patients without a clinical suspicion of recurrence found a sensitivity of 0.92 (0.77-0.98) and specificity of 0.74 (0.69-0.90). There is insufficient evidence on the diagnostic accuracy of PET compared to CT or MRI. No studies were identified that compared the accuracy of these tests in women with a clinical suspicion of cervical cancer recurrence. Diagnostic impact - Three small studies addressed the diagnostic impact of PET (The Lai and Belhocine studies were discussed in the Havrilesky meta-analysis). The Lai and Yen studies were both conducted among women with biopsy-documented recurrent cervical cancer. The Belhocine study included women with a clinical suspicion of recurrence as well as a small number of women who were undergoing routine post-treatment surveillance. Lai et al. (2004) reported that 22 out of 40 patients with known cervical cancer recurrence had their treatment changed after PET imaging, 15 changed from curative to palliative care. In the Yen et al. (2005) study, 36 out of 55 patients had their treatment plans modified after PET, 9 had a change in curative therapy and 27 switched to palliative therapy. Belhocine et al. (2002) reported that PET findings "induced a treatment" in 24 of the 25 patients with confirmed recurrence, and that PET was "particularly contributive" to the treatment plans of the 13 patients with an equivocal or false-negative result in the routine protocol. The studies on diagnostic impact were all limited by small sample sizes, particularly for sub-group analysis. Moreover, none of the studies provided detailed descriptions of treatment decisions based on CT or MRI versus treatment decisions based on PET. In addition, in the Yen and Lai studies, PET images were fused with CT/MRI results for patients with positive findings, so decisions were based on the combination imaging, not PET alone. Therapeutic impact - There is insufficient evidence on therapeutic impact. None of the studies reported health outcomes in patients managed by PET to those managed without PET. The Lai study included a historical control group; none of the other studies identified had comparison groups. Compared to historical controls, the 15 patients who had undergone surgery for their initial cervical cancer had a better 2-year survival rate. There was no significant difference in survival in the 25 patients who received radiation for their initial cervical cancer compared to historical controls.

**Articles:** There was a meta-analysis of observational studies on the use of FDG-PET for managing cervical cancer (Havrilesky et al., 2005). The authors systematically searched the literature through April, 2003. The Havrilesky analysis was critically appraised, as well as two studies included in the meta-analysis that reported on changes in treatment plan after PET scans (Belhocine et al., 2002 and Lai et al., 2004). Two studies published after the Havrilesky meta-analysis were considered for review. One study (Chung et al., 2006) was ultimately

excluded because did not systematically select patients for scanning or evaluate the impact of PET findings on therapy. The other study (Yen et al., 2005) examined change in treatment following PET and was critically appraised. The studies that were critically appraised include:

Havrilesky LJ et al. FDG-PET for management of cervical and ovarian cancer. *Gynecol Oncol* 2005; 97: 183-191. See [Evidence Table](#). Lai G-H, Huang K-G, See L-C et al. Restaging of recurrent cervical carcinoma with dual-phase 18F fluoro-2-deoxy-d-glucose positron emission tomography. *Cancer* 2004; 100: 544-552. See [Evidence Table](#). Belhocine T, Thille A, Fridman V et al. Contribution of whole-body FDG PET imaging in the management of cervical cancer. *Gynecol Oncol* 2002; 87: 90-97. See [Evidence Table](#). Yen T-C, See L-C, Change T-C et al. Defining the priority of using FDG-PET for recurrent cervical cancer. *J of Nuclear Med* 2005; 45: 1632-1639. See [Evidence Table](#).

The use of FDG-PET in the diagnosis of cervical cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Colorectal Cancer, Staging and Re-Staging**

### **BACKGROUND**

Positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG) has the potential for demonstrating tumor metabolic activity before structural changes can be shown by other methods such as computed tomographic (CT) imaging. FDG is a biological tracer that allows the evaluation of glucose metabolism. Tumor cells have increased glucose metabolism compared to benign cells and PET imaging with FDG takes advantage of this metabolic difference. Elevated uptake of FDG has been shown in several types of malignant primary tumors. On March 12, 2000, the FDA published a notice in the Federal Register that expanded approval of FDG for new indications. The use of FDG PET for the diagnosis, staging and restaging of colorectal cancer is one of the newly approved indications. In particular, FDG PET may be potentially useful for distinguishing local recurrences from postoperative scarring, for detecting hepatic and extrahepatic metastases prior to any surgery/therapy and for assessing recurrent colorectal cancer when there are indicators other than rising carcinoembryonic (CEA) levels. For these uses, a high negative predictive value (NPV) (the proportion of people who test negative who actually do not have the disease) is desired.

### **05/30/2001: MTAC REVIEW**

#### **Colorectal Cancer, Staging and Re-Staging**

**Evidence Conclusion:** Diagnosing/ Primary staging: The evidence supporting the effectiveness FDG PET for primary staging of colorectal cancer in the absence of CT testing is weak. The strongest article (Abdel-Nabi et al.) was limited by the small sample size and the fact that assessors had access to CT information when they reviewed PET scans. Recurrence/Restaging: There is evidence to support the accuracy of FDG PET in identifying colorectal cancer recurrence and metastases. There were two reasonably well done comparison of diagnostic test studies (Staib, Imdahl), more recent than the meta-analysis. Study quality was defined as having a sample size >50 (ideally >100), prospective, blinded evaluation of FDG PET scans and use of an appropriate gold standard. Both studies found that PET performed well and was more accurate than CT. There is evidence from Staib that PET findings influence surgical decision-making (61% of patients in the study). The meta-analysis, which had weak methodology, found that there was a change in management for 29% of patients based on PET findings. However, there is no published evidence on the impact of FDG PET for colorectal cancer on health outcomes (e.g. survival).

**Articles:** The search yielded 63 articles. Articles on primary staging and diagnosis of colorectal cancer and colorectal cancer recurrence were examined separately. There were two articles. There were 7 empirical studies examining primary staging/diagnosis of colorectal cancer and 17 empirical studies examining staging of colorectal cancer recurrences. Most of the studies were case series on FDG PET findings or a comparison of diagnostic tests and had small sample sizes. There was 1 meta-analysis of colorectal cancer recurrence. The rest of the articles were reviews or opinion pieces, assessed non-clinical outcomes or concerned technical aspects of FDG PET usage. The meta-analysis and the case series studies with the strongest methodology and the largest sample sizes were evaluated in detail. Evidence tables were created for the following articles: Diagnosing/ Primary staging: Abdel-Nabi H, Doerr RJ, Lamonica DM, Cronin VR, Galantowicz PJ, Carbone GM, Spaulding MB. Staging of primary colorectal carcinomas with fluorine-18 fluorodeoxyglucose whole-body PET: Correlation with histopathologic and CT findings. *Radiology* 1998; 206: 755-760. See [Evidence Table](#). The use of FDG PET as a diagnostic tool for Colon cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Esophageal Cancer, Diagnosis, Staging and Re-Staging**

#### **BACKGROUND**

2 fluoro-2-deoxy-D-glucose (FDG) freely enters glycogen pathways; however, it gets trapped in these cycles, and significant intracellular accumulation occurs in cells with active glucose metabolism. Degeneration of this radioactive material can be detected by PET. Malignant tumor cells have increased glucose metabolism compared to benign cells. This increased glycolytic activity can be used to detect early-stage disease before any structural abnormality is evident. It can also help exclude the presence of malignant disease in an anatomically altered structure. Esophageal cancer is associated with unfavorable prognosis, and thus accurate determination of the tumor size, extent of local invasion, lymph node involvement, and distant metastases, provides valuable information for prognosis, assessment, and treatment selection. The standard noninvasive staging modalities are CT of the chest and abdomen for evaluating the local tumor extent, and detecting distant metastases, and endoscopic esophageal ultrasound (EUS) for the evaluation of tumor depth and locoregional LN staging in non-obstructing esophageal cancer. However, these techniques entirely depend on structural characteristics for diagnosis. This may cause limitations in diagnostic specificity (false positive findings in enlarged inflammatory LN) and sensitivity (false negative findings in non enlarged invaded LN). FDG PET has been reported to accumulate in 92% to 100% of esophageal cancers and is potentially useful for diagnosis, staging, and restaging.

#### **05/30/2001: MTAC REVIEW**

### **Esophageal Cancer, Diagnosis, Staging and Re-Staging**

**Evidence Conclusion:** Apparently, three of these studies, two on staging (Flamen and Lerut) and one on restaging (Flamen) of esophageal cancer were made by the same group, and published in different medical journals. These were reasonably well done studies, yet not without biases. The Luketich study had several threats to its validity. Diagnosing and staging: These studies showed that FDG PET is not an appropriate first line diagnostic procedure in the detection of esophageal cancer. It also did not solve the problem of accurate clinical staging. There was no relationship between the primary tumor standardized uptake value (SUV) and the depth of the tumor invasion (T classification). FDG PET, could not define the esophageal wall, or paraesophageal tissue, and was not helpful in detecting local invasion by the primary tumor. It over staged when it did not distinguish inflammatory from neoplastic nodes, and under-staged when it could not identify minimally involved nodes, or tumors. It also did not discriminate the primary tumor from peritumoral lymph nodes. However, FDG PET was more sensitive than CT scan in detecting distant nodes and occult organ metastases. It also had a higher specificity than CT and EUS combined, in detecting distant nodal metastases. It was recommended by Flamen et al, in their two studies, that the positive findings on a FDG PET scan must be interpreted cautiously and verified histologically or radiologically, before a patient is considered as having unresectable disease and denied a curative treatment. Restaging: There was only one study found that focussed on the utility of FDG PET for the diagnosis and staging of recurrent esophageal cancer. The Flamen study showed that FDG PET was highly sensitive in staging symptomatic recurrent esophageal cancer. However, its higher sensitivity was statistically insignificant compared to the other conventional diagnostic procedures. Moreover, the false positive uptake at inflammatory lesions offered a major problem. More studies are recommended to study the potential benefit of PET on earlier diagnosis of recurrent disease. Change in patient management: In two of these studies, Luketich (staging) and Flamen (re-staging), patient management was changed in 15% and 11% of cases respectively. The effect of changing the treatment course on the patient survival and quality of life was not studied.

**Articles:** The search yielded 22 articles. Articles on diagnosis and primary staging of esophageal cancer and cancer recurrence were examined separately. There were six empirical studies on diagnosis and primary staging of esophageal cancer, and only one study on esophageal cancer recurrence. Most of the articles were case series on FDG PET findings or a comparison of diagnostic tests and had small sample sizes. Some were reviews or opinion pieces. There was no meta-analysis done. The studies with the strongest methodology and larger sample sizes were evaluated in detail. Three of the stronger studies, Flamen (J Clin Oncol), Flamen (J Thorac Cardiovasc Surg), and Lerut, were made by the same group. The Luketich study, that had several threats to its validity, was included to add a different view. Evidence tables were created for the following studies:

Staging: Flamen P, Lerut A, Van Cutsem E, De Wever W, Peeters M, et al. Utility of Positron Emission Tomography for the Staging of Patients with Potentially Operable Esophageal Carcinoma. J Clin Oncol 2000; 18:3202-3210. [See Evidence Table](#) . Luketich JD, Friedman DM, Wiegel TL, Meehan MA, Et al. Evaluation of Distant Metastases in Esophageal Cancer: 100 Consecutive Positron Emission Tomography Scans. Ann Thorac Surg 1999; 68: 1133-7. [See Evidence Table](#) . Lerut T, Flamen P, Ectors N, Van Cutsem E, Peeters M, et al.

Histopathologic Validation of Lymph Node Staging with FDG-PET Scan in Cancer of the Esophagus and Gastroesophageal Junction. A Prospective Study Based on Primary Surgery with Extensive Lymphadenectomy. *Annals of Surgery* 2000; 232(6): 743-752. [See Evidence Table](#). Restaging: Flamen P, Lerut A, Van Cutsem E, Cambier JP, Et al. The Utility of Positron Emission Tomography for the Diagnosis and Staging of Recurrent Esophageal Cancer. *J Thorac Cardiovasc Surg* 2000; 120: 1085-92. [See Evidence Table](#).

The use of FDG PET As a diagnostic tool for Esophageal Cancer failed criterion 1 of the diagnostic modality evidence criteria for evaluating efficacy of the evidence for re-staging and passed all criteria for diagnosis.

### **18F Fluoro-Estradiol to Measure Estrogen Receptor Expression in Advanced Breast Cancer**

#### **BACKGROUND**

Estrogens are involved in the growth and development of both normal and cancerous breast tissues. The activity of estrogens in breast tissue is mediated by ligand-dependent transcription factors called estrogen receptors (ER). ER expression is generally categorized as ER-positive (ER+) and ER-negative (ER-). ER+ means that a significant number of cancer cells have receptors, generally 5-10% of cells. About 70% of invasive breast cancers are ER-positive. Higher ER expression has been found to be associated with an increased likelihood of response to endocrine therapy. (Murphy & Watson, 2006; Linden et al., 2006). Measurement of ER expression by biopsy at the time of primary diagnosis of breast cancer is standard care. However, it may be difficult to accurately measure ER expression in metastatic breast cancer because ER expression can be heterogeneous. That is, cells at one site may be ER+, while other sites may be ER-. In addition, ER expression may change over time. Recurrent breast cancer may have low ER expression even when the original primary tumor is ER+ (Murphy & Watson, 2006; Linden et al., 2006). 18F Fluoro-Estradiol PET (FES-PET) is proposed as an alternative to biopsy to assess ER expression in metastatic breast cancer. FES-PET for advanced breast cancer has not been previously reviewed by MTAC.

#### **12/04/2006: MTAC REVIEW**

### **18F Fluoro-Estradiol to Measure Estrogen Receptor Expression in Advanced Breast Cancer**

**Evidence Conclusion:** The evidence on accuracy of FES-PET for assessing ER expression in breast cancer tumors is insufficient due to the availability of only one small study on this topic. Mortimer et al., (1996) compared biopsy and FES-PET findings in 41 breast cancer patients. Out of 21 patients identified on biopsy to be ER+, FES-PET identified 16 (sensitivity=76%). All 20 patients identified on biopsy as ER- were also negative according to FES-PET (specificity=100%). In addition to the limited quantity of evidence, biopsy is an imperfect gold standard so when there is discordance between biopsy and FES-PET findings, it is not possible to conclusively determine which method identified the "true" ER status. There are preliminary data from another small study with 47 patients (Linden et al., 2006). This study found that quantitative but not qualitative analysis of FES-PET significantly predicted response to hormonal therapy among patients with ER+ breast tumors confirmed by immunochemical analysis. The Linden study was not designed to evaluate the diagnostic accuracy of FES-PET.

**Articles:** The ideal study would evaluate the ability of FES-PET to identify ER-positive tumors using biopsy as the best available gold standard. One study (Mortimer et al., 1996) was identified that included both FES-PET imaging and biopsy of breast cancer tumors, although the primary purpose of the study was to correlate ER status with response to systemic therapy, not diagnostic accuracy. One other study was identified (Linden et al., 2006) that evaluated the ability of FES-PET to predict response to hormonal therapy in patients with breast cancer; the second study was restricted to patients with tumors already known to be ER-positive. These two studies were critically appraised: Mortimer JE, Dehdashti F, Siegel BA et al. Positron emission tomography with (FDG and FES) in breast cancer: correlation with estrogen receptor status and response to systemic therapy. *Clin Cancer Res* 1996; 2: 933-939. [See Evidence Table](#). Linden HM, Stekhova SA, Link JM et al. Quantitative fluoroestradiol positron emission tomography imaging predicts response to endocrine treatment in breast cancer. *J Clin Oncol* 2006; 24: 2793-2799. [See Evidence Table](#).

The use of <sup>18</sup>F Fluoro-Estradiol PET (FES-PET) in the treatment of advanced breast cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Head and Neck Cancer, Diagnosis, Staging and Re-Staging**

#### **BACKGROUND**

Positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG) has the potential for demonstrating tumor metabolic activity before structural changes can be shown by other methods such as computed tomographic (CT) imaging. FDG is a biological tracer that allows the evaluation of glucose metabolism. Tumor cells have increased glucose metabolism compared to benign cells and PET imaging with FDG takes advantage of this metabolic differences. Elevated uptake of FDG has been shown in several types of malignant primary tumors.

With head and neck cancer, FDG PET can be used to identify lymph node involvement to stage newly diagnosed patients. Lymph node status is the principal prognostic factor affecting the survival of head and neck cancer patients. Another possible application of FDG PET in initial staging is identification of unknown sites of primary cancer in patients who present with cervical nodal disease. An unknown primary cancer site occurs for only 1-5% of patients (Chisin & Macapinlac), but this group presents special challenges in diagnosis and treatment. FDG PET could also be used to identify disease post-treatment residual disease or disease recurrence. Recurrent head and neck cancer is difficult to diagnose with conventional imaging techniques or clinical examination because of the anatomic changes, inflammation and scarring caused by surgery and radiotherapy.

#### **05/30/2001: MTAC REVIEW**

##### **Head and Neck Cancer, Diagnosis, Staging and Re-Staging**

**Evidence Conclusion:** Diagnosing and staging (including identifying lymph node metastases): There were two reasonably well-done prospective studies with sample sizes > 50 comparing FDG PET with other diagnostic modalities. Both showed FDG PET to have superior performance (higher sensitivity and specificity). Positive predictive value of FDG PET and CT varied considerably in the two studies. This provides some evidence about the effectiveness of FDG PET, although the variation in estimates across studies is concerning. Neither of the studies specifically discussed the ways in which FDG PET findings affect patient management. Restaging: Studies were not as strong methodologically as those for staging (e.g. had inconsistent use of a "gold standard"). In the Lapela study, FDG PET did not clearly perform better than CT (in one classification system, FDG PET had higher sensitivity and somewhat lower specificity; in the other classification system, FDG PET performed slightly better, statistical difference in performance is unknown). In the Lonneux study, FDG PET clearly performed better than CT plus MRI, but specificity was low. The available evidence does not permit clear conclusions about the effectiveness of FDG PET at detecting recurrence of head and neck cancer.

**Articles:** The search for the period 1997 through February 2001 yielded 83 articles. Articles that were opinion or discussion pieces or addressed technical aspects of FDG PET were excluded. There were 4 prospective comparisons of diagnostic test studies with sample sizes for diagnosis/staging and 1 for restaging. Evidence tables were created for the two staging articles with n>50 and with the strongest methodologies. An evidence table was created for the prospective restaging article and for a study of restaging where n=44 but that presented data on the impact of FDG PET on patient management. There are evidence tables for the following studies: Adams S, Baum RP, Stuckensen T, Bitter K, Hor G. Prospective comparison of 18F-FDG PET with conventional imaging modalities (CT, MRI, US) in lymph node staging of head and neck cancer. *Eur J Nucl Med* 1998; 25: 1255-1260. [See Evidence Table](#). Stokkel MPM, ten Broek F-W, Hordijk G-J, Kooke R, van Rijk PP. Preoperative evaluation of patients with primary head and neck cancer using dual-head 18-fluorodeoxyglucose positron emission tomography. *Ann Surg* 2000; 231: 229-234. [See Evidence Table](#). Lapela M, Eigved A, Jyrkkio S, Grenman R, Kurki T, Lindholm P. et al. Experience in qualitative and quantitative FDG PET in follow-up of patients with suspected recurrence from head and neck cancer. *Eur J Cancer* 2000; 36: 858-67. [See Evidence Table](#). Lonneux M, Lawson G, Ide C, Bausart R, Remacle M, Pauwels S. Positron emission tomography with fluorodeoxyglucose for suspected head and neck tumor recurrence in the symptomatic patient. *Laryngoscope* 2000; 110: 1493-97. [See Evidence Table](#).

The use of FDG PET As a diagnostic tool for head and neck cancers failed criterion 4 of the diagnostic modality evidence criteria for evaluating efficacy of the evidence.

##### **Melanoma, Staging and Re-Staging**

###### **BACKGROUND**

Positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG) has the potential for demonstrating tumor metabolic activity before structural changes can be shown by other methods such as computed tomographic (CT) imaging. FDG is a biological tracer that allows the evaluation of glucose metabolism. Tumor cells have increased glucose metabolism compared to benign cells and PET imaging with FDG takes advantage of this metabolic differences. Elevated uptake of FDG has been shown in several types of malignant primary tumors. A potential benefit of FDG PET for patient outcome is the ability to improve the selection of patients for surgery and other treatments. On March 12, 2000, the FDA published a notice in the Federal Register that expanded approval of FDG for new indications. One new indication was the use of FDG PET for the diagnosis, staging and restaging of melanoma. FDG PET is not covered for regional lymph node evaluation.

#### **05/30/2001: MTAC REVIEW**

##### **Melanoma, Staging and Re-Staging**

**Evidence Conclusion:** The evidence concerning the effectiveness of FDG PET for diagnosing, staging and restaging melanoma is inconclusive. The three best studies identified that examined the efficacy of FDG PET (excluding Wagner which looked only at regional lymph node basins) varied in their findings on sensitivity and specificity:

## PET (By lesion) Sensitivity Specificity

Schwimmer\* 92 87

Tyler (restaging) 87 43

Rinne (staging) 100 94

Rinne (restaging) 92 94

\*Unclear whether staging and/or restaging

In particular, Tyler found substantially lower specificity than the other studies. The Tyler study included patients with advanced melanoma (Stage III) whereas the Rinne study had at least some patients with less advanced disease. Possibly, effectiveness varies by stage of disease but this is not clear from the available evidence. Only the Rinne study compared FDG PET results with conventional imaging and found that PET had superior sensitivity and specificity. However, conventional diagnostics may not have been consistently performed. No study directly compared PET and CT. In addition, the Wagner study found that sentinel node biopsy was more effective than PET for regional lymph node metastases. FDG PET may be useful for some aspects of melanoma staging and not others. There is a deficiency of evidence on long-term patient outcome following FDG PET for melanoma and on any possible adverse effects.

**Articles:** The search yielded 37 articles. Many of the studies included mixed groups of patients (primary and recurrent melanoma). There was one meta-analysis and several case series or cross-sectional analyses of FDG PET. The rest of the articles were reviews or opinion pieces, assessed non-clinical outcomes or concerned technical aspects of FDG PET usage. Evidence tables were created for the meta-analysis (staging vs. restaging unclear) and the three evaluations of FDG PET with the strongest methodologies. These articles are: Restaging: Tyler DS, Onaitis M, Kherani A, Hata A, Nicholson E, Keogan M et al. Positron emission tomography scanning in malignant melanoma. *Cancer* 2000; 89: 1019-25. [See Evidence Table](#). Staging and restaging: Rinne D, Baum RP, Hor G, Kaufmann R. Primary staging and follow-up of high risk melanoma patients with whole-body 18f-fluorodeoxyglucose positron emission tomography. *Cancer* 1998; 82: 1664-71 [See Evidence Table](#). Wagner JD, Schuwecker D, Davidson D, Coleman JJ, Saxman S, Hutchins G, Love C, Hayes JT. Prospective study of fluorodeoxyglucose positron emission tomography imaging of lymph node basins in melanoma patients undergoing sentinel node biopsy. *J Clin Oncol* 1999; 17: 1508-15 [See Evidence Table](#). Staging/restaging not specified: Schwimmer J, Essner R, Patel A, Jahan A, Shephard JE, Park K et al. A review of the literature for whole-body FDG PET in the management of patients with melanoma. *Q J Nucl Med* 2000; 44: 153-67 [See Evidence Table](#).

The use of FDG PET As a diagnostic tool for Melanoma permits conclusions about the accuracy for diagnosing distant metastases. This excluded accuracy for diagnosing local disease and regional lymph node metastases.

## **Prostate Cancer, C-11 Acetate for Diagnosing Primary and Metastatic**

### BACKGROUND

Positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG) is used to identify tumors by their increased rates of glucose metabolism compared to benign cells. Prostate tumors grow slowly and have lower rates of glucose metabolism than other types of tumors. Thus, FDG PET is less useful for the diagnosis and monitoring of prostate cancers than for other cancers such as such as colorectal and head and neck cancer. Carbon-11 (C-11) acetate has been proposed as a more promising tracer for prostate tumor cells. C-11 has a short half-life, only about 20 minutes and the application of C-11 acetate PET is limited to sites that have an on-site medical cyclotron for radiotracer production. An on-site cyclotron is available at Group Health Cooperative.

### 02/13/2003: MTAC REVIEW

#### **Prostate Cancer, C-11 Acetate for Diagnosing Primary and Metastatic**

**Evidence Conclusion:** There is insufficient evidence to determine the ability of C-11 acetate PET to accurately diagnose or monitor prostate cancer. Only one study was identified that compared C-11 acetate PET to a gold standard (Kotzerke et al., 2002) and this study had too small a sample size for meaningful statistical analysis.

**Articles:** The search yielded 11 articles. All of the empirical studies had small sample sizes (fewer than 50 patients). One study (Kotzerke) compared C-11 acetate PET to a gold standard (transrectal ultrasound and biopsy). However, this study had only 31 patients and the authors did not calculate sensitivity and specificity or do any other statistical analysis due to the small number of patients evaluated. This study was not critically appraised because of its small sample size and lack of statistical analysis.

The use of C-11 Acetate PET in the evaluation of Primary and Metastatic Prostate Cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Refractory Seizures, Pre-Surgical Evaluation**

### BACKGROUND

Positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG) has the potential for identifying areas of seizure focus (epileptogenic region). FDG is a biological tracer that allows the evaluation of glucose metabolism and areas of seizure focus have decreased glucose metabolism (hypometabolism). For patients whose seizures are uncontrolled by medication, surgery may eliminate seizures or make them easier to control. Most patients who are surgical candidates have complex partial seizures of temporal lobe origin. The most common surgical procedure performed is an anterior temporal lobectomy which consists of resection of the lateral temporal neocortex and the mesiobasal temporal cortex. Invasive recording techniques are the most accurate way to localize the epileptogenic region but noninvasive tests are preferred. Possible noninvasive tests are surface EEG, MRI, ictal single photon emission computed tomography (SPECT) and FDG PET.

#### **05/30/2001: MTAC REVIEW**

##### **Refractory Seizures, Pre-Surgical Evaluation**

**Evidence Conclusion:** The studies evaluating FDG-PET for the presurgical evaluation of seizures tended to be small and have methodological flaws. Studies suggest that FDG-PET may be useful for presurgical evaluation, but larger, better-done studies need to be done.

**Articles:** The search yielded 101 studies. Articles that were opinion or discussion pieces, addressed technical aspects of FDG PET, only included children or did not address presurgical evaluation of seizures were excluded. Nine case series/evaluation of diagnostic test studies remained. Two were by the same research group. None of the studies had sample sizes > 50. The two studies with the strongest methodology were reviewed. Strong methodology was defined as including as many of the following elements as possible: prospective, relatively large sample size, comparative studies, quantified PET results, blinded interpretation of FDG PET, consecutive patients. Only one study (Theodore) was prospective, quantified PET results and included > 30 patients. Evidence tables were created for: Theodore WH, Sato S, Kufta CV, Gaillard WD, Kelly K. FDG-positron emission tomography and invasive EEG: Seizure focus detection and surgical outcome. *Epilepsia* 1997; 38: 81-86. (The more recent Theodore study). [See Evidence Table](#). Knowlton RC, Lazer KD, Ende G, Hawkins RA, Wong STC, Matson GB et al. Presurgical multimodality neuroimaging in electroencephalographic lateralized temporal lobe epilepsy. *Ann Neurol* 1997; 42: 829-37. [See Evidence Table](#).

The use of FDG PET As a diagnostic tool for Refractory Seizures failed criterion 2 of the diagnostic modality evidence criteria for evaluating efficacy of the evidence for pre-surgical evaluation.

#### **18 F-NaF PET for the Detection of Bone Metastases**

##### **BACKGROUND**

Bone metastases occur in 50% of oncologic patients, and in up to 70% of patients with breast and prostate cancer. These may result in significant morbidity including pain, pathological fractures, spinal cord compression, bone marrow suppression, and hypercalcemia. In the initial phase, metastatic lesions in the bone infiltrate the bone marrow disturbing the balance and enhancing osteolytic or osteoblastic processes. Fast-developing and aggressive metastases are usually lytic while the slow developing lesions are typically accompanied by osteoblastic processes. Prostate cancer predominantly demonstrates osteoblastic metastases, lung cancer predominantly demonstrates osteolytic metastases, and breast cancer often demonstrates osteolytic or mixed osteolytic and osteoblastic metastases (Cook 2010, Qu 2011, Tarnawska-Pierscinska 2011). Evaluation of metastatic bone lesions is crucial for determining the therapeutic plan and improving patient prognosis. Radionuclide whole-body bone scintigraphy (BS) using technetium-99m-labelled radiopharmaceuticals, such as methylene diphosphonate (99mTc MDP) tracers has been the standard modality used for the evaluation of skeletal malignancy for decades. It is widely available and has the ability of evaluating the entire skeleton within a reasonable amount of time, and at a relatively low cost. BS provides information on the presence, location, extent, and response to therapy of bone metastases. However, it identifies an increased turnover state associated with osteoblastic activity rather than proliferation of tumor cells, and therefore may be less sensitive in detecting early metastases, metastatic tumors that are small in size or confined to the bone marrow, osteolytic lesions, or lesions with minimal or no osteoblastic activity. Lytic lesions are visible by scintigraphy studies as "cold" areas that are difficult to interpret. BS may also lead to false positive findings in cases of osteoarthritis, healing fractures, and inflammation (Yen 2010, Cheng 2011, Chang 2012, Tarnawska-Pierscinska 2011). More recent improvements and developments of other non-invasive methods are increasingly being used for detecting bone metastases. These include multidetector computed tomography (CT), magnetic resonance imaging (MRI), SPECT/CT, and positron emission tomography (PET) with or without computed tomography (PET/CT). Each modality has its advantages and limitations, as well as imaging capability which could be morphologic, functional, or a combination of both. MRI and CT are anatomic imaging modalities that analyze tumor tissue based on their morphologic appearance; while 99mTc MDP bone scintigraphy and PET are functioning imaging modalities. Bone scintigraphy identifies bone metastasis by detecting the osteoblastic response to bone destruction by tumor cells and the accompanying increase in blood flow. 18F-FDG PET identifies viable tumors based on the higher glycolytic rates in the neoplasm than in normal tissue, and 18F-labeled sodium fluoride (18 F-NaF), a radiotracer used with PET

bone scans, has a skeletal uptake mechanism similar to that of  $^{99m}\text{Tc}$ , but clears from circulation faster as it does not bind to plasma proteins.  $^{18}\text{F}$ -NaF relies on the exchange of hydroxyl ions in the in the hydroxyapatite crystal and is an indicator of bone metabolic activity. The increased uptake of the tracer in malignant bone lesions reflects the increase in regional blood flow and bone turnover characterizing these lesions.  $^{18}\text{F}$ -NaF PET scans may identify lytic bone metastases that may not be detected by  $^{99m}\text{Tc}$  scintigraphy. The accumulation of fluoride however, is not tumor specific and it may be difficult to differentiate metastases from benign bone lesions such as degenerative diseases (Hetzl 2003, Evan-Sapir 2006, Cook 2010, Liu 2011, Tarnawska-Pierscinska 2012).  $^{18}\text{F}$ -NaF, introduced in the early 1960s, was the first radiopharmaceutical agent used for imaging bone lesions. It was initially used as a planar scintigraphy tracer and has the advantage of high and rapid bone uptake and very rapid blood clearance. It was abandoned however, with the introduction of  $^{99m}\text{Tc}$  in the 1970s, because the relatively high energy of the annihilation photons produced by the decay of  $^{18}\text{F}$  required the use of special scanners. More recently,  $^{18}\text{F}$ -NaF for bone imaging re-emerged with the introduction of PET and the availability of electronic generators that may allow its use. The interest in  $^{18}\text{F}$ -NaF was also increased due to the worldwide shortages of  $^{99m}\text{Tc}$ -MDP (Grant 2008, Chua 2009, Cook 2009, Yen 2010).

$^{18}\text{F}$ -NaF was cleared by the Food and Drug Administration (FDA) for clinical use in 1972. The approval was then withdrawn, and it is unclear whether it was re-approved.

### 10/15/2012: MTAC REVIEW

#### 18 F-NaF PET for the Detection of Bone Metastases

**Evidence Conclusion:** There is limited published evidence on the use of  $^{18}\text{F}$ -NaF PET for the detection of bone metastases. The majority of published studies were on the use of  $^{18}\text{F}$ -FDG PET and  $^{18}\text{F}$ -FDG PET/CT. The studies that evaluated  $^{18}\text{F}$ -NaF PET were small in size, more than half were retrospective in design, and the specific diagnosis was not reported in some and was a variety of carcinomas in others.  $^{18}\text{F}$ -NaF PET with or without CT was mainly compared with bone scintigraphy or FDG PET. No direct comparisons were made vs. MRI. In addition histopathological confirmation as a gold standard was performed in a small number of these studies and not for all participants in the studies. Tateishi and colleagues' meta-analysis as well as Lagaru et al's study show that  $^{18}\text{F}$ -NaF PET or  $^{18}\text{F}$ -NaF PET/CT, may be more sensitive, but with similar specificity to bone scintigraphy and  $^{18}\text{F}$ -FDG PET in the detection of bone metastases. Patients included in the studies had a variety of carcinomas which may affect the accuracy of the imaging modalities used. Safety and effect of the using  $^{18}\text{F}$ -NaF PET on patient management were not evaluated. The results of the published studies to date should be interpreted with caution. Larger prospective studies among cohorts of patients with specific malignancies are needed to determine whether  $^{18}\text{F}$ -NaF PET is safe, improves the detection rate of bone metastases, and has a positive impact on patient management. A randomized prospective multicenter study of almost 500 patients is conducted by the Academy of Molecular Imaging (AMI) is underway in the US to compare  $^{18}\text{F}$ -NaF PET with  $^{99m}\text{Tc}$ .

**Articles:** There literature search revealed one meta-analysis and a limited number of small studies that evaluated  $^{18}\text{F}$ -NaF PET and compared its performance to one or more other diagnostic modalities used for the detection of bone metastases in patients with lung cancer, breast cancer, prostate cancer, and/or hepatocellular carcinoma. The meta-analysis and a more recent study with generally valid methodology were selected for critical appraisal. Tateishi U, Morita S, Taquri M, et al. A meta-analysis of  $^{18}\text{F}$ -Fluoride positron emission tomography for assessment of metastatic bone tumor. *Ann Nucl Med* 2010;24:523-531. See [Evidence Table](#). Lagaru A, Mitra E, Dick DW, et al. Prospective evaluation of  $^{99m}\text{Tc}$  MDP scintigraphy,  $^{18}\text{F}$  NaF PET/CT, and  $^{18}\text{F}$  FDG PET/CT for detection of skeletal metastases. *Mol Imaging Biol.* 2012;14:252-259. See [Evidence Table](#).

The use of  $^{18}\text{F}$ -FDG PET and  $^{18}\text{F}$ -FDG PET/CT for bone metastases does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 18 F-florbetapir (Amyvid) PET for Alzheimer's disease

##### BACKGROUND

Alzheimer's disease (AD) is the most common cause of dementia in the elderly people. It is an age-dependent neurodegenerative disease characterized by progressive cognitive impairment, behavior disturbance, and irreversible memory loss. It is estimated that approximately 5 million people aged 65 years or older in the US are diagnosed with AD. The number continues to increase and is estimated to reach 6.7 million by 2025. The etiology of AD has not been established and there is no proven treatment to prevent or slow the progression the disease. It is however, necessary to examine the accuracy of the currently used diagnostic methods as these are critically important for AD research and prevention and treatment studies. Traditionally diagnosis of dementia in North America is based on clinical criteria defined by the National Institute of Neurological and Communicative Disorders and Stroke and Alzheimer's disease and related Disorders Association (NINCDS-ADRDA) Work Group in 1984. In 2011, the National Institute of aging (NIA) and the Alzheimer's Association recommended broadening and refining the 1984 criteria by proposing some changes in the classification criteria of AD, and incorporating

biomarkers into the AD criteria. By most diagnostic criteria currently in use, AD is a diagnosis of exclusion based on evidence of chronic progressive cognitive and functional decline of insidious onset in middle aged and elderly patients with no other identifiable alternative explanation such as major, stroke, brain tumor, or systemic disease. Definitive diagnosis of AD depends on the histological examination of brain tissue, which is contraindicated for AD during the patient's lifetime due to the high risk/benefit ratio. While the clinical criteria for diagnosing AD have not changed substantially since they were introduced in 1984, the neuropathological diagnostic criteria have been changed several times in the past three decades. A recent analysis of clinical and neurologic data collected by the National Alzheimer's Coordinating Center from 2005-2010, showed that the sensitivity for AD diagnosis ranged from 70.9-87.3% and the specificity ranged from 44.3-70.8% depending on clinical criteria used. It was also found that as many as 20% of patients diagnosed with AD do not have AD pathology at autopsy ( Jack 2011, Beach 2012, Kingwell 2012, Grundman 2013, Newberg 2012). The pathological process of AD is still unclear, but the most widely accepted theory is the amyloid cascade hypothesis, which explains that the accumulation and aggregation of amyloid - $\beta$  protein in the brain triggers a pathologic cascade ultimately leading to neuronal degeneration and dementia. Autopsy studies showing extracellular accumulation of amyloid plaques and intracellular neurofibrillary tangles support this hypothesis. On the other hand, some investigators postulate that the amyloid- $\beta$  aggregates are protective, and that the soluble oligomers and not the aggregates are toxic. Another argument against the amyloid- $\beta$  theory is the failure of a drug that reduces the amyloid - $\beta$  from the brain to improve cognition in patients with AD. Despite the disagreement about the role that the amyloid- $\beta$  protein plays in AD, the currently accepted pathologic definitions of AD require the presence of abnormal levels of amyloid- $\beta$  deposits throughout the cerebral cortex of the patient. Some argue that fibrillary plaques containing amyloid- $\beta$  may be necessary but insufficient for the diagnosis of AD. Amyloid plaques are also seen in other diseases such dementia with Lewy bodies, vascular dementia, and spongiform encephalopathy. They can also be detected in cognitively normal older adults, and according to researchers, individuals' brains may differ in their ability to tolerate amyloid aggregates based on genetic factors, lifestyle choices, environmental factors, and neuropathological comorbidities, all of which may alter the threshold for the onset of cognitive impairment associated with  $\beta$ -amyloid aggregation (Okamura 2010, Clark 2011, Lister-James 2011, Herholz 2012, Newberg 2012). Lately, *in vivo* amyloid imaging techniques have received a lot of attention for their potential pre-symptomatic detection of amyloid - $\beta$  pathology. It is believed that *In vivo* imaging agents that are specific and sensitive for detecting amyloid plaques would be very useful for the molecular diagnosis of AD. Investigators suggest that a test which can rule out the presence of pathologically significant levels of amyloid- $\beta$  plaque in the brain, can rule out a diagnosis of AD even in patients with signs and symptoms consistent with the common forms of dementia. In contrast, the test that indicates abnormal levels of amyloid- $\beta$  in the brain, may add confidence to the clinical diagnosis of AD, but does not provide a definite diagnosis of AD. On this basis, a number of  $\beta$ -sheet-binding radiotracers have been developed for PET. The most widely used agent is the  $^{11}\text{C}$ -labeled Pittsburgh compound B ( $^{11}\text{C}$ -PIB). However, the short half- life (20 minutes) of the radioisotope  $^{11}\text{C}$  limits the utility of the compound in the clinical setting as a tool for diagnosis and therapeutic evaluation of AD (Okamura 2010, Wong 2010, Lister-James 2011, Newberg 2012). More recently Avid Radiopharmaceuticals have developed an  $^{18}\text{F}$ -labeled amyloid-  $\beta$  PET tracer for the potential detection of AD. The  $^{18}\text{F}$ -florbetapir is an amyloid-  $\beta$  avid imaging agent selected from four styryl- pyridine derivatives due to its high affinity and specific binding for amyloid, fast uptake, and fast washout kinetics in the brain.  $^{18}\text{F}$ -florbetapir is a radioactive agent with a half-life of 110 minutes that is given before positron emission tomography (PET) imaging of the brain. According to the manufacturer,  $^{18}\text{F}$ -florbetapir crosses the blood brain barrier and binds to amyloid aggregates in the brain. A PET scanner can detect the signal emitted by the drug's radioactive fluorine and the resultant image will show the density of amyloid- $\beta$  neuritic plaques in the brain. The PET-tracer  $^{18}\text{F}$ - florbetapir does not measure tau proteins (proteins that stabilize microtubules), which some experts believe plays a crucial role in AD (Okamura 2010, Wong 2010, Lister-James 2011, Newberg 2012, Rosenberg 2013). The PET-tracer  $^{18}\text{F}$ -florbetapir (Amyvid,[ Avid Radiopharmaceuticals, a subsidiary of Eli Lilly &Co), received FDA approval in 2012 for imaging of the brain in subjects under evaluation for AD and other cases of cognitive impairment. The FDA approval announcement indicated that Amyvid is not a test for predicting the development of AD-associated dementia and is not for monitoring patient response to AD therapy, nor does it replace other diagnostic tests used for the evaluation of cognitive impairment. The labeling explicitly states that a positive scan does not establish a diagnosis of AD or other cognitive disorder.

### 10/21/2013: MTAC REVIEW

#### 18 F-florbetapir (Amyvid) PET for Alzheimer's disease

**Evidence Conclusion:** Analytic validity: Clark and colleagues (2011, 2012), evaluated the accuracy of the  $^{18}\text{F}$ -florbetapir -PET scans among terminally ill patients who consented to undergo a postmortem biopsy. The mean age of the participants was 79.3 years, 48.6% had AD as their diagnosis, 8.6% had mild cognitive impairment, 17% had another dementing disorder, and 25.7% were cognitively normal. In the initial study (Clark et al, 2011) participants were followed-up until 35 individuals had died and underwent postmortem brain biopsy. Surviving individuals were followed for an additional 1 year after initial study or for up to 2 years after the florbetapir PET scan (Clark et al, 2012). The premortem scan was then compared to the postmortem brain autopsy findings. Each

scan was interpreted with at least three nuclear medicine physicians who had undergone training on reading the florbetapir-PET scans. The results of the study showed a mean (among readers) sensitivity of florbetapir-PET scan of 87% and mean specificity of 95% with an overall mean accuracy of 90%. The authors performed a florbetapir -PET scan on a group of 74 healthy young individuals (mean age 26.7 years) to evaluate the specificity of the test. They assumed, and interpreted a negative scan in these patients as amyloid negative without comparing it to the gold standard. The study had the advantage of comparing <sup>18</sup>F-florbetapir-PET findings with the gold standard of histopathological findings. However, it also had a number of limitations, many of which were acknowledged by the investigators. These include but are not limited to: The accuracy of Florbetapir-PET was assessed in a nonrandom sample of terminally ill patients who were generally older and/or with poorer health conditions than those in the population that would typically be evaluated for AD in clinical practice. Mean time interval from onset of symptoms of AD (among patients with the disorder) to enrollment was 9 years. This makes it hard to determine how early in the disease course, the amyloid plaques can be detected. Relatively small number of patients underwent postmortem brain biopsies. 22% of the autopsies were performed more than 12 months after the scan: according to the authors, "The relation between post-mortem pathological changes and actual changes in the brain at the time of PET scan might decrease with increasing scan-to autopsy interval (majority reading sensitivity of scan was 96% when autopsy was performed within 1 year from scan and 92% for that performed within 2 years). Both the imaging and histopathological results were distributed bimodally i.e. amyloid positive (moderate to frequent plaques) or negative (no or sparse plaques). There was no intermediate category (sparse to moderate). It is hard to determine whether measurable, but low levels of amyloid at pathology that are not associated with amyloid positive scan represent an early stage of the disease, variant of amyloid deposition, or normal aging. Each scan was interpreted with 3-5 nuclear medicine physicians who had undergone extensive training on reading the scan, which would not be the case outside of an investigational setting. There were variations between the readers interpreting the scan especially with borderline amyloid levels leading to more false negative results. It is worth noting that the study was sponsored by Avid Radiopharmaceuticals, the developer of Amyvid, which was also involved in the collection, analysis, and interpretation of the data, as well as writing the report.

**Clinical validity** - There is weak, insufficient published evidence to determine the usefulness of florbetapir-PET imaging in identifying individuals with mild cognitive impairment or cognitive symptoms who would progress to AD. Doraiswamy and colleagues (2012) investigated whether <sup>18</sup>F-florbetapir- PET scan can predict subsequent cognitive decline in older at-risk subjects. The study included 69 cognitively normal individuals at baseline, 51 with mild cognitive impairment (MCI), and 31 patients with AD. All underwent <sup>18</sup>F-florbetapir- PET scanning at baseline, and the images were interpreted by three readers as amyloid - $\beta$  (A $\beta$ ) positive or A $\beta$  negative. The participants were followed-up for 18 months after which they were re-assessed for their cognitive status and function. The results showed that MCI patients who were amyloid positive had significantly greater decline in the majority of psychomotor tests vs. those who were amyloid negative. There was a small yet significantly higher conversion rate from MCI to AD among those who were amyloid positive versus amyloid negative patients. These results have to be interpreted with caution due to limitations of the study. It was relatively small, conducted in an investigational setting, had only 18 months of follow-up, the authors did not adjust for multiple comparisons, and the images were interpreted with three readers with some disagreement.

**Clinical utility** - Grundman and colleagues (2013) conducted a study to determine the impact of amyloid imaging with <sup>18</sup>F-florbetapir PET on the physicians' diagnostic thinking and intended management of 229 patients with progressive cognitive decline undergoing evaluation for suspected AD and diagnostic uncertainty. The treating physicians provided a provisional diagnosis, an estimate of their diagnostic confidence, and their plan for diagnostic evaluation and management both before and after receiving the results from amyloid imaging with <sup>18</sup>F-florbetapir. The scan was amyloid positive in 133 patients and amyloid negative for 116 patients. No histopathological confirmations were done. The results of the analysis shows that after receiving the results of the florbetapir scan, diagnosis changed in 125/229 (54.6%) patients. Intended medication management of AD increased by 17.7% for patients with positive scans and decreased by 23.3% among those with negative scans. Among subjects who had not yet undergone a completed work up, planned brain structural imaging decreased by 24.4% and planned neuropsychological testing decreased by 32.8%. The analysis also showed that 55% of the subjects were classified with an indeterminate diagnosis after a negative scan rather than a non-AD diagnosis which may reflect lack of confidence in the scan results. The study had the advantage of investigating the clinical utility of <sup>18</sup>F-florbetapir PET scan. However, the physicians were asked whether they would change their management plan, rather than observing the actual patient management over time. The study included patients with progressive cognitive decline and diagnostic uncertainty, and was conducted in a clinical trial setting by memory disorder experts experienced in the diagnosis and treatment of AD, and the scans were over-read by expert nuclear medicine specialists, thus the results may not be generalizable to the overall population evaluated for cognitive complaints. The effect of <sup>18</sup>F-florbetapir PET scan on patient outcome has not been examined and to date, there is no proven therapy for Alzheimer's disease or for lowering and/or reversing amyloid aggregates.

**Safety** - The most common adverse reactions reported in these published clinical trials include headache (1.8%), musculoskeletal pain (0.8%), fatigue (0.6%), nausea (0.6%), anxiety (0.4%), back pain (0.4%), increased blood pressure (0.4%), claustrophobia (0.4%), feeling cold (0.4%), insomnia (0.4%), and neck pain (0.4%). In

conclusion, there is insufficient evidence to determine whether the use of <sup>18</sup>F-florbetapir-PET can accurately predict the risk of AD, would have impact on patient management, or improve net health outcomes of patients at risk of AD. More prospective studies are needed to verify its accuracy and role in the diagnosis and management of the AD. Alzheimer’s Disease Neuroimaging initiative 2 (ADNI2) is an ongoing large longitudinal multicenter study that may determine the relationships among clinical, imaging, genetic, and biochemical biomarker characteristics of the entire spectrum of Alzheimer’s Disease (AD), as the pathology evolves from normal aging through very mild symptoms, to mild cognitive impairment (MCI).

**Articles:** The literature search revealed a large number of articles on amyloid-β imaging with PET, but only a limited number of studies was related to the current review. There was one phase III trial and a small number of phases I and II studies on the use of 18F-florbetapir-PET in patients with mild cognitive impairment (MCI) or dementia due Alzheimer’s disease. The search also identified one study on the prognostic utility of the scan, and another on the potential impact of the imaging on patient management. The phase III study (submitted to the FDA), the study on the prognostic utility the imaging, as well as the larger study on its impact on patient management were selected for critical review. Doraiswamy PM, Sperling RA, Coleman RE, et al. Amyloid-β assessed by florbetapir F 18 PET and 18-month cognitive decline: a multicenter study. *Neurology*.2012;79:1636-1644. [See Evidence Table](#). ## Clinical Review Criteria

### Pharmacogenomic/Pharmacological Testing for Predicting Response of Chemotherapeutic Agents

- ALK Gene Rearrangement and Non-Small-Cell Lung Cancer
- BRAF-v600E Mutation
- ChemoFx® Assay
- Conductance Regulator (CFTR) Gene
- Cytochrome P450 Genotyping Test Drug Metabolizing
- Enzyme Genotyping System
- Epidermal Growth Factor Receptor (EGFR) Testing for Predicting Response of Patients with NSCLC to Tyrosine Kinase Inhibitors (TKIs)
- G551D Mutation in the Cystic Fibrosis Transmembrane
- IL28B Polymorphisms in Patients with Hepatitis C
- Invader UGT1A1 Molecular Assay
- KRAS
- NS5A Resistance Testing
- Oncotype DX
- Platelet Function Testing (VerifyNow P2Y12 Assay)
- Trophile Testing
- Warfarin Sensitivity DNA Test

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Palmetto GBA is the Medicare contractor for Molecular Diagnostic Testing – this site has the most up to date Medicare coverage guidelines for genetic testing.

[Palmetto GBA](#)

Molecular DX: [GeneSight® Assay for Refractory Depression \(L36324\)](#) GeneSight® Psychotropic (AssureRx Health, Inc, Mason, OH)

See [National Coverage Determination \(NCD\) for Pharmacogenomic Testing for Warfarin Response \(90.1\)](#).

See [LCD MoIDX: CYP2C19, CYP2D6, CYP2C9, and VKORC1 Genetic Testing \(L36311\)](#) CYP2C19 (CPT 81225) CYP2D6 (CPT 81226) CYP2C9 (CPT 81227) VKORC1 (CPT 81355)

#### For Non-Medicare Members

Genetic Test	Criteria Used
Abacavir HLA-B*5701	This test is covered when: 1) Prior initiation of therapy with abacavir
Anaplastic Lymphoma Kinase (ALK) Gene Rearrangement Testing for Locally Advanced or Metastatic Non-Small-Cell Lung Cancer	This test is covered when: 1) Crizotinib is being considered, AND 2) A positive test is required to initiate use of this drug
BRAF-v600E Mutation	This test is covered when: 1) Patient has unresectable or metastatic melanoma and therapy with vemurafenib is being considered 2) Patient has metastatic colorectal cancer and therapy with cetuximab or panitumumab is being considered.

Genetic Test	Criteria Used
GenoSure Archive	These tests are covered when:
Carbamazepine Pharmacogenetics - HLA-B*1502 Allele	MCG* (A-0649)
ChemoFx Assay	There is insufficient evidence in the published medical literature to show clinical utility.
CYP2:	
<ul style="list-style-type: none"> <li>CYP2B6/ CYP3A4/CYP2A6 Efavirenz</li> <li>CYP2C19 Proton Pump Inhibitors (PPI) for Treating Helicobacter Pylori</li> <li>CYP3A5 and CYP3A4</li> <li>Immunosuppressants for Organ Transplant</li> </ul>	There is insufficient evidence in the published medical literature to show clinical utility.
Clopidogrel (Plavix) Pharmacogenetics - CYP2C19 Gene	MCG* (A-0631)
Selective Serotonin Reuptake Inhibitors (SSRIs) - Cytochrome P450 Polymorphism Testing(only covers CYP2D6 and CYP2C19)	MCG* (A-0692)
Tamoxifen Pharmacogenetics – CYP2D6 Gene	MCG* (A-0647)
Epidermal Growth Factor Receptor (EGFR) Testing for Predicting Response of Patients with NSCLC to Tyrosine Kinase Inhibitors (TKIs) Such as VeriStrat	Epidermal Growth Factor Receptor Testing is covered when: 1) Diagnosis of NSCLC
G551D Mutation in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Gene	MCG* (GHC-0597)
IL28B Polymorphisms in Patients with Hepatitis C	There is insufficient evidence in the published medical literature to show clinical utility.
TPMT Gene	MCG* (A-0628)
Irinotecan Dosing - UGT1A1 Gene (Invader)	MCG* (A-0624)
KRAS &/or NRAS	The following criteria must be met: 1) The test is ordered by the treating oncologist 2) The test is being used to determine whether the patient has the mutant KRAS or NRAS genes and the presence of the mutation would change treatment decisions with Cetuximab or Panitumumab.
NS5A Resistance Testing	Covered for patients who have failed prior Hepatitis C therapy
Oncotype Dx	Covered when the following criteria are met: 1) Estrogen-receptor-positive breast cancer that is node-negative has been diagnosed. 2) There is a question of chemotherapy benefit. 3) The patient is counseled to understand that if the test results show a low recurrence risk that chemotherapy is of limited benefit. <b>Not covered for colorectal cancer</b> because of insufficient evidence in the published medical literature showing this test adds benefit to treatment.
Platelet Function Testing (VerifyNow P2Y12 Assay) CPT code 85576	Medical necessity review no longer required

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Genetic Test	Criteria Used
Psychotropic Medication Pharmacogenetic Testing	MCG* (A-0692)
Rasburicase Pharmacogenetics - G6PD Gene	MCG* (A-0653)
PROOVE® Pharmacogenetic Panels Drug Metabolism Opioid Risk Opioid Response Opioid Pain Perception Non Opioid Response	Not considered medically necessary because the current scientific evidence is not yet sufficient to establish how test results from all components of these panels should be used to direct treatment decisions.
Trophile or Trophile DNATesting	Covered when an experienced HIV practitioner who is considering use of maraviroc as part of an HIV regimen OR when a member is failing a regimen that contains maraviroc.
Warfarin Sensitivity DNA Test	This test is covered once in a lifetime to guide the Warfarin dosing strategies when the patient has had no more than 5 doses of Warfarin prior to testing.
5-Fluorouracil Pharmacogenetics - DPYD, MTHFR, and TYMS Genes	MCG* (A-0665) GHC will not cover this per MCG guideline

\*MCG Manuals are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.)

**If requesting any of these services, please send the following documentation to support medical necessity:**

- Any genetic counseling notes if applicable
- Last 6 months of specialist notes of that is being reviewed (neurological - neurology notes)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Pharmacogenetics is defined as the study of the genetic basis for differences in a population's response to a drug. It seeks to identify polymorphisms (genetic variations) that result in different systemic concentration levels of drugs, which may help explain differing responses to the same medication. The field of pharmacogenetics began as the study of gross ethnic variations (e.g., variation by ethnic groups) and evolved into the study of variations of genes and proteins within individuals. Group Health is evaluating the evidence for each test as the evidence is published.

## Medical Technology Assessment Committee (MTAC)

### **ALK Gene Rearrangement and Non-Small-Cell Lung Cancer**

#### BACKGROUND

Lung cancer is one of the most common causes of cancer death, accounting for over 1 million deaths annually.

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Lung cancer is comprised of two histological types: small-cell lung cancers and non-small-cell lung cancers. Non-small-cell lung cancer (NSCLC) accounts for approximately 85% of lung cancers. Traditionally, treatment decisions have been based on histological type. For patients with NSCLC, platinum-based chemotherapy constitutes standard first-line treatment. However, a therapeutic plateau has been reached with conventional chemotherapy for NSCLC patients. Advances in the knowledge of molecular mechanisms of carcinogenesis have led to a change in the treatment strategy for patients with NSCLC. Research efforts are now focusing on new therapies that target molecular subtypes of NSCLC (Janku 2010, Pao 2011, Sasaki 2010). Anaplastic lymphoma kinase (ALK) is a tyrosine kinase that is not normally expressed in lung cancer. Fusions of ALK with echinoderm microtubule-associated protein-like 4 (EML4), an upstream promoter, were found in NSCLC in 2007. However, EML4 does not appear to be the exclusive fusion partner with ALK. Biologically, these fusions result in constitutive activation of the kinase. It has been reported that approximately 3 to 7% of tumors harbor EML4-ALK fusions. Although associations with clinical and pathological characteristics are not well established, research suggests that EML4-ALK fusions are associated with never smokers or light smokers, younger patient age, patients with adenocarcinomas, and patients with more advanced NSCLC. While the frequency of epidermal growth factor receptor (EGFR) mutations also increases in patients with these characteristics, EML4-ALK rearrangements are generally not found in patients with EGFR or KRAS mutations (Janku 2010, Pao 2011, Sasaki 2010). Currently, clinical trials are underway to determine the safety and efficacy of ALK kinase inhibitors for the treatment of NSCLC in patients with EML4-ALK rearrangements.

### **08/15/2011: MTAC REVIEW**

#### **ALK Gene Rearrangement and Non-Small-Cell Lung Cancer**

**Evidence Conclusion:** Analytic validity: Several methods are available for detecting EML4-ALK rearrangements in patients with NSCLC; however, there is currently no gold standard method. Clinical validity: There is insufficient evidence to determine the clinical validity of testing for EML4-ALK rearrangements in patients with NSCLC. Clinical utility: There is insufficient evidence to determine the clinical utility of testing for EML4-ALK rearrangements in patients with NSCLC.

**Articles:** Assessment objective: Analytic validity: Are the clinical assays for the detection of ALK gene rearrangements accurate and reliable? Clinical validity: Does the presence of an ALK gene rearrangement predict clinical outcome? Clinical utility: Will the results of the clinical assays for the detection of ALK gene rearrangements alter clinical management and improve clinical outcomes? Several methods including polymerase chain reaction (PCR), immunohistochemistry (IHC), and fluorescence in situ hybridization (FISH) are currently being evaluated for the detection of EML4-ALK rearrangements. Each of these methods has its advantages and limitations. Currently, there is no gold standard method for detecting EML4-ALK rearrangements in patients with NSCLC (Sasaki 2010). A small retrospective cohort study was identified that addressed the clinical validity of testing patients with NSCLC for EML4-ALK gene rearrangements; however, this study was not selected for review as it only included 19 patients with EML4-ALK rearrangements. Results from this study suggest that patients with EML4-ALK rearrangements have similar response rates to platinum-based combination chemotherapy as patients without these mutations. Additionally, patients with EML4-ALK rearrangements do not appear to respond to tyrosine kinase inhibitors (Shaw 2009). Larger studies are needed to confirm these findings. To date there are no FDA approved agents for the treatment of NSCLC in patients with EML4-ALK gene rearrangements. Results from a phase 1 open-label, prospective case-series that included 82 subjects with EML4-ALK rearrangements suggest that crizotinib, an orally available small-molecule inhibitor of the ALK tyrosine kinase, may be effective for the treatment of NSCLC in patients with EML4-ALK rearrangements. The overall response rate, which included confirmed partial and complete responses, was 57% and 33% of patients had stable disease. The most commonly reported adverse effects were nausea (54% of patients) and diarrhea (48% of patients) (Kwak 2010). Phase 3 clinical trials are now underway to determine the safety and efficacy of crizotinib compared to pemetrexed or docetaxel in patients with advanced NSCLC and EML4-ALK gene arrangements (ClinicalTrials.gov number, NCT00932893).

The use of ALK gene rearrangement does not meet the *Group Health Medical Technology Assessment Criteria*.

#### ***BRAF*<sup>V600E</sup> Mutation**

##### **BACKGROUND**

In the past year, several therapies for late-stage melanoma have been approved, including peg-interferon  $\alpha$ -2b (Sylatron) and ipilimumab (Yervoy). Until now, ipilimumab was the only agent to demonstrate an improvement in overall survival for patients with advanced melanoma. Vemurafenib is approved for the treatment of advanced melanoma as well, but targets a specific patient population. It is an inhibitor of mutated forms of BRAF serine-threonine kinase, including BRAF<sup>V600E</sup>, and also inhibits other kinases at similar concentrations. Some mutations in the BRAF gene, including V600E, result in constitutively activated BRAF proteins, which can cause cell proliferation in the absence of growth factors that would normally be required for proliferation.

Confirmation of BRAF<sup>V600E</sup> mutation-positive melanoma as detected by the cobas® 4800 V600 Mutation Test, is required for selection of patients prior to administration of vemurafenib. This test is designed to detect BRAF<sup>V600E</sup> mutations in DNA isolated from formalin-fixed, paraffin-embedded human melanoma tissue. This test is marketed by the same company that manufactures vemurafenib, and its FDA approval is based on the same data that supported approval of vemurafenib.

**09/2011: Pharmacy and Therapeutics Committee (P&T)**

**BRAF<sup>V600E</sup> Mutation**

**Evidence Conclusion:** From P&T Committee: Evidence of benefit<sup>2-4</sup>:

Preliminary data from BRIM-2, a phase 2 trial, showed that patients with BRAF<sup>V600E</sup> mutation + melanoma who had received prior treatment and were subsequently treated with vemurafenib, had an objective response rate >50%. Based on this data, the FDA recommended modification of the statistical plan for BRIM-3, a phase 3 trial, to accommodate an interim analysis and accelerate the approval process. Median follow-up in BRIM-3 was ~3 months. In the BRIM-3 trial, vemurafenib, 960mg BID was superior to dacarbazine in progression-free survival (5.3 months vs 1.6 months; p<0.001) and objective tumor response rate (48% vs 5%, p<0.001).

Complete responses were seen in 2 patients (0.9%) of patients in the vemurafenib group and 0 in the dacarbazine group. Median overall survival was not reached in the vemurafenib group, but was 7.9 months in the dacarbazine group. At 6 months, overall survival was 84% in the vemurafenib group and 64% in the dacarbazine group; p<0.001. In BRIM-2 and BRIM-3, all enrolled patients tested positive for the BRAF<sup>V600E</sup> mutation using the cobas® 4800 V600 Mutation Test. Evidence of harm<sup>1-3</sup>: The most common adverse reactions of any grade (≥ 30% in either study) reported in patients receiving vemurafenib were arthralgia, rash, alopecia, fatigue, photosensitivity reaction, nausea, pruritus and skin papilloma. The most common (≥5%) Grade 3 adverse reactions were cutaneous squamous cell carcinoma (cuSCC) and rash; 24% of patients treated with vemurafenib were reported to have at least one cuSCC. These lesions were excised, and none required dose-modifications. The incidence of Grade 4 adverse reactions was ≤ 4% in both studies. In BRIM-3, the incidence of adverse events resulting in discontinuation was 7% in the vemurafenib arm and 4% for the dacarbazine arm. There are no contraindications to vemurafenib. Safety issues addressed in the package insert include cuSCC, serious hypersensitivity reaction, Stevens-Johnson syndrome and toxic epidermal necrolysis, QT-prolongation, liver laboratory abnormalities, photosensitivity, uveitis and other ophthalmologic reactions, and new primary malignant melanomas.

Pregnancy category D, may cause fetal harm based on its mechanism of action. Women of childbearing potential and men should be advised to use appropriate contraceptive measures during therapy and for at least 2 months after discontinuation.

**Articles: Table 1. Summary of results from BRIM-2: an open-label, single-arm, Phase II trial**

Study population	Outcome	Vemurafenib 960mg BID (95% CI) , n=132
BRAF <sup>V600E</sup> mutation + melanoma who have completed prior 1 <sup>st</sup> line therapy	Best overall response rate	52.3% (43, 61)
	Median duration of response	6.8 months (5.6, not reached)
	Median PFS	6.2 months (5.6, 6.8)

**Table 2. Summary of results from BRIM-3: a randomized double-blind placebo-controlled Phase III trial**

Study population	Outcome	Vemurafenib n=337	Dacarbazine n=338	HR (95% CI) p-value	ARR (95% CI)	NNT (95% CI)
Unresectable stage IIIC or IV melanoma, + BRAF <sup>V600E</sup> mutation, treatment naïve	Overall survival	Median not reached 84% at 6 months	7.9 months (7.3, 9.6) 64% at 6 months	0.37 (0.26, 0.55) p<0.001	20% (13, 26)	5 (4, 7)
	Progression-free survival	5.3 months (4.9, 6.6)	1.6 months (1.6, 1.7)	0.26 (0.2, 0.33) p<0.001	NA	NA
	Objective tumor response rate	48% (n=219)	5% (n=220)	p<0.001	43% (35, 50)	2 (2, 3)

HR – Hazard ratio    ARR – Absolute Risk Reduction    NNT – Number Needed to Treat to benefit one person

This was not considered at MTAC but went to P&T instead.

**ChemoFx® Assay**

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

## BACKGROUND

It is widely recognized that patients with the same histological stage and grade of cancer may vary considerably in their clinical response and tolerability to chemotherapy. An individual may be resistant to one chemotherapeutic and sensitive to another, suggesting that there is considerable clinical heterogeneity in tumor chemosensitivity. Unfortunately, resistance to chemotherapy cannot be predicted by clinical or histological examination. The administration of an ineffective therapy is associated with unnecessary toxicity, delay of potentially useful drug, added risk of the development of resistant clones, and needless cost. Many attempts have been made over the years to develop an ex-vivo test that would provide clinically relevant tumor-specific information, i.e. measures how a patient cancer cells respond to specific types, doses and combinations of chemotherapy (Gallion 2006, Cree 2007). A number of in-vitro chemosensitivity response tests have been, and are currently used. These include assays that measure cellular metabolic activity, tests that measure radioactive precursor incorporation, and tests that measure cell viability. Chemoresponse assays are not intended to be used as an alternative to the traditional empiric methods for selecting chemotherapy but as an aid to the oncologists when selecting the most appropriate chemotherapy regimens on an individual basis especially when a number of equivalent options are available (Ness 2002, Gallion 2006, Cree 2007). ChemoFx® (Precision Therapeutics) is an ex-vivo, cell death assay based on the biological phenomenon that when cells that grow adherent in culture as a monolayer, die they lose their adherent qualities and lift from the culture surface. The test is reported to use as little as 35 mg of tissue, and have the results available in about 3 weeks after receiving the specimen. It involves growing tumor cells (excised from individual cancer patients through biopsy or surgery, or recovered from fluid specimens), in primary cultures as monolayers. Once a sufficient number of cells are grown, they are exposed to a variety of chemotherapeutic agents in a range of concentrations. A full dose-response curve is generated for each drug evaluated, and the data are presented graphically as the cytotoxic index (% kill), defined as  $1 - [\text{No. of cells in treated wells} / \text{No. of cells in control wells}] \times 100$ . Features of each dose-response curve are used to score a tumor's response to each ex vivo treatment as responsive, intermediate response, or nonresponsive. Drug responses are scored from 0-5 and is determined by the number of drug doses where the cytotoxic index was >35%. Collectively these scores may be used by the oncologist in his treatment decisions (Peters 2005, Zhibao 2008).

### 10/05/2009: MTAC REVIEW

#### ChemoFx® Assay

**Evidence Conclusion:** Clinical validity: ChemoFx assay was not prospectively compared head to head to another cellular or molecular chemoresponsive test or gold standard. Two retrospective cases series correlated the results of ChemoFx with cancer free survival in ovarian cancer patients, and one small series correlated its results with pathological complete response of small breast lesions to neoadjuvant therapies. Gallion, and colleagues 2006, retrospectively correlated the results of ChemoFx assay to progression free-interval (PFI) in a case series of 304 patients with ovarian or peritoneal carcinoma. The study was a case series with potential selection and observational biases. It was not blinded, had no comparison group, and while selection of chemotherapy was at the discretion of the treating physician, some used the results of the assay to help determine the appropriate regimen. Overall the results of show that 256 cases had an exact or partial match between drugs assayed and received, and 135 cases had an exact match. In the latter group the median PFI was 9 months for patients treated with drugs assayed as resistant, 14 months for those treated with drugs assayed as intermediate, and had not been achieved (during study period) for those with drugs assayed as sensitive. The calculated hazard ratio for progression of the resistant group vs. the sensitive group was 2.9 (95% CI: 1.4-6.3), and that of the intermediate vs. sensitive group was 1.7 (95% CI: 1.2-2.5). Clinical utility: The literature search did not identify any published randomized or nonrandomized controlled trials that evaluated the effect of ChemoFx testing on individualizing chemotherapeutic regimen and /or its impact on survival. Other observational non-comparative prospective studies examining the outcomes associated with the use ChemoFx are underway. Conclusion: There is insufficient evidence to date to determine the clinical validity and utility of ChemoFx in selecting the most appropriate chemotherapy regimens and improving survival of cancer patients.

**Articles:** The published literature on ChemoFx® is very limited. There were only two case series (N=304, and N=18) that retrospectively evaluated the predictive value of ChemoFx assay by correlating its results with progression free interval (PFI) in patients with ovarian cancer, and another small case series among 34 women with breast cancer, that correlated the pathological complete response to a neoadjuvant chemotherapy with the results of ChemoFx® testing. As regards the clinical utility of the test, the literature search did not reveal any randomized or non-randomized controlled trials that compared outcomes among patients managed with and without ChemoFx® testing. The larger case series on the predictive value of ChemoFx was critically appraised Gallion H, Christopherson WA, Coleman RI, et al. Progression –free interval in ovarian cancer and predictive value of an ex vivo chemoresponsive assay. *Int J Gynecol Cancer* 2006;16:194-201. See [Evidence Table](#)

The use of ChemoFx Assay for predicting response of solid tumors to chemotherapeutic agents does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Cytochrome P450 Genotyping Test Drug Metabolizing**

### **BACKGROUND**

Pharmacogenetics is the study of the genetic causes of individual variation in drug response. There has been growing interest in the use of pharmacogenetics to predict response to medications in terms of safety and efficacy. Cytochrome P450s, in particular CYP3A4, CYP2D6, CYP2C19, CYP1A2, and CYP2B6, have a central role in the metabolism of many clinically used drugs. Genetic polymorphisms in the cytochrome P450 enzymes may help to explain the observed variation in the concentrations of certain drugs and their metabolites. Genetic variability can significantly affect drug metabolism and lead to distinct subgroups of the populations that differ in their ability to metabolize various drug. The resulting phenotypes are poor metabolizers (PM), intermediate metabolizers (IM), extensive metabolizers (EM), and ultrarapid metabolizers (UM). Clinically, the most important phenotypes are ultrarapid metabolizers and poor metabolizers. Subjects who possess the ultrarapid metabolizer phenotype may experience a reduced response to standard doses of medications because their ability to rapidly metabolize these medications makes it difficult to sustain therapeutic levels. They are also more likely to suffer from adverse drug reactions due to the formation of toxic metabolites and excess levels of the active drug. Because poor metabolizers have low metabolic capacity, usual doses may lead to higher than expected drug concentrations, placing them at increased risk for adverse drug reactions. Additionally, PM may not respond to drugs that require activation by the enzyme in question (Ingelman-Sunberg 2010). It is thought that knowledge of the genetic metabolizer status may enable physicians to more accurately identify the appropriate drug and/or drug dose that maximizes efficacy and minimizes toxicity in each individual patient. The AmpliChip test uses microarray DNA chip technology developed by Affymetrix. The microarray chip is similar to a computer microchip, but instead of circuits, the microarray chip contains millions of DNA fragments, called probes, that are chemically synthesized at precise locations on the coated quartz surface. The genetic test is performed by extracting DNA from the patient's blood. Prepared DNA samples are applied to the array and matched to the sequence of the probe molecules. The AmpliChip cytochrome P450 genotyping test was cleared for marketing by the FDA in December 2004. It is the first FDA-approved laboratory gene test to evaluate genetic information for medication selection. *PLAVIX* In the United States, cardiovascular disease is the leading cause of death in both men and women (Heron 2009). Clinical trials have shown that clopidogrel (Plavix), an anti-blood clotting medication, reduces the morbidity and mortality associated with several cardiovascular diseases. However, there is a significant amount of inter-individual variability in clopidogrel responsiveness, which leads some patients to experience decreased platelet inhibition (poor response) with clopidogrel (Momary 2010b). It is thought that the primary source of variability in clopidogrel responsiveness lies in the pharmacogenetics of clopidogrel. Clopidogrel is a pro-drug that is metabolized into its active metabolite through the action of several enzymes (CYP2C19, CYP1A2, CYP3A4, CYP3A5, and CYP2B6). A polymorphism in any of the enzymes could result in decreased responsiveness. One of the enzymes associated with clopidogrel non-responsiveness is CYP2C19. Patients with the wild-type CYP2C19\*1 allele have normal metabolic activity. However, four variant CYP2C19 alleles are associated with reduced metabolic activity. Drug interactions, clinical factors, such as diabetes and increased weight, and patient non-compliance are other proposed mechanisms of clopidogrel non-responsiveness. The prevalence of clopidogrel resistance varies from 3-30% (Momary 2010a, Momary 2010b, Ma 2010). On March 12th, 2010, the FDA added a boxed warning to the label for clopidogrel to alert healthcare professionals and patients of the reduced effectiveness of clopidogrel for patients who are poor metabolizers and includes information on the role of CYP2C19 genotype in clopidogrel responsiveness. There has been growing interest in the use of CYP2C19 genotyping to identify patients who are non-responsive to clopidogrel. The AmpliChip CYP450 Test (Roche Diagnostics Inc, Indianapolis, IN) has received FDA approval for CYP2C19 genotyping. *TAMOXIFEN* Aside from non-melanoma skin cancer, breast cancer is the most common form of cancer in women. It is the number one cause of cancer death in Hispanic women, and the second leading cause of cancer death in white, black, Asian/Pacific Islander, and American Indian/Alaska Native women (CDC 2010). Tamoxifen is used as an adjuvant endocrine therapy to prevent estrogen receptor-positive breast cancer recurrence, as a treatment for metastatic breast cancer, and to prevent disease in high-risk women with ductal carcinoma in situ (Lash 2009). Tamoxifen is a "pro-drug", several enzymes (CYP2B6, CYP2C8, CYP2C9, CYP2C10, CYP3A4, CYP3A5, and CYP2D6) transform the pro-drug into its active metabolites 4-hydroxytamoxifen (4-OH tamoxifen) and 4-hydroxy-N-desmethyltamoxifen (endoxifen). Research indicates that both endoxifen and 4-OH tamoxifen have nearly 100-fold higher affinity for estrogen receptors than tamoxifen; however, endoxifen is found at a 6 to 12 fold higher concentration than 4-OH tamoxifen. Every secondary tamoxifen metabolite except for endoxifen is formed by two enzymes CYP3A4 and CYP3A5. Endoxifen production is almost totally dependent on the enzymatic activity of CYP2D6. In vivo studies suggest that endoxifen is the major active metabolite of tamoxifen (Higgins 2009). The observed variation in the concentrations of tamoxifen and its metabolites might be explained through genetic polymorphisms in the genes that encode the CYP2D6 enzyme. There are more than 100 allelic variants of CYP2D6 with incidence varying according to race and ethnicity. The most prevalent allele is the wild-type allele CYP2D6\*1. Patients with two copies of this allele produce an enzyme with normal activity. Because individuals have two CYP2D6 alleles, various combinations of the alleles result in a spectrum of CYP2D6 function ranging from no activity to increased activity. In the Caucasian population, approximately 5-10% of patients are

poor metabolizers and 10-15% of patients are intermediate metabolizers of tamoxifen. It is thought that tamoxifen-treated patients who are poor metabolizers and intermediate metabolizers are at an increased risk for recurrence (Dezentjé 2009, Higgins 2009, Lash 2009). CYP2D6 inhibiting drugs, such as SSRIs, may also decrease tamoxifen metabolism (Lash 2009). Due to the association between tamoxifen metabolism and the CYP2D6 genotype, there is growing interest in the use of CYP2D6 genotyping to direct treatment for patients with breast cancer. *Atomoxetine* Atomoxetine is a norepinephrine reuptake inhibitor that is used to treat attention-deficit hyperactivity disorder (ADHD). Atomoxetine is metabolized via the CYP2D6 enzyme and has a broad therapeutic window. Currently, dosing is determined by the patient's weight with dose adjustments according to clinical response and adverse effects. Studies have suggested that in PM the plasma concentration of atomoxetine is higher and the half-life is longer compared to EM (Michelson 2007). *Codeine for nursing mothers* Opioid analgesics, such as codeine, are commonly used for pain relief in labor and postpartum. Codeine is a pro-drug that is predominantly metabolized by the CYP2D6 enzyme into morphine. While codeine is effective for the majority of individuals, a subset of patients, CYP2D6 poor metabolizers, do not possess any active gene copies and experience poor analgesia due to the deficient formation of the active metabolite (morphine). Additionally, approximately 2-40% of individuals (depending on ethnic background) are ultrarapid metabolizers and possess functional duplications of the CYP2D6 gene. These duplications lead to enhanced biotransformation of codeine into morphine and have been associated with adverse effects including death in breastfed infants (Madadi 2009a, Alfirevic 2010). *Efavirenz* Efavirenz is a non-nucleoside reverse transcriptase inhibitor (NNRTI). Treatment with efavirenz plus two nucleoside reverse transcriptase inhibitor (NRTI) is recommended among the first line regimens in patients initiating highly active antiretroviral therapy (HAART). In addition, efavirenz is used with other antiretroviral agents as a part of post exposure prophylaxis regimen to prevent HIV transmission. Efavirenz is metabolized primarily by CYP2B6 with partial involvement from CYP3A4 and CYP2A6. It is hypothesized that polymorphisms in these genes may contribute to interindividual differences in efavirenz plasma concentration and half-life. Studies have found that poor metabolizers were at greater risk of high plasma levels of efavirenz. It had been suggested that high plasma levels may be associated with central nervous system (CNS) side effects, such as abnormal dreams, dizziness, somnolence, insomnia, and impaired concentration (Rakhmanina 2010, Tozzi 2010). *Proton pump inhibitors (PPI) for treating Helicobacter pylori* H. pylori infection is closely related to many gastrointestinal diseases, including gastritis, peptic ulcer disease, and gastric cancer. Eradication of H. pylori is important for reducing the relapse rate of ulcers and the risk of gastric cancers. Current treatment for the eradication of H. pylori consists of a PPI and two antibiotics (amoxicillin and either clarithromycin or metronidazole). The majority of proton pump inhibitors are metabolized primarily by the CYP2C19 enzyme. PPIs work by raising the intragastric pH, which increases the stability and bioavailability of antibiotics making them more effective. Factors associated with treatment failure include, but are not limited to: antibiotic resistance, non-compliance, smoking habits, bacterial and host-related factors, and CYP2C19 genotype (Yang 2010, Sugimoto 2009). *Immunosuppressants for organ transplant* Immunosuppressant drugs are used in transplant patients to prevent rejection. Regimens usually include a combination of different drugs. Immunosuppressants have a narrow therapeutic range. Overdosing can lead to infection, malignancy, and organ toxicity, whereas underdosing can lead to rejection. The current approach to prevent over- or underdosing is therapeutic drug monitoring where blood or plasma concentrations are measured and dosage is adjusted to ensure that drug concentrations remain within a narrow therapeutic range. The first 72 hours after transplantation is the most critical time as inadequate drug exposure increases the risk for rejection. Therapeutic drug monitoring is not useful for predicting the initial dose. Thus, there has been growing interest in using a pharmacogenetic approach to predict initial dose. Tacrolimus is a calcineurin inhibitor that is metabolized by CYP3A5 and CYP3A4. Patients with a functional copy of the CYP3A5 enzyme are referred to as functional expressers; patients without a functional copy of the CYP3A5 enzyme are referred to as functional non-expressers. CYP3A5 expression is thought to be associated with reduced tacrolimus exposure following oral administration, thus patients who are functional expressers may be more likely to experience rejection (Ware 2010, Staats 2010). *Selective serotonin reuptake inhibitors (SSRIs)* SSRIs are a popular class of antidepressant medications. CYP2D6 and CYP2C19 are the primary CYP450 enzymes involved in the metabolism of SSRIs. Other CYP450 and non-CYP450 enzymes also play a role in the metabolism of some SSRIs. It is thought that polymorphisms in the CYP450 enzymes can lead to variability in response to some SSRIs. Knowing a patient's genotype may be helpful in choosing an initial SSRI that is more likely to be effective (Berg 2007).

#### **10/03/2005: MTAC REVIEW**

#### **Cytochrome P450 Genotyping Test Drug Metabolizing**

**Evidence Conclusion:** There is no published evidence on using the AmpliChip cytochrome P450 genotyping test to help select medications or doses of medications. The ideal study would compare the safety and effectiveness of medications selected with and without the results of the AmpliChip cytochrome P450 genotyping test, preferably in a randomized trial. This type of study has not been published.

**Articles:** No empirical studies were identified that reported on medication selection using the AmpliChip test, or clinical outcomes following medication selection guided by the AmpliChip test. Several articles on the Affymetrix

GeneChip were identified, but none of the mentioned using the technology with the AmpliChip test. In addition, the studies on the Affymetric GeneChip used it for genetic profiling (e.g., to estimate prognosis of colon cancer patients), not to aid physicians in the selection of medications.

The use of in the evaluation of does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 08/16/2010: MTAC REVIEW

#### **Cytochrome P450 Genotyping Test Drug Metabolizing Evidence**

**Conclusion:** *Plavix*: Analytic validity

No published studies on the accuracy of commercially available tests for detecting CYP2C19 variants were identified. Clinical validity A recent meta-analysis investigated the relationship between CYP2C19\*2 polymorphisms and adverse clinical outcomes in patients with coronary artery disease (CAD) being treated with clopidogrel. Results from this analysis showed that the presence of the CYP2C19\*2 allele was associated with an increased risk of a subsequent cardiovascular event (RR 1.96,  $p=0.02$ ) and stent thrombosis (RR 3.82,  $p<0.01$ ). There was significant heterogeneity between the studies. Studies varied with regard to clopidogrel dose, duration of follow-up, and patient type. Additionally, not all studies adjusted for confounding factors. Because only one CYP2C19 variant was studied misclassification is possible (Sofi 2010). While the majority of data suggest that patients possessing at least one variant CYP2C19 allele are at an increased risk for adverse cardiovascular events, not all studies have found this association. A genetic sub-study of the Impact of the Extent of Clopidogrel- Induced Platelet Inhibition on Clinical Event Rate (EXCELSIOR) study, found that the CYP2C19 genotype was not associated with risk of death or myocardial infarction (MI); however, increased platelet reactivity was associated with the risk of death or MI and patients with at least one CYP2C19\*2 allele had increased platelet reactivity. The study was not powered to address this issue (Trenk 2008). Clinical utility No published studies were identified that prospectively compared patient outcomes managed with and without CYP2C19 genotyping. Conclusion: Analytic validity: There is insufficient evidence to determine whether CYP2C19 genotyping assays accurately and reliably detect variant CYP2C19 alleles. Clinical validity: There is insufficient evidence to determine whether the presence of CYP2C19 variant genotypes predict clinical outcomes. Clinical utility: There is insufficient evidence to determine if using CYP2C19 gene testing for predicting clopidogrel responsiveness will improve clinical outcomes.

*Tamoxifen*: Analytic validity No published studies on the accuracy of commercially available tests for detecting CYP2D6 variants were identified. Clinical validity The results of the published studies on the clinical validity of CYP2D6 gene testing for tamoxifen metabolism were conflicting. Goetz et al conducted a retrospective review of archived sample of patients from the North Central Cancer Treatment Group RCT (89-30-52) tamoxifen only arm. The objective of this study was to determine the effect of CYP2D6 metabolism on breast cancer recurrence and survival. By taking into account genotype and CYP2D6 inhibitor use, patients were classified as either poor metabolizers, intermediate metabolizers, or extensive metabolizer (normal). When extensive metabolizers were compared to decreased metabolizers (intermediate and poor metabolizers), patients with decreased metabolism had significantly shorter time to recurrence ( $p=0.034$ ), relapse-free survival ( $p=0.017$ ), and disease-free survival ( $p=0.027$ ). Overall survival did not differ significantly between extensive and decreased metabolizers. When poor metabolizers were compared to extensive metabolizers, poor metabolizers had significantly shorter time to recurrence ( $p=0.007$ ), relapse-free survival ( $p=0.005$ ), and disease-free survival ( $p=0.008$ ) than extensive metabolizers. Overall survival did not differ significantly between poor and extensive metabolizers. There was no significant difference in any of the measures of recurrence or survival between intermediate and extensive metabolizers. The major advantage of this study is that it accounted for CYP2D6 inhibitor use. One of the limitations of this study is that there were only sixteen poor metabolizers and forty intermediate metabolizers. Because of the small number of subjects the study may lack the power to detect significant differences. Also, the study only accounts for one CYP2D6 variant. Because only one variant was studied there is the possibility for misclassification (Goetz 2007). A retrospective analysis of 1,325 subjects from German and U.S. cohorts found that patients with reduced or absent CYP2D6 function had significantly shorter time to recurrence, event-free survival, and disease-free survival compared to extensive metabolizers. There was no difference in overall survival between decreased and extensive metabolizers. Patients from the 89-30-52 trial, the same population studied by Goetz, were included in this analysis. One of the limitations of the study was that the cohorts that were combined had different lengths of follow-up. Additionally, the study did not account for CYP2D6 inhibitor use. Advantages of this trial include its size and that it accounted for 5 different variant alleles (Schroth 2009). Another retrospective cohort study also found that relapse-free survival and event-free survival were significantly poorer for decreased metabolizers compared to extensive metabolizers (Schroth 2007). Not all studies have shown an association between CYP2D6 metabolism and treatment outcomes. Nowell and colleagues conducted a retrospective review of 337 archived samples. The objective of this study was to determine whether genetic variability in the tamoxifen metabolic pathway influenced overall survival in breast cancer patients treated with tamoxifen. In the study, extensive metabolizers were compared to decreased metabolizers (intermediate and poor metabolizers). Relapse-free and overall survival did not differ significantly between extensive and decreased metabolizers. One of the limitations of the study was that the authors did not control for CYP2D6 inhibitor use. Because of the small number

of subjects the study may lack power to detect significant differences. There is a potential for misclassification as only one CYP2D6 allele was accounted for. Additionally, the effects of CYP2D6 genotype on tamoxifen metabolism were not assessed separately for poor and intermediate metabolizers (Nowell 2005). Clinical utility No published studies were identified that prospectively compared patient outcomes managed with and without CYP2D6 genotyping. Conclusion: Analytic validity: There is insufficient evidence to determine whether CYP2D6 genotyping assays accurately and reliably detect variant CYP2D6 alleles. Clinical validity: There is insufficient evidence to determine whether the presence of CYP2D6 variant genotypes predict clinical outcomes. Clinical utility: There is insufficient evidence to determine if using CYP2D6 gene testing for predicting tamoxifen metabolism will improve clinical outcomes.

**Articles:** Plavix: Assessment objective: Analytic validity: Do the CYP2C19 genotyping assays accurately and reliably detect variant CYP2C19 alleles? Clinical validity: Does the presence of CYP2C19 variant genotypes predict clinical outcome? Clinical utility: Will the results of the CYP2C19 genotype assay alter clinical management and improve clinical outcomes? Medline was searched through June 2010 with the search terms *clopidogrel*, *plavix*, and *CYP2C19* with variations. The search was limited to English language publications and human populations. The reference lists of relevant studies were reviewed to identify additional publications. Sofi F, Giusti B, Marcucci R, et al. Cytochrome P450 2C19\*2 polymorphism and cardiovascular recurrences in patients taking clopidogrel: a meta-analysis. *Pharmacogenomics J* 2010; 30 March 2010. [Epub ahead of print] See [Evidence Table Tamoxifen](#): Assessment objective: Analytic validity: Do the CYP2D6 genotyping assays accurately and reliably detect variant CYP2D6 alleles? Clinical validity: Does the presence of CYP2D6 variant genotypes predict clinical outcome? Clinical utility: Will the results of the CYP2D6 genotype assay alter clinical management and improve clinical outcomes? No randomized controlled trials were identified. The literature consisted mainly of retrospective case series and cohort studies. The results from the studies evaluating the association between tamoxifen metabolism and breast cancer recurrence and survival were conflicting, with some showing a positive association and some showing a negative association. The study by Goetz et al was selected because it took into account CYP2D6 inhibitor use. Goetz MP, Knox SK, Suman VJ, et al. The use of in the evaluation of Plavix and Tamoxifen metabolization does not meet the *Group Health Medical Technology Assessment Criteria*.

## 12/20/2010: MTAC REVIEW

### Cytochrome P450 Genotyping Test Drug Metabolizing

**Evidence Conclusion:** Atomoxetine The literature search did not reveal any studies pertaining to the analytic validity or clinical utility of CYP2D6 genotyping to predict response to atomoxetine. Several studies were found that combined data from various clinical trials to address the clinical validity of CYP2D6 genotyping. The results from these studies are presented below. Michelson et al combined data from multiple studies to examine the effect of CYP2D6 on the efficacy and safety of atomoxetine. Efficacy data was available for 589 patients (559 EM and 30 PM). The primary outcome measure was defined as a  $\geq 25\%$  decrease in ADHD total symptoms measured using the Attention-Deficit Hyperactivity Disorder Rating Scale-Parent Version: Investigator Scored and Administered (ADHDRS-IV-Parent:Inv). Significantly more PM than EM responded to treatment (80% vs. 59.4%,  $P=0.033$ ). However, PM were more likely to experience insomnia ( $P=0.035$ ), abrasion ( $P=0.012$ ), tremor ( $P<0.001$ ), and decreased appetite ( $P=0.008$ ) compared to EM. Limitations: small sample size, power was not addressed, not controlled for concomitant medications or other confounding factors, subjects were grouped into either PM or EM, included studies differed with regard to dosing and follow-up, and the research was funded by Eli Lilly (Michelson 2007). Another study combined data from two clinical trials to determine the effect of CYP2D6 genotype on the efficacy and tolerability of atomoxetine. Data was available for 1,326 patients (1,239 EM and 87 PM). Unlike the Michelson study, Trzepacz and colleagues did not find a significant difference in response, defined as a  $\geq 25\%$  decrease in the ADHDRS-IV-Parent:Inv, between PM and EM (84.9% vs. 81.6%,  $P=0.56$ ). There were no significant differences in adverse events or treatment discontinuation. Limitations: power was not addressed, not controlled for concomitant medications or other confounding factors, subjects were grouped into either PM or EM, and the research was funded by Eli Lilly (Trzepacz 2008). Ramoz and colleagues combined data from two cohort studies and also found no significant difference in treatment response, defined as a  $\geq 25\%$  decrease in the ADHDRS-IV-Parent:Inv, between PM and EM (Ramoz 2009). Codeine for nursing mothers No randomized controlled trials or cohort studies were identified pertaining to the analytic validity, clinical validity, or clinical utility of genotyping nursing mothers for CYP2D6 status before prescribing codeine. The literature search revealed one case-control study with 17 infants with symptoms of opioid toxicity, central nervous system (CNS) depression, and 55 infants without symptoms of opioid toxicity following exposure to codeine while breastfeeding. Findings from this

study indicate that there was good concordance between maternal and infant CNS depression. When the baby exhibited CNS depression, there was a 71% probability (12/17) that the mother also exhibited such signs. Mothers of symptomatic infants were 8 times more likely to have the combined CYP2D6 UM and UGT2B7\*2 genotype. UGT2B7\*2 is also associated with higher production of the active morphine metabolite. Results from this analysis are inconclusive as there were only 2 women with the combined genotype (Madadi 2009b). Efavirenz No studies were identified that addressed the analytic validity or clinical utility of genotyping to predict dosing of efavirenz. The literature pertaining to clinical validity consisted mainly of small cohort studies. Several small studies have demonstrated an association between CYP2B6 poor metabolizers and efavirenz plasma concentration. However, the number of poor metabolizers included in these studies ranged from 6 to 14. Additionally, not all individuals who were poor metabolizers had higher plasma concentrations (Haas 2004, Gatanaga 2007, Leger 2009). CYP2B6 polymorphisms are not the only factors that affect plasma levels, other drugs and enzymes may also predict efavirenz plasma concentration. To date there is insufficient evidence regarding the effects of CYP2B6 polymorphisms on clinical outcomes such as long-term virological and immunological response to efavirenz therapy.

The literature search revealed several studies pertaining to the clinical validity of genotyping to predict response to proton pump inhibitors. The majority of these studies were small and performed in Asian populations, which are known to have a higher percentage of CYP2C19 poor metabolizers, as such the results may not be generalizable to other populations. A small randomized controlled trial was identified that compared *H. pylori* eradication rates in patient receiving rabeprazole with different antibiotic regimens was not selected for review as it did not have adequate power to address differences in eradication rates by CYP2C19 metabolizer status (Yang 2009). A meta-analysis of 20 observational studies was selected for review (Zhao 2008). No studies were identified that addressed the analytic validity or clinical utility of genotyping to predict response to proton pump inhibitors. The objective of the meta-analysis was to determine whether CYP2C19 polymorphisms affect *H. pylori* eradication rates obtained with first-line PPI-based triple therapies. Eradication rates using the PPI lansoprazole and omeprazole were significantly higher for PM and IM compared to EM; however, there was no significant difference between PM and IM. There was no significant difference in eradication rates among the three genotypes for therapies using the PPI rabeprazole. The studies included in this analysis were mostly observations and thus are more prone to bias and confounding. Studies using difference antibiotic combinations were analyzed together. Additionally, other factors such as antibiotic resistance rates may affect *H. pylori* eradication rates (Zhao 2008). Not all studies have found an association between CYP2C19 genotype and *H. pylori* eradication rates. A cohort study conducted in Korea that included 174 subjects and was published after the meta-analysis found no significant difference in eradication rates by CYP2C19 genotype for patient treated with pantoprazole, amoxicillin, and clarithromycin twice daily. As this study was not randomized it may be prone to bias. There were only 39 poor metabolizers included in the study, so it may lack the statistical power to detect a difference between the CYP2C19 genotypes (Oh 2009).

Immunosuppressant for organ transplantation The literature search did not reveal any studies addressing the analytic validity of genotyping to predict response to tacrolimus. With regard to clinical validity, several cohort, case-control, and cross sectional studies were identified that looked at the effect of CYP3A5 polymorphisms on tacrolimus concentrations. A prospective cohort study was selected for review (Hesselink 2008). One randomized controlled trial was identified that addressed the clinical utility of genotyping to predict initial doses; however, this study was not selected for review as patients were genotyped after transplantation and tacrolimus was not initiated until 7 days after transplantation (Thervet 2010). RCT are currently underway to determine the efficacy of genotype guided initial dosing. A recent prospective cohort study compared the effect of CYP3A5 genotype on (weight-adjusted) tacrolimus exposure and dose, as well as the incidence of acute rejection after kidney transplantation. Results from this study suggest that CYP3A5 expressers require higher drug doses than non-expressers to reach target predose concentrations. The overall daily tacrolimus dose was 60% higher for CYP3A5 expressers compared to non-expressers (95% CI, 35-89%,  $P < 0.001$ ). Additionally, significantly more CYP3A5 expressers had a predose concentration below 10 ng/ml, which is the recommended minimum predose concentration in the early phase after transplantation, compared to non-expressers on day 3 after transplantation (28 vs. 10%,  $P = 0.02$ ). On study day 10 and thereafter predose concentration was comparable between the two groups. There was no statistically significant difference in the incidence of biopsy-proven acute rejection ( $P = 0.36$ ) (Hesselink 2008). A prospective study of 44 renal transplant patients also failed to find an association between genotype and risk of rejection; however, this study did find that CYP3A5 expressers required a higher dose of tacrolimus to reach target concentrations (Roy 2006). It should be noted that the pharmacogenetics of tacrolimus are complex. Other factors such as genetic polymorphisms in drug transporters, differences between the donor organ and recipient's intestinal genotype, and drug interactions may all contribute to differences in the pharmacogenetics of tacrolimus. Selective serotonin reuptake inhibitors (SSRIs) The literature search revealed several case-control and cohort studies pertaining to the clinical validity of genotyping patients to predict their response to SSRIs. No studies were identified that addressed analytic validity or clinical utility. In general, studies of clinical validity were limited by inadequate power, poor and intermediate metabolizers were analyzed together, studies grouped different SSRIs together or with other classes of antidepressant medications, and studies did not provide information on variables such as diet, other medications, race/ethnicity, and other genetic factors that may influence SSRI efficacy and tolerability. The

majority of studies evaluating the clinical validity of genotyping patients to predict their response to SSRIs found no association between genotype and adverse drug reactions (Murphy 2003, Roberts 2004, Suzuki 2006, Peters 2008). One study did find an association between genotype and the occurrence of adverse events; however, there were only 8 (29%) poor metabolizers and 3 (19%) UM included in the study (Rau 2004).

**Conclusion:** There is insufficient evidence to determine the analytic validity, clinical validity, or clinical utility of genotyping for the following indications: Atomoxetine (dosing), Codeine (deciding whether to prescribe codeine for nursing mothers), Efavirenz (dosing), *Helicobacter pylori* (managing treatment), Immunosuppressant for organ transplantation (dosing), Selective serotonin reuptake inhibitors (selection or dosing)

**Articles:** There is limited evidence pertaining to the analytic validity, clinical validity, and clinical utility of CYP450 genotyping. The majority of studies identified were small observational studies that addressed the association between CYP450 genotype and intermediate outcomes. A prospective cohort study that evaluated the effect of CYP3A5 genotype on tacrolimus exposure, dose, and incidence of acute rejection, and a meta-analysis that looked at the association between CYP2C19 polymorphisms and H. pylori eradication rates were selected for review. The following studies were critically appraised: Zhao F, Wang J, Yang Y, et al. Effect of CYP2C19 genetic polymorphisms on the efficacy of proton pump inhibitor-based triple therapy for Helicobacter pylori eradication: a meta-analysis. *Helicobacter* 2008; 13:532-541. See [Evidence Table](#)  
Hesselink DA, van Schaik RHN, van Agteren M, et al. CYP3A5 genotype is not associated with a higher risk of acute rejection in tacrolimus-treated renal transplant recipients. *Pharmacogenet Genomics* 2008; 18: 339-348. See [Evidence Table](#)

The use of in the evaluation of Atomoxetine, Codeine for nursing mothers, Efavirenz, Proton pump inhibitors (PPI) for treating *Helicobacter pylori*, Immunosuppressants for organ transplant, and selective serotonin reuptake inhibitors (SSRIs) metabolism does not meet the *Group Health Medical Technology Assessment Criteria*.

## 02/13/2012: MTAC REVIEW

### Cytochrome P450 Genotyping Test Drug Metabolizing

**Evidence Conclusion:** Analytic validity No published studies on the accuracy of commercially available tests for detecting CYP2C19 variants were identified. Clinical validity Results from the 2010 MTAC review were based on a meta-analysis that included 7 cohort studies. Results from the meta-analysis showed that the presence of CYP2C19\*2 allele was associated with an increased risk of a subsequent cardiovascular event (RR 1.96, p=0.02) and stent thrombosis (RR 3.82, p<0.01); however, there was significant heterogeneity between the studies.

Studies varied with regard to clopidogrel dose, duration of follow-up, and patient type. Because of this, it was determined that there was insufficient evidence to determine whether the presence of CYP2C19 variant genotypes predict clinical outcomes (Sofi 2011). Results from both of the most recent meta-analyses suggest that there is no significant association between major cardiovascular events and CYP2C19 genotype. Both studies also found some evidence that the loss of function genotype may be associated with stent thrombosis; however, the quality of this evidence is weak due to evidence of publication bias. Meta-analyses are only as good as the studies that they include. The majority of the studies included in these analyses were small, there was variation between the studies with regard to the components of the primary endpoint, and misclassification is possible as not all alleles were typed (Bauer 2011, Holmes 2011). Clinical Utility No published studies were identified that prospectively compared patient outcomes managed with and without CYP2C19 genotyping.

**Articles:** The literature consisted mainly of cohort studies and genetic sub-studies of randomized controlled trials. No studies were identified that examined the analytic validity of CYP2C19 genotyping. Several meta-analyses were identified that evaluated the association between CYP2C19 and the clinical efficacy of clopidogrel. However, only 2 of these analyses included additional studies that were not included in the 2010 MTAC review. Both of these meta-analyses were selected for review. Several studies were identified that looked at the effect of higher doses of clopidogrel or other medications on platelet reactivity in patients with the CYP2C19 loss of function genotype; however, since platelet reactivity is an intermediate marker, none of these studies were selected for review. No studies were identified that looked at the effect of CYP2C19 genotyping on long term clinical outcomes such as major cardiovascular events. The following studies were critically appraised: Bauer T, Bouman HJ, van Werkum JW, Ford NF, ten Berg JM, Taubert D. Impact of CYP2C19 variant genotypes on clinical efficacy of antiplatelet treatment with clopidogrel: systematic review and meta-analysis. *BMJ*. 2011;343:d4588. See [Evidence Table](#)  
Holmes MV, Perel P, Shah T, Hingorani AD, Casas JP. CYP2C19 genotype, clopidogrel metabolism, platelet function, and cardiovascular events: a systematic review and meta-analysis. *JAMA*. 2011;306:2704-2714. See [Evidence Table](#)

The use of in the evaluation of Plavix and Tamoxifen metabolism does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Epidermal Growth Factor Receptor (EGFR)**

### **BACKGROUND**

Lung cancer is one of the most common causes of cancer death, accounting for over 1 million deaths annually. Non-small-cell lung cancer (NSCLC) accounts for approximately 80% of lung cancers and the majority of cases present at an advanced stage. For patients with good performance status, platinum-based chemotherapy constitutes standard first-line treatment. However, a therapeutic plateau has been reached with conventional chemotherapy for NSCLC patients. Advances in the knowledge of molecular mechanisms of carcinogenesis has led to the development of new molecular-targeted agents. Current research efforts focus on a number of promising agents targeted against the epidermal growth factor receptor (Yoshida 2010, Campbell 2010). The epidermal growth factor receptor (EGFR) is normally present on the surface of epithelial cells, and plays an important role in regulating cellular processes such as proliferation, differentiation, survival, and maintenance of normal epidermal tissues. Researchers observed that when the function of EGFR becomes deregulated, it contributes to the growth and survival of cancer cells (Huang 2004, Ettinger 2006). The role of EGFR in carcinogenesis led to the development of several therapeutic agents which specifically target growth factor pathways that are deregulated in tumor cells. Tyrosine kinase inhibitors (TKIs) are one of these agents. Results of clinical trials on TKIs are conflicting and show a significant variability in response and survival rates. Some trials showed an improved survival when used after first or second-line chemotherapy, while others failed to show significant response and/or survival benefit. The investigators attributed the lack of benefit to the lack of patient selection in the trials, i.e. the inclusion of unselected NSCLC population in the studies. This was based on the observation that cancer cell lines and tumors are selectively susceptible to inhibition of the EGFR pathway. Results of subgroup analysis of data from observational studies suggest that the response to TKIs is also associated with a number of clinical and biological factors including gender, ethnic origin, smoking status, and histology of the cancer. More recently in 2004, the clinical responsiveness to the TKIs gefitinib and erlotinib were correlated to specific somatic EGFR mutations in the TK domain in NSCLC. The two most common activating mutations seen in patients are exon 19 deletions, and the exon 21 mutation L858R. Data from retrospective studies suggested that these mutations occurred more frequently among females, non-smokers, patients from East Asia, and those with adenocarcinoma histology (Linardou 2009). Extensive research is underway to identify the optimal molecular or genetic biomarkers that can predict the efficacy of a therapeutic agent for treating NSCLC and other malignancies. Predictive biomarkers include EGFR protein expression, gene copy number, mutation status, and others. A qualitative immunohistochemical (IHC) kit for EGFR gene expression testing (the Dako Cytomation EGFR pharmDx™ assay) was approved by the FDA in 2004 as an aid to identify colorectal cancer patients eligible for treatment with the cancer drug cetuximab. In June 2005, the FDA issued an alert that new patients should not be given gefitinib, and limited its use to cancer patients who have already taken the medicine and whose doctor believe it is helping them. Erlotinib is another TKI that was approved by the FDA for treatment of locally advanced or metastatic non-small-cell lung cancer (NSCLC) after failure of at least one prior chemotherapy regimen. In June, 2005 the FDA issued an alert that new patients should not be given gefitinib, and limited its use to cancer patients who have already taken the medicine and whose doctor believes it is helping them. Erlotinib is another TKI that was approved by the FDA for treatment of locally advanced or metastatic non-small-cell lung cancer (NSCLC) after failure of at least one prior chemotherapy regimen.

### **08/04/2008: MTAC REVIEW**

#### **Epidermal Growth Factor Receptor (EGFR)**

**Evidence Conclusion:** In order to identify the optimal molecular or genetic biomarkers that predict the efficacy of a therapeutic agent, the biomarker should have a plausible relationship with the biology of the disease, and should have a standardized reproducible test, as regards the reagent, performance, analysis and interpretation. There also should be standards for the tumor sample size and fixation. Several potential biomarkers have been identified, but none was validated in randomized controlled trials, to date. Moreover, as the literature indicates, there is no standardized methodology for tissue sampling, nor a standardized reproducible assay for EGFR- expression that would allow a direct comparison of the results obtained from different laboratories. The majority of the published trials on EGFR testing and the use of TKIs in patients with NSCLC were small prospective and retrospective case series. There were variations in the inclusion criteria, time of taking and fixation of the tumor tissue samples, as well as other differences in the study designs, which could be potential sources of bias and confounding. In several studies, biomarker assessment was done among a small proportion of patients due to lack of tissue availability. The studies used different tests and arbitrary cut-offs for identifying EGFR mutations as well as unvalidated techniques with no standardized criteria for quantification, processing, scoring, and reporting of the results. Most importantly TKI therapy was not compared to an alternative therapy. Without an appropriate control it is not possible to differentiate between the predictive and prognostic significance of a biomarker.\* Moreover, the published trials retrospectively correlated the response to TKIs treatment and/or survival with the EGFR status based on tumor specimens collected at initial diagnosis. This may confound the correlation analysis of EGFR mutations and response as additional mutations could have occurred during therapy. In conclusion, the role of EGFR expression

testing as a predictive factor is not well defined. There is insufficient evidence from the published studies, to determine whether EGFR mutation is a predictive marker of clinical benefit from treatment with TKIs or only a prognostic biomarker of better survival, independent of TKI treatment. \* A prognostic marker is defined as a characteristic associated with prognosis or outcome, usually in terms of relative hazard, whereas a predictive marker is defined as a characteristic that is associated with, and predicts, treatment response.

**Articles:** The literature search revealed over 800 articles on epidermal growth factor receptor (EGFR) and TKIs. There were 4 meta-analyses of observational studies, and a number of phase II and phase III clinical trials that studied the effects of specific TKIs and retrospectively correlated the outcomes with EGFR. The phase III trial (Tsao 2005) that compared erlotinib (a TKI) to placebo retrospectively correlated the outcome to EGFR mutation. The three most recent meta-analyses were critically appraised. The use of Epidermal growth factor receptor (EGFR) testing in the treatment of NSCLC to Tyrosine Kinase Inhibitors (TKIs) does not meet the *Group Health Medical Technology Assessment Criteria*.

## 10/18/2010: MTAC REVIEW

### Epidermal Growth Factor Receptor (EGFR)

**Evidence Conclusion:** Analytic validity There are variety of methods used to detect EGFR mutations. Each of these assays has its advantages and limitations. Rapid detection of EGFR mutations with multiplex PCR and primer was found to be highly accurate compared to direct sequencing. In a sample of 81 tumors the two methods identified the same 26 mutations (Lin 2010). Clinical validity The Iressa Pan-Asian Study (IPASS) was a phase 3, multicenter, randomized, open-label trial comparing gefitinib with carboplatin plus paclitaxel as first-line treatment in 1217 clinically selected patients in East Asia with advanced non-small-cell lung cancer. In the overall population, the median progression-free survival (PFS) was 5.7 months in the gefitinib group and 5.8 months in the carboplatin plus paclitaxel group. The probability that a patient would be free of disease progression was greater with carboplatin-paclitaxel in the first 6 months and greater with gefitinib in the following 16 months. The objective response rate was significantly higher with gefitinib than with carboplatin plus paclitaxel. Overall survival did not differ between the two treatment groups; however, there were less than 100 events in each group. A preplanned subgroup analysis by EGFR mutation status was also performed. EGFR mutation status could be determined for 437 subjects (35.9%). Patients with sensitive EGFR mutations who received gefitinib had longer PFS, higher response rates, and a lower rate of adverse events compared to patients with sensitive EGFR mutations taking carboplatin plus paclitaxel. However, results should be interpreted with caution as EGFR status could only be evaluated for 35.9% of the original study population and patients were not randomized based on EGFR status. The results from this study are generalizable to patients of Asian ethnicity, who were nonsmokers or former light smokers, and had adenocarcinoma of the lung. Another limitation of this study lies in the analysis. The Cox proportional-hazards model is based on the assumption that the hazard ratio of the two treatments is constant overtime. Since the curves cross, this assumption is violated. However, in the subgroup analysis (patients with EGFR mutations) this assumption is not violated (Mok 2009). The results from a preplanned subgroup analysis of the INTEREST trial, a RCT comparing gefitinib to docetaxel in a Western pretreated population, were consistent with the results from the IPASS trial. However, only 44 subjects in the study were EGFR mutation-positive (Douillard 2010). **Clinical utility** Two RCT recently evaluated the efficacy of gefitinib compared to chemotherapy in patients with sensitive EGFR mutations and non-small-cell lung cancer. The first trial compared gefitinib to carboplatin plus paclitaxel chemotherapy. Patients treated with gefitinib had significantly longer progression-free survival than patients treated with carboplatin plus paclitaxel (median 10.8 vs. 5.4 months,  $P < 0.001$ ) and higher response rates (73.7% vs. 30.7%,  $P < 0.001$ ). There was no difference in overall survival between the two groups; however, the incidence of severe toxic effects was significantly higher in the chemotherapy group than in the gefitinib group (71.1% vs. 41.2%,  $P < 0.001$ ). The results from this trial are generalizable to nonsmoking patients from Asia who had not previously received chemotherapy (Maemondo 2010). The second RCT assessed the efficacy of gefitinib compared to cisplatin plus docetaxel chemotherapy in patients with sensitive EGFR mutations. Findings from this trial are similar to the aforementioned trial with progression-free survival being longer (9.2 vs. 6.3 months,  $P < 0.001$ ) and response rate being higher (61.2% vs. 32.2%,  $P < 0.001$ ) in patients treated with gefitinib compared to patients treated with cisplatin plus docetaxel. Results for overall survival could not be determined as data were immature and follow-up is still ongoing. Results from this study are generalizable to patients of Asian origin (Mitsudomi 2010). **Conclusion: Analytic validity:** There is fair evidence that rapid detection of EGFR mutations with multiplex PCR and primer extension produce

good results compared to direct sequencing. However, there is insufficient evidence concerning the reproducibility of this test. **Clinical validity:** There is fair evidence that for patients with EGFR mutations the use of the tyrosine kinase inhibitors gefitinib and erlotinib is associated with an improvement in progression-free survival and response rate. **Clinical utility:** There is fair evidence that patients managed with the genetic test had better outcomes than patients managed without the genetic test.

**Articles:** There were several articles that addressed analytic validity. One of the most recent articles was selected for review. Several trials assessed the clinical validity and clinical utility of EGFR testing. Trials were selected for review if they were published after the 2008 review and addressed the safety or efficacy of TKI in patients with EGFR mutations. The following studies were critically appraised: Mok TS, Wu YL, Thongprasert S, et al. Gefitinib or carboplatin-paclitaxel in pulmonary adenocarcinoma. *N Engl J Med* 2009; 361:947-957. See [Evidence Table](#) Maemondo M, Inoue A, Kobayashi K, et al. Gefitinib or chemotherapy for non-small-cell lung cancer. *N Engl J Med* 2010; 362:2380-2388. See [Evidence Table](#). Mitsudomi T, Morita S, Yatabe Y, et al. Gefitinib versus cisplatin plus docetaxel in patients with non-small-cell lung cancer harboring mutations of the epidermal growth factor receptor (WJTOG3405): an open label, randomized phase 3 trial. *Lancet Oncol* 2010; 11:121-128. See [Evidence Table](#)

The use of Epidermal growth factor receptor (EGFR) testing in the treatment of NSCLC to Tyrosine Kinase Inhibitors (TKIs) does meet the *Group Health Medical Technology Assessment Criteria*.

### **Genetic Testing for IL28B Polymorphisms in Patients with Hepatitis C**

#### **BACKGROUND**

Hepatitis C virus (HCV) is a single-stranded, enveloped RNA virus that is spread through contact with the blood of an infected person. In the United States, roughly 4.1 million Americans have been infected with the HCV, making it one of the most common blood borne pathogens. After acute infection with HCV, approximately 70-80% of infected individuals will go on to develop chronic HCV, which is a leading cause of cirrhosis, liver cancer, and liver transplant in the western world (Armstrong 2006, CDC 2009, Rosen 2011). For patients with chronic HCV infection, treatment includes a combination of pegylated interferon (PEG-INF) plus ribavirin given for 24 or 48 weeks depending on genotype. Results from recent RCTs also suggest that treatment for patients with HCV genotype 1, the most common isolate in the United States, may also include a protease inhibitor in conjunction with PEG-INF plus ribavirin. Treatment success, referred to as sustained viral response (SVR), is defined as the absence of virus 24 weeks after treatment completion. Less than 50% of patients HCV genotype 1 respond to therapy with PEG-INF plus ribavirin compared to around 80% of patients with HCV genotype 2 and 3. Besides genotype, female gender, white ethnicity, age less than 45 years, low HCV RNA levels at baseline, and lack of cirrhosis are considered to be predictors of viral response. Treatment for HCV is expensive and associated with numerous side effects such as anemia and neutropenia, which can lead to dose reduction or premature termination, thus increasing the risk of treatment failure. Research is currently underway to identify factors that could help patients and clinicians make more informed decisions regarding the risk and benefit of treatment and the likelihood of treatment response. Recent studies suggest that polymorphisms in the IL28B gene may be a useful predictor of treatment response (Clark 2011, Ghany 2009, Mangia 2011, Rauch 2010, Rosen 2011). The IL28B gene encodes interferon (INF) lambda, a cytokine that shares the same intercellular pathway of INF alpha, the drug currently used in combination with ribavirin for the treatment of chronic HCV. Genome wide association studies suggest that polymorphisms in the IL28B gene may be associated with response to antiviral treatment with PEG-INF plus ribavirin in patients with HCV genotype 1. However, it is important to note that IL28B polymorphisms do not explain all treatment failure, and patients with the non-responder genotype may still respond to therapy (Ahlenstiel 2010, Mangia 2011).

#### **10/17/2011: MTAC REVIEW**

### **Genetic Testing for IL28B Polymorphisms in Patients with Hepatitis C**

#### **Evidence Conclusion:** Analytic validity

No studies were identified that evaluated the analytic validity of genetic testing for IL28B polymorphisms in patients with chronic hepatitis C infections. **Clinical validity** A recent genome-wide association study (GWAS) identified seven single nucleotide polymorphisms (SNPs) around the IL28B gene that were associated with SVR in patients with chronic genotype 1 HCV infection. The most strongly associated SNP was rs12979860 followed by rs8099917. Results from this study suggest that the rate of viral response in European-Americans and Hispanics with the CC genotype was twofold higher compared to patients with the TT genotype. The rate of viral response in African-Americans was threefold higher compared to patients with the TT genotype. No replication cohort was performed (Ge 2009). Two other GWAS in different populations also found that polymorphisms on the IL28B gene locus were associated with SVR. The first study found that the rs8099917 SNP on the IL28B gene was associated with SVR in Australian patients with chronic HCV infection. These results were replicated in an independent cohort of Europeans from the United Kingdom, Germany, Italy, and Australia (Suppiah 2009). The second study found that in Japanese patients with genotype 1 HCV, SNPs near the IL28B chromosome (rs8099917 and rs12980275) were associated with SVR. These results were replicated in an independent cohort on Japanese patients with

HCV infection (Tanaka 2009). Clinical utility No studies were identified that evaluated the clinical utility of genetic testing for IL28B polymorphisms in patients with chronic hepatitis C infections. Conclusion: Analytic validity: No studies were identified that evaluated analytic validity of genetic testing for IL28B polymorphisms in patients with chronic hepatitis C infections. Clinical validity: Results from several GWAS suggest that SNPs around the IL28B gene may be associated with SVR in patients with chronic genotype 1 HCV infection. Clinical utility: No studies were identified that evaluated the clinical utility of genetic testing for IL28B polymorphisms in patients with chronic hepatitis C infections.

**Articles:** The literature search identified several genome-wide association studies that identified polymorphisms near the IL28B gene locus as predictors of response to treatment in patients with chronic hepatitis C infection. The largest study was selected for review. No studies were identified that evaluated the analytic validity or clinical utility of genetic testing for IL28B polymorphisms in patients with chronic hepatitis C infection. The following study was critically appraised: Ge D, Fellay J, Thompson AJ, et al. Genetic variation in IL28B predicts hepatitis C treatment-induced viral clearance. *Nature*. 2009;461:399-401. See [Evidence Table](#)

The use of IL28B polymorphisms does not meet the *Group Health Medical Technology Assessment Criteria*.

### **KRAS Mutation Testing for Predicting Response to Treatment in Patients with Advanced Colon Cancer**

#### BACKGROUND

Nearly a million new cases of colorectal cancer (CRC) are diagnosed worldwide each year, and about half a million people die from CRC annually. In the United States, CRC is the most common form of cancer in people aged 75 and older (Boyle and Leon, 2002). The length of survival of people with metastatic colorectal cancer has increased from approximately 12 months to 20 months in the past decade. This improvement has been attributed largely to the introduction of new treatments, including chemotherapeutic agents and novel targeted drugs (Di Fiore et al., 2007). Novel therapies include those that target the epidermal growth factor receptor (EGFR) signaling pathway which is believed to be involved in colorectal carcinogenesis. EGFR expression has been found in 60-80% of colorectal tumors (Heinemann et al., 2008). Two new monoclonal antibody inhibitors, cetuximab (Merck) and panitumumab (Amgen), are designed to block EGFR, thereby preventing the activation of downstream signaling pathways and inhibiting tumor cell proliferation. The new targeted therapies are costly and potentially increase the toxicity of treatment. It is thus desirable to select the patients most likely to respond to these treatments. Research is underway to identify biomarkers that predict response to the EGFR inhibitors. One biomarker under investigation is mutations in the K-ras gene (KRAS). KRAS mutations occur in approximately 20-50% of CRC tumors. It is believed that, in patients with mutant KRAS genes, treatment with the new monoclonal antibody inhibitors does not prevent signaling of EGFR, and consequently that the therapies should only be given to patients with wild-type (i.e. non-mutant) KRAS genes (Heinemann et al., 2008). Research first suggested that KRAS mutation selection might be useful for metastatic CRC patients who failed initial chemotherapy and are considering second-line treatment with cetuximab, as monotherapy, or in combination with irinotecan. KRAS mutation selection is also being proposed for first-line treatment with FOLFIRI, with or without cetuximab. A genetic test is available to determine whether the KRAS gene contains mutations. Response Genetics (Los Angeles) has a PCR-based test. KRAS mutation testing for colorectal cancer patients has not been previously reviewed by MTAC.

#### **02/02/2009: MTAC REVIEW**

#### **KRAS Mutation Testing for Predicting Response to Treatment in Patients with Advanced Colon Cancer**

**Evidence Conclusion:** Analytic validity: No published articles on the accuracy of commercially available tests for detecting KRAS mutations were identified. Clinical validity: The three retrospective cohort studies evaluated (Lievre et al. 2008; DeRoock et al., 2008; DiFiore et al., 2007) all found that second-line treatment with cetuximab monotherapy or combination treatment was not effective in any of the patients with mutant KRAS genes (0% treatment response). The response rate in patients without mutations varied from 28-44%. Two of the three studies found a significantly higher rate of progression-free survival in patients with wild-type KRAS versus mutant forms. Only two studies reported overall survival; both found a significantly higher rate in patients with wild-type versus mutant KRAS. Limitations common to the three studies is that the analyses were retrospective, and subject to confounding--there may have been other differences between patients with wild-type and mutant KRAS genes that affected outcome. In addition, the vast majority of patients in the cohort studies received combination therapy as second-line treatment. Thus, one cannot disentangle the effectiveness of cetuximab from the irinotecan-based chemotherapy. This makes it difficult to make conclusions about what treatment patients should receive. Even if one concluded that KRAS mutation status impacts treatment outcomes, it is not possible from these studies to conclude that a monoclonal antibody inhibitor is necessary for treatment success. The Bokemeyer RCT provides some evidence on the added impact of treatment with cetuximab, as first-line treatment. Overall, there was no significant difference in response rate when cetuximab was added to FOLFOX-4 compared to FOLFOX-4 alone. However, in the sub-analysis by KRAS mutation status, there was a better response when cetuximab was added to chemotherapy for patients with wild-type KRAS genes. Clinical utility: No

published articles were identified that prospectively managed patients with and without KRAS mutation testing were identified.

**Articles:** No published articles were identified on the accuracy of any commercially available test for detecting KRAS mutations. There were several retrospective cohort studies that evaluated the statistical association between KRAS mutation status and clinical outcomes with second-line treatment. Three studies (Lievre et al. 2008; DeRoock et al., 2008; DiFiore et al., 2007) were critically appraised. In addition, there was one published RCT evaluating first-line treatment, with a secondary analysis by KRAS mutation status (Bokemeyer et al., 2008), and this was critically appraised. Two unpublished RCTs were also identified that included analyses of outcomes by KRAS status. Both trials were presented as abstracts at the 2008 annual meeting of American Society of Clinical Oncology. The CRYSTAL study (Van Cutsem et al., 2008) evaluated patients receiving first-line treatment and the EVEREST study (Tejpar et al., 2008) evaluated second-line treatment. In terms of clinical utility of KRAS mutation testing for treatment selection, the ideal study would randomize patients to be managed with and without KRAS testing. For those managed with KRAS mutation testing, only patients with wild-type KRAS genes would receive cetuximab (second-line treatment) or FOLFIRI with or without cetuximab (first-line treatment). No randomized or non-randomized controlled trial that prospectively conducted KRAS testing was identified. Citations for the studies that were reviewed are as follows: Bokemeyer C et al. Fluorouracil, leucovorin, and oxaliplatin with and without cetuximab in the first-line treatment of metastatic colorectal cancer. *J Clin Oncol* 2008 (Epub ahead of print). [See Evidence Table](#). The use of KRAS mutation testing for predicting response to treatment in patients with advanced colon cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 08/16/2010: MTAC REVIEW

#### **KRAS Mutation Testing for Predicting Response to Treatment in Patients with Advanced Colon Cancer**

**Evidence Conclusion:** Analytic validity No studies were identified that directly compared the Response Genetics test to another test. A recent study compared four different methods of KRAS mutation testing—Sanger sequencing, array analysis, melting curve analysis, and pyrosequencing. The study included samples from 263 patients with colorectal cancer. Results from this study indicate that there was very good agreement between the four methods ( $\kappa > 0.9$ ). As to date there is no reliable, predetermined gold standard method for comparison, direct estimates of the sensitivity and specificity of the respective methods is not possible (Weichert 2010). Clinical validity Treatment regimens differed across the studies; however, there was a consistent message that for patients with mutant KRAS tumors the addition of the monoclonal antibodies cetuximab and panitumumab did not increase progression-free, overall survival, or response rate compared to mutant KRAS tumor patients who were not treated with a monoclonal antibody. *First-Line* Three RCTs conducted retrospective subgroup analyses to investigate the influence of KRAS mutation status on progression-free survival (PFS), overall survival (OS), and response rate. The Von Cutsem study analyzed data from the CRYSTAL trial. This trial was a randomized, open-label, multi-centered study that compared 14-day cycles of cetuximab plus FOLFIRI to FOLFIRI alone. For patients with mutant KRAS tumors, there was no difference between response rate, PFS, or OS between the two treatment groups. When patients with wild-type KRAS tumors were compared to patients with mutant KRAS tumors there was no difference between the groups for PFS or OS; however, the response rate was higher for patients with wild-type tumors (Von Cutsem 2009). Tol et al analyzed data from the CAIRO2 trial. This was an open-label randomized trial that evaluated the addition of cetuximab to capecitabine, oxaliplatin, and bevacizumab as first-line treatment in patients with metastatic colorectal cancer. Patients with mutant KRAS tumors who did not take cetuximab had significantly longer PFS and OS and higher response rates compared to patients who took cetuximab. Compared to patients with mutant KRAS tumors taking cetuximab, patients with wild-type KRAS tumors taking cetuximab had longer PFS, OS, and higher response rates. There was no significant difference in PFS, OS, or response rates for between mutant and wild-type patients not taking cetuximab (Tol 2009). Hecht and colleagues used data from the PACCE trial that evaluated panitumumab added to bevacizumab and oxaliplatin-based chemotherapy (cohort 1) or irinotecan-based chemotherapy (cohort 2). There was no significant difference in PFS or OS for patients with mutants KRAS tumors in either cohort (Hecht 2008). *Second-Line* No new information was identified since the 2008 MTAC review. Evidence for the 2008 MTAC review: The three retrospective cohort studies evaluated (Lievre 2008; DeRoock 2008; DiFiore 2007) all found that second-line treatment with cetuximab monotherapy or combination treatment was not effective in any of the patients with mutant KRAS genes (0% treatment response). The response rate in patients without mutations varied from 28- 44%. Two of the three studies found a significantly higher rate of progression-free survival in patients with wild-type KRAS versus mutant forms. Only two studies reported overall survival; both found a significantly higher rate in patients with wild-type versus mutant KRAS tumors. *Third-Line* Two RCTs conducted

retrospective subgroup analyses to investigate the influence of *KRAS* mutation status on progression-free survival (PFS), overall survival (OS), and response rate. Amado and colleagues used data from a trial that evaluated panitumumab monotherapy versus best supportive care (BSC) for patients with chemotherapy-refractory metastatic colorectal cancer. In this trial, patients in the BSC arm could receive panitumumab after disease progression. The effects of panitumumab on PFS were significantly greater for patients with wild-type tumors compared to patients with mutant tumors. As this was a crossover study, reliable overall survival measures cannot be obtained. Response rate data were missing for 19% of the population (13% wild-type *KRAS* and 26% mutant *KRAS*). For patients with wild-type *KRAS* taking panitumumab 17% had a partial response; no responders were identified in any other group (Amado 2008). Karapetis and colleagues used data from a phase 3 trial that examined the effects of cetuximab on patients with chemotherapy-refractory colorectal cancer versus BSC. There was no difference in PFS or OS for patients with mutant *KRAS* tumors between the treatment groups. The effects of cetuximab on PFS and OS were significantly greater for patients with wild-type tumors compared to patients with mutant tumors. In the cetuximab group, the response rate was 12.8% for wild-type *KRAS* tumors and 1.2% for mutant *KRAS* tumors. None of the patients in the BSC group had an objective tumor response (Karapetis 2008). All analyses were retrospective and therefore are subject to confounding – other differences between patients with wild-type and mutant *KRAS* genes could have affected the outcome. Patients in the RCTs were not randomized based on their *KRAS* mutation status. A subset of subjects from the RCT was used for analysis. Samples could only be obtained from 45%-92% of the primary analysis populations. Not all *KRAS* mutations were assessed. Mutations in codon 62 would have been missed even though this is a less prevalent mutation (~3% of mutations) it still may result in misclassification. The trials received industry funding. In the study conducted by Hecht and colleagues, censoring could have altered the PFS results. Additionally, response rate data was missing from 19% of the subjects in the Amado study. Clinical utility No studies were identified that specifically addressed clinical utility. However, identifying patients who will not respond to therapy will avoid the administration of an ineffective treatment and its associated toxicities.

**Conclusion:** A medical technology review from Blue Cross Blue Shield (BCBS) in conjunction with Kaiser Permanente from 2008 was identified. BCBS found sufficient evidence to approve the use of *KRAS* mutation analysis to predict non-response to the anti-EGFR monoclonal antibodies cetuximab and panitumumab based on retrospective genetic sub-studies from randomized controlled trials. Analytic validity: There is fair evidence that there is very good agreement between Sanger sequencing, array analysis, melting curve analysis, and pyrosequencing for the detection of a *KRAS* mutation. However, there is insufficient evidence concerning the sensitivity, specificity, and reproducibility of these tests. Clinical validity: There is fair evidence that for patients with *KRAS* mutations the use of the monoclonal antibodies cetuximab and panitumumab is not associated with an improvement in overall or progression-free survival. Clinical utility: There is insufficient evidence to determine that patients managed with the genetic test had better outcomes than patients managed without the genetic test. However, identifying patients who will not respond to therapy will avoid the administration of an ineffective treatment and its associated toxicities.

**Articles:** A number of studies comparing different methods of *KRAS* mutation detection were identified. The trial with the largest sample size was selected for review. Several randomized controlled trials were identified that included a retrospective subset analysis of treatment efficacy in relations to *KRAS* mutation status. No studies were identified that addressed the clinical utility of *KRAS* mutation testing. A recent retrospective cohort study that evaluated the efficacy of cetuximab in patients with chemotherapy-refractory metastatic colorectal cancer treated with cetuximab plus chemotherapy was not included in this review as the study population was heterogeneous with regard to treatment regimen and line of chemotherapy. Additionally, approximately one third of the study population was included in previous reports. The results from this study were consistent with the studies that were selected for review (De Roock 2010). The following studies were critically appraised: Weichert W, Schewe C, Lehmann A, et al. *KRAS* genotyping of paraffin-embedded colorectal cancer tissue in routine diagnostics. *J Mol Diagn* 2010; 12:35-42. [See Evidence Table](#) Van Cutsem E, Claus-Henning K, Hitre E, et al. Cetuximab and chemotherapy as initial treatment for metastatic colorectal cancer. *N Engl J Med* 2009; 360:1408-1417. The use of *KRAS* mutation testing for predicting response to treatment in patients with advanced colon cancer does meet the *Group Health Medical Technology Assessment Criteria*.

### **Oncotype DX**

#### **BACKGROUND**

**Breast Cancer-** About 15-30% of breast cancer cases are estrogen-dependent and node-negative cancer (INTC presentation). After surgery, women with this type of breast cancer are generally prescribed anti-estrogen therapy such as tamoxifen that has mild adverse effects and proven benefits. In addition, chemotherapy is often prescribed. The likelihood of distant recurrence in patients with estrogen-dependent, node-negative breast cancer treated with tamoxifen alone after surgery is about 15% at 10 years (Fisher et al., 2004). That is, about 85% of women do not need adjuvant chemotherapy. Chemotherapy has adverse effects, both short-term (e.g. nausea, vomiting, fatigue, risk of thrombosis) and long-term (e.g. premature menopause, weight gain, cardiotoxicity). A reliable method of determining which patients would derive benefit from chemotherapy would save many women from unnecessary adverse effects. Traditional prognostic criteria for predicting breast cancer recurrence include age, tumor size and tumor grade. Use of these criteria, however, lacks precision. Several groups of researchers are developing panels of genetic markers to predict the likelihood of breast cancer recurrence in women with node-negative breast cancer. Oncotype Dx, developed and marketed by Genomic Health Inc.(GHI) in Redwood City, CA, is the first commercially available test using genetic markers to guide breast cancer treatment. Oncotype Dx was developed using a multi-step process. First, GHI developed a real-time, reverse-transcriptase-polymerases-chain-reaction (RT-PCR) method to quantify gene expression with the use of sections of fixed, paraffin-embedded tumor tissue. RT-PCR is one of several current techniques for gene expression analysis. Next, the developers selected 250 potential genes based on reports in the literature or in genomic databases. Third, they analyzed data from three independent studies of breast cancer patients (total n=447) to test the relation between the expression of each of the 250 genes and breast cancer recurrence. The results of the three studies were then used to select a panel of 21-genes. GHI developed an algorithm to compute a recurrence score (Paik, 2004). Oncotype Dx tests are performed in the GHI laboratory. The recurrence score is calculated using the proprietary Oncotype Dx algorithm. Results are provided as the likelihood of distant recurrence at 10 years. Oncotype Dx is intended for women with newly diagnosed stage 1 or II breast cancer that is node-negative and estrogen-receptor-positive and who will be treated with tamoxifen (manufacturer's Website). Oncotype Dx has not been reviewed by the FDA. The FDA has technical authority but does not currently actively regulate tests that are developed and conducted in-house by clinical laboratories.

**Colorectal Cancer** - Nearly a million new cases of colorectal cancer (CRC) are diagnosed worldwide each year and about half a million people die from CRC annually. In the United States, CRC is the most common form of cancer in people aged 75 and older (Boyle 2002). The length of survival of people with metastatic colorectal cancer has increased from approximately 12 months to 20 months in the past decade. This improvement has been attributed largely to the introduction of new treatments, including chemotherapeutic agents and novel targeted drugs (DiFiore 2007). Several randomized controlled trials (RCT) have shown that adjuvant chemotherapy improves overall survival in patients with stage III disease; however, a clear benefit for patients with stage II disease has not been established. Findings from the QUASAR trial, a RCT designed to determine the effects of 5-FU/LV (fluorouracil/leucovorin) compared to observation in patients with predominantly stage II colorectal cancer, suggest that stage II patients may benefit from 5-FU-based adjuvant therapy. However, since the majority of patients with stage II disease can be cured with surgery alone it is important to identify patients who are likely to develop metastasis and who will benefit from adjuvant chemotherapy (Gangadhar 2010). Currently, the risk of recurrence in stage II disease is clinically determined by histologic staging, extended to include evidence of lymphatic or vascular invasion, tumor grade, and the number of lymph nodes identified and examined in the surgical specimen (Midgley 2010). Biomarkers could also be useful in this assessment. Recently, a quantitative multigene expression assay has been developed with the aim of improving treatment decision-making in the setting of stage II colon cancer and is now being marketed as the Oncotype DX® colon cancer assay (Genomic Health Inc., Redwood City, CA). The Oncotype DX® colon cancer assay was derived from an initial set of 761 candidate genes to create a 12-gene panel assay that uses real-time PCR to measure the expression of 7 genes prognostic for relapse-free survival 5 reference genes used for normalization. The assay is performed on excised tumors and yields a prognostic recurrence score that ranges from 0 to 100. The recurrence score is used to improve patient selection criteria for adjuvant chemotherapy (Kerr 2009).

#### **04/04/2005: MTAC REVIEW**

##### **Oncotype DX**

**Evidence Conclusion:** Oncotype Dx is a test that is used to predict risk of distant recurrence in women with node-negative and estrogen-receptor-positive breast cancer. There is one published validation study (Paik, 2004) in which Oncotype test results were divided into three risk categories (low, intermediate or high) and the risk categories were correlated with the likelihood of distant recurrence over 10 years. Significantly fewer patients who were categorized as low-risk experienced distant recurrence compared to those categorized as high-risk (6.8% vs. 30.5%). The risk score contributed information on recurrence beyond that provided by age and tumor size. The Paik study included only patients who were treated with tamoxifen. The primary authors of the published study have substantial financial links to the Genomic Health Inc., the company that developed Oncotype Dx. There are

no published data on the use of Oncotype Dx on women who are not treated with tamoxifen. There is no evidence that the recommendation for chemotherapy would change based on Oncotype Dx results or that changing treatment based on Oncotype Dx results would improve health outcomes.

**Articles:** The search yielded 43 articles. Many were on technical aspects of developing genetic assays. There was one published article on methods used to develop the test; this was not evaluated further because it did not address test accuracy. One published validation study was identified and this was critically appraised. There were also several unpublished abstracts and posters, including presentations at the 27th San Antonio Breast Cancer Symposium (SABCS) in December 2004. One of the SABCS posters reported on a case-control study conducted at Kaiser, Northern California to evaluate the Oncotype Dx recurrence score (Habel et al, unpublished manuscript). The study includes both women treated with and without tamoxifen. In the presentation, findings were primarily presented on the group treated with tamoxifen. The unpublished abstracts and posters do not meet the GHC criteria for evaluable evidence. *The reference for the published validation study is as follows:* Paik S, Shak S, Tang G. et al. A multigene assay to predict recurrence of tamoxifen-treated, node-negative breast cancer. *NEJM* 2004; 351: 2817-2826. See [Evidence Table](#)

The use of Oncotype Dx in the evaluation of the likelihood of distal recurrence in patients with estrogen-dependent, node-negative breast cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **10/18/2010: MTAC REVIEW**

##### **Oncotype DX**

**Evidence Conclusion:** There is insufficient evidence to determine the analytic validity, clinical validity, and clinical utility of the *Oncotype DX*<sup>®</sup> colon cancer assay.

**Articles:** No articles were identified that addressed the analytic validity, clinical validity, or clinical utility of the *Oncotype DX*<sup>®</sup> colon cancer assay. Conclusion: There is insufficient evidence to determine the analytic validity, clinical validity, and clinical utility of the *Oncotype DX*<sup>®</sup> colon cancer assay.

The use of Oncotype Dx in the evaluation of the colorectal cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **04/16/2010: MTAC REVIEW**

##### **Oncotype DX**

**Evidence Conclusion:** Analytic validity No studies were identified that assessed the sensitivity and specificity of the *Oncotype DX*<sup>®</sup> colon cancer assay. Clinical validity A recent retrospective analysis of the Quick Simple and Reliable (QUASAR) trial evaluated whether the Oncotype<sup>®</sup> DX assay can provide clinically relevant information to assist treatment decision making in patients with resected stage II colon cancer. The assay yields a prognostic recurrence score that ranges from 0 to 100 and a treatment score. Results from this trial suggest that recurrence score (RS) was significantly associated with the risk of recurrence even after controlling for other factors such as tumor location, T stage, grade, nodes examined, lymphovascular invasion, and MMR deficient. The estimated recurrence risk at 3 years was 12% for the low recurrence risk group (RS<30), 18% for the intermediate recurrence risk group (RS 30-40), and 22% for the high recurrence risk group (RS≥40). The treatment score was not predictive of chemotherapy benefit (Gary 2011). Clinical utility No studies were identified that assessed the clinical utility of the *Oncotype DX*<sup>®</sup> colon cancer assay.

Conclusion: Analytic validity: There is insufficient evidence to determine the analytic validity of the *Oncotype DX*<sup>®</sup> colon cancer assay. Clinical validity: Results from a retrospective analysis suggest that the *Oncotype DX*<sup>®</sup> colon cancer assay recurrence score may be associated with recurrence risk in patients with stage II colon cancer. Results from this study also suggest that the *Oncotype DX*<sup>®</sup> colon cancer assay treatment score was not predictive of chemotherapy benefit. Clinical utility: There is insufficient evidence to determine the clinical utility of the *Oncotype DX*<sup>®</sup> colon cancer assay.

**Articles:** Screening of articles: No studies were identified that addressed the analytic validity or clinical utility of the Oncotype DX<sup>®</sup> colon cancer assay. The following study was selected for critical appraisal: Gray RG, Quirke P, Handley K, et al. Validation study of a quantitative multigene reverse transcriptase-polymerase chain reaction assay for assessment of recurrence risk in patients with stage II colon cancer. *J Clin Oncol.* 2011;29:4611-4619. See [Evidence Table](#)

#### **Invader UGT1A1 Molecular Assay**

##### **BACKGROUND**

The Invader UGT1A1 molecular assay tests variations in a gene called UGT1A1 that produces the enzyme UDP-glucuronosyltransferase. The UDP enzyme is active in the metabolism of certain drugs, including irinotecan, a chemotherapy agent commonly used to treat colorectal and lung cancer. The active metabolite of irinotecan, SN-

38, is glucuronidated by hepatic UGTs. The main dose-limiting toxicity of irinotecan treatment is diarrhea, which is believed to be secondary to the biliary excretion of SN-38. Diarrhea associated with irinotecan-treatment can be serious and often does not respond to conventional antidiarrheal agents. The diarrhea may be due to direct enteric injury caused by the active metabolite of irinotecan, SN-38. A phase 1 clinical trial found an inverse relationship between SN-38 glucuronidation rates and severity of diarrheal incidence in patients treated with increasing doses of irinotecan. This suggests that decreased glucuronidation of SN-38 increases the risk of irinotecan-induced toxicity. Differential rates of SN-38 glucuronidation may help explain individual variation in toxicity rates among cancer patients treated with irinotecan. There may be a genetic predisposition to the metabolism of irinotecan. Research has found that the UGT1A1 gene is responsible for SN-glucuronidation. Patients with low UGT1A1 activity, such as those with Gilbert's syndrome, may be at increased risk of irinotecan-induced toxicity. The Invader UGT1A1 molecular assay is marketed as a test to aid physicians in making individualized decisions about treatment and medication dosage. By detecting variations in the UGT1A1, the Invader UGT1A1 molecular assay might be able to predict which patients are at an increased risk of toxicity from irinotecan. The Invader UGT1A1 molecular assay was approved by the FDA in 2005 as substantially equivalent to the Amplichip cytochrome P450 genotyping test. Both are genetic tests that detect single nucleotide polymorphisms. Since it was approved as substantially equivalent to an existing test, the manufacturer was not required to data on clinical sensitivity and specificity to the FDA. (References: Innocenti and Ratain, 2003; Iyer et al., 1998; Rouits et al. 2004; FDA documents).

## **06/05/2006: MTAC REVIEW**

### **Invader UGT1A1 Molecular Assay**

**Evidence Conclusion:** There is insufficient evidence to draw conclusions on the diagnostic accuracy of the Invader UGT1A1 molecular assay. No published peer-reviewed studies were identified. The only article with empirical data is a letter to the editor of Clinical Chemistry. The authors of the letter reported that findings from the Invader assay had a high rate of agreement with direct DNA sequencing for detecting UGT1A1 polymorphisms in 60 patients. Diagnostic accuracy studies that are published and peer-reviewed are needed. There is insufficient evidence that more appropriate therapy is used after application of the Invader assay than would be used if the test were not available. There was no published evidence on the impact on health outcomes of using UGT1A1 genotype information from the Invader test to adjust irinotecan treatment. There is some evidence that the UGT1A1 genotype is associated with irinotecan-induced toxicity. The studies reviewed found statistically significant associations between UGT1A1 genotype and irinotecan-induced toxicity. Two of the three studies (Marcuello et al., 2004; Ando et al., 2000) used multivariate analysis. In general, limitations of the studies were that they had relatively small sample sizes and estimates may be imprecise. Their findings provide preliminary data suggesting that information on UGT1A1 genotype may help physicians make better treatment decisions. Results of the studies reviewed cannot necessarily be generalized to use of the Invader assay to identify UGT1A1 polymorphisms, since this test was not used in any of the studies.

**Articles:** Accuracy of Invader UGT1A1 molecular assay: No published peer-reviewed studies were identified on the accuracy of the invader test for identifying variations in the UGT1A1 gene. There was a letter to the editor that presented data on test accuracy. Letters to the editor do not meet MTAC criteria for acceptable evidence because the scientific methods are not peer reviewed. Does adjusting the dose of irinotecan treatment based on UGT1A1 genotype identified using the Invader assay result in improved health outcomes? No published studies that directly address this question were identified. However, several studies were identified that examined the association between UGT1A1 variants and rates of toxicity related to irinotecan treatment. If there is a significant association between UGT1A1 genotypes and irinotecan-induced toxicity, then using information on UGT1A1 genotypes to inform irinotecan dosing decisions has the potential for improving health outcomes. The three largest studies evaluating the association between UGT1A1 genotype and toxicity (two cross-sectional studies and one case-control study) were critically appraised. *The studies reviewed were:* Marcuello E, Altes A, Menoyo A et al. UGT1A1 gene variations and irinotecan treatment in patients with metastatic colorectal cancer. Br J Cancer 2004; 91: 678-682. See [Evidence Table](#) Rouits E, Boisdron-Celle M, Dumont A et al. Relevance of different UGT1A1 polymorphisms in irinotecan-induced toxicity. Clin Can Res 2004; 10: 5151-5159. See [Evidence Table](#) Ando Y, Saka H, Ando M et al. Polymorphisms of UDP-Glucuronosyltransferase gene and irinotecan toxicity: A pharmacogenetic analysis. Can Res 2000; 60: 6921-6926. See [Evidence Table](#)

The use of Invader UGT1A1 molecular assay in the treatment of polymorphisms in the UGT1A1 gene does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Platelet Function Testing (VerifyNow P2Y12 Assay)**

#### **BACKGROUND**

In the United States, cardiovascular disease is the leading cause of death in both men and women (Heron 2009). Clinical trials have shown that clopidogrel (Plavix), an anti-blood clotting medication, reduces the morbidity and mortality associated with several cardiovascular diseases. However, there is a significant amount of inter-individual

variability in clopidogrel responsiveness, which leads some patients to experience decreased platelet inhibition (poor response) with clopidogrel (Momary 2010).

Studies suggest that approximately 4% to 30% of patients treated with clopidogrel do not have adequate antiplatelet response. The mechanism for poor response is not fully understood; however, poor compliance, drug interaction, clinical factors such as increased body mass index and diabetes, as well as genetic factors such as polymorphisms in the enzymes that metabolized clopidogrel into its active metabolite are all proposed mechanisms of clopidogrel non-responsiveness (Fileti 2011).

Platelet function testing is a way to monitor response to clopidogrel. It has been hypothesized that monitoring platelet reactivity and then tailoring treatment accordingly may improve clinical outcomes such as major adverse cardiovascular events. There are several different laboratory-based and point-of-care testing systems used to measure platelet response. These methods all have different definitions of high on-treatment platelet reactivity and are known to correlate poorly with each other. All of these methods have advantages and limitations. This review will focus on the VerifyNow P2Y12 Assay (Acumetrics Inc., San Diego, California), which is a fast, standardized point-of-care testing system that does not require special training to perform. The VerifyNow P2Y12 Assay evaluates platelet aggregation of fibrinogen-coated beads in response to adenosine diphosphate (ADP) and prostaglandin E1. Results are expressed as P2Y12 Reaction Units (PRU) with a common cutoff of  $\geq 240$  PRU for indicating suboptimal response to clopidogrel. However, one of the limitations of this test is that the cutoff for suboptimal response has not been firmly established (Sambu 2011, Smock 2011). The VerifyNow P2Y12 Assay has received approval from the FDA.

## 02/13/2012: MTAC REVIEW

### Platelet Function Testing (VerifyNow P2Y12 Assay)

**Evidence Conclusion:** Analytic validity Light transmission aggregometry (LTA) is considered by many to be the gold standard in platelet function testing; however, even though this method is the gold standard it is not without limitations. It is time consuming, it has poor reproducibility, and it requires experienced technicians (Sambu 2011). A recent study evaluated the correlation between platelet function tests to measure clopidogrel-mediated platelet inhibition in 80 patients on dual antiplatelet therapy after percutaneous intervention with stent implantation. The cut-off value for defining residual ADP-platelet aggregation despite treatment with clopidogrel was maximal aggregation  $\geq 62\%$  for LTA and PRU  $\geq 273$  for the VerifyNow P2Y12 Assay. There was significant correlation between the two assays ( $r=0.61$ ). When using LTA as the gold standard, the VerifyNow P2Y12 Assay had a sensitivity of 55% and a specificity of 85% (Gremmel 2009). Clinical validity Results from a recent meta-analysis that included 3,058 subjects suggest that high on-treatment platelet reactivity (PRU  $\geq 230$ ) after percutaneous coronary intervention was associated with cardiovascular events. However, the results of this analysis should be interpreted with caution due to methodological limitations. For example, study quality was not reported and confidence intervals were wide due to the small number of events (Brar 2011). Clinical utility A recent RCT evaluated the effect of high-dose compared with standard-dose clopidogrel in 2,214 patients with high on-treatment platelet reactivity after percutaneous coronary intervention (PCI). Results from this study suggest that the use of high-dose clopidogrel in patients with high on-treatment platelet reactivity after PCI did not reduce the incidence of death from cardiovascular causes, nonfatal myocardial infarction, or stent thrombosis compared to standard-dose clopidogrel. Due to the fact that fewer events occurred than anticipated, a treatment effect of high-dose clopidogrel cannot be excluded (Price 2011). Conclusion: **Analytic validity:** Results from a recent study suggest that when using LTA as the gold standard, the VerifyNow P2Y12 assay has a sensitivity of 55% and a specificity of 85%. **Clinical validity:** Results from a recent meta-analysis with methodological limitations suggest that high on-treatment platelet reactivity may be associated with cardiovascular events. **Clinical utility:** Results from a recent RCT suggest that high-dose compared to standard-dose clopidogrel in patients with high on-treatment platelet reactivity may not reduce cardiovascular events.

**Articles:** The literature search revealed several studies and review articles addressing the analytic validity of platelet function testing. Results of a recent study are presented below. Several observational studies and meta-analyses were identified that addressed the clinical validity of platelet function testing with the VerifyNow P2Y12 Assay. Studies were excluded if they were: retrospective, did not look at clinical outcomes, were not powered to evaluate clinical outcomes, or did not measure platelet function using the VerifyNow P2Y12 Assay. A meta-analysis of studies using the VerifyNow P2Y12 Assay to measure platelet reactivity was selected for review. Two randomized controlled trials (RCTs) were identified that looked at the clinical utility of VerifyNow P2Y12 Assay to measure platelet reactivity. One trial was excluded because it had a short duration of follow-up and the results combined patients who were poor responders to clopidogrel with patients who were poor responders to aspirin and patients who were poor responders to both aspirin and clopidogrel. The GRAVITAS trial, which evaluated the effect of high-dose compared with standard-dose clopidogrel in patients with high on-treatment platelet reactivity, was selected for review. The following studies were critically appraised: Brar SS, ten Berg J, Marcucci R, et al. Impact of platelet reactivity on clinical outcomes after percutaneous coronary intervention. A collaborative meta-analysis of individual participant data. *J Am Coll Cardiol.* 2011;58:1945-1954. See [Evidence Table](#) Price MJ, Berger PB, Teirstein PS, et al. Standard- vs high-dose clopidogrel based on platelet function testing after

percutaneous coronary intervention: the GRAVITAS randomized trial. *JAMA*. 2011;305:1097-1105. See [Evidence Table](#)

The use of Platelet function testing (VerifyNow P2Y12 Assay) does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Warfarin Sensitivity DNA Test**

#### **BACKGROUND**

Warfarin, an anticoagulant, is used to help prevent and treat blood clots. It is commonly used to treat patients with deep vein thrombosis, atrial fibrillation, stroke, and artificial heart valves. Blood clots are potentially dangerous because they can detach and travel in the bloodstream, where they can get wedged in a blood vessel and block the blood supply to a vital organ such as the lungs, heart or brain (Yin 2007). Blood clots are initiated when platelets clump together at the site of bleeding and produce chemicals that activate clotting factors in the blood. Vitamin K is essential for the production of these clotting factors. Warfarin prevents blood clots by inhibiting the action of vitamin K, thereby preventing the activation of clotting factors. The anticoagulant effect of warfarin is measured in terms of the prothrombin time, the time taken for blood clotting to occur in a sample of blood to which calcium and thromboplastin have been added. This time is expressed as the International Normalized Ratio (INR). The higher the INR, the longer time it takes for blood to clot. If the INR is too high, there is an increased risk of bleeding. If it is too low, there may be an increased risk of clot formation. The goal is to adjust the dose of warfarin so that the INR reaches and stays within a narrow therapeutic range. The initial dose of warfarin is an approximation, generally based on a standard protocol or dosing algorithm. Over the first several weeks on the medication, the patient's INR is tested regularly and the dose adjusted. The risk of anticoagulant-related bleeding is highest at the beginning of therapy (Tan 2010). Warfarin dosing is influenced by a variety of factors such as sex, age, smoking status, medications, diet, height, and weight. Another factor that may be associated with the optimal dose of warfarin is the presence of certain genetic variants (Jonas 2009). Two relevant genes have been identified: Vitamin K epoxide reductase (VKORC1) is a gene which codes for the enzyme that warfarin targets for its effect. Patients with the sensitive AA halotype generally require a lower dose of warfarin than average. Patients with the BB halotype generally require larger doses. The common halotype is AB. The sensitive AA variant of VKORC1 is estimated to occur in approximately 35-37% of Caucasians, 10-23% of African Americans, and in up to 89% of Asians. Cytochrome P450 (CYP) 2C9 (called CYP2C9) is a gene which codes for the specific liver enzyme that is largely responsible for metabolizing the most active component of warfarin. Some patients have a genetic variation in the CYP2C9 enzyme that causes them to metabolize warfarin more slowly. Patients with this genetic variation generally require a lower dose of warfarin. The usual variant of CYP2C9 that is associated with normal enzyme activity is CYP2C9\*1. The variants associated with slower metabolism of warfarin are CYP2C9\*2 and CYP2C9\*3. The prevalence of these variants varies considerably by ethnic group with Caucasians having the highest prevalence (Tan 2010). In 2007, the FDA approved new labeling for warfarin indicating that patients with variations in CYP2C9 and VKORC1 may respond differently to the drug. Due to the fact that warfarin has a narrow therapeutic window and over- or underdosing of warfarin can lead to catastrophic hemorrhagic or thrombotic complications there has been increasing interest in warfarin genotyping to aid in optimizing initial and maintenance warfarin dosing. There are several FDA-approved warfarin sensitivity genotyping test kits; all of them test for mutations in both the CYP2C9 and VKORC1 genes.

#### **10/06/2008: MTAC REVIEW**

##### **Warfarin Sensitivity DNA Test**

**Evidence Conclusion:** Analytic validity: No published evidence was identified.

Clinical validity: A meta-analysis of observational studies (Sanderson et al., 2005) found a statistically significant association between variants of the CYP2C9 gene and both a lower dose of warfarin and lower risk of bleeding. The meta-analysis did not study the VKORC1 gene. Two cohort studies, published after the meta-analysis (Schwartz et al., 2008; Wadelius et al., 2008) found significant associations between genetic variants of VKORC1 and efficacy outcomes (time to therapeutic INR or dose of warfarin). Associations with genetic variants of CYP2C9 were significant in one study but not the other. Both cohort studies were underpowered to assess the association between bleeding and genetic variants. Clinical utility: Two RCTs, one pilot study (Hillman et al., 2005) and one completed trial (Anderson et al., 2007) compared outcomes in patients managed with pharmacogenetic-guided dosing and those managed with standard dosing. The Anderson et al., 2007 study did not find a significant difference in the primary outcome, the per-patient percentage of out-of-range INR (30.7% in pharmacogenetic-guided dosing, and 33.1% in standard dosing). There was also no significant between-group difference in the secondary outcomes, achieving a therapeutic INR by day 5 or day 8, or the proportion of patients with adverse events. There were, however, significantly fewer dose adjustments (mean of 3.6 vs. mean of 3.0) with pharmacogenetic-guided dosing. The Hillman et al., 2005 focused on the feasibility of pharmacogenetic-guided dosing in a clinical setting, which was found to be feasible. The study also described clinical outcomes, but did not

do statistical testing. Outcomes (e.g. percent time INR in range and percent of patients with maximum INR>4) were similar in the two groups and the number of adverse effects was somewhat higher in the standard-dosing group. In conclusion: There is no published evidence on the accuracy or reliability of commercially available kits for identifying variants in the CYP2C9 and VKORC1 genes. There is fair evidence that variants of the genes are associated with warfarin-related intermediate outcomes (dosing, time to therapeutic INR). There is insufficient evidence due to lack of statistical power that genetic variants are related to risk of bleeding. There is insufficient evidence to determine that managing patients using pharmacogenetic-guided dosing improves outcomes. To date, there is one published completed RCT (Anderson et al., 2007), and this study did not find significant differences in the primary outcome, percentage of out-of-range INR and most secondary outcomes. Several additional RCTs are underway.

**Articles:** Analytic validity: No published studies were identified that discuss the accuracy or reliability of commercially available test kits for measuring genetic variants in the CYP2C9 and VKORC1 genes. Clinical validity: There is a meta-analysis of studies evaluating the association between CYP2C9 genetic variants and bleeds and drug dosing (Sanderson et al., 2005). This study, and the two largest prospective studies evaluating VKORC1 (Wadelius et al., 2008; Schwartz et al., 2008) were critically appraised. Clinical utility: There is one published RCT that compares outcomes in patients managed with pharmacogenetic-guided dosing versus standard dosing (Anderson et al., 2007). In addition, there is an earlier published pilot RCT examining the feasibility of using pharmacogenetic-guided dosing (Hillman et al., 2005). These two studies were critically appraised. The Hillman study was included because, although its primary purpose was examining feasibility, it also included some clinical outcome variables. Several additional randomized controlled trials are underway examining health outcomes in patients starting warfarin therapy who are managed with pharmacogenetic-guided dosing compared to standard methods of dosing. These include the prospective evaluation comparing initiation of warfarin strategies (PRECISE) trial, a study of patients receiving total hip or knee replacement, and a Creighton University study comparing these two types of dosing (ClinicalTrials.gov). *The following studies were critically appraised:* Sanderson S, Emery J, Higgins J. CYP2C9 gene variants, drug dose and bleeding risk in warfarin-treated patients: A HuGenet systematic review and meta-analysis. *Genet Med* 2005; 7: 97-104. See [Evidence Table](#). Schwarz UI, Ritchie MD, Bradford Y et al. Genetic determinants of response to warfarin during initial anticoagulation. *NEJM* 2008; 358: 999-1008. See [Evidence Table](#). Wadelius M, Chen LY, Lindh JD et al. The largest prospective warfarin-treated cohort supports genetic forecasting. *Blood* 2008. June 23 (E-pub ahead of print). See [Evidence Table](#). Anderson JL, Horne BD, Stevens SM et al. for the Couma-Gen investigators.

Randomized trial of genotype-guided versus standard warfarin dosing in patients initiating oral anticoagulation. *Circulation* 2007; 116: 2563-2570. See [Evidence Table](#). Hillman MA, Wilke RA, Yale SH et al. A prospective, randomized pilot trial of model-based warfarin dose initiation using CYP2C9 genotype and clinical data. *Clin Med & Res* 2005; 3: 137-145. See [Evidence Table](#).

The use of a DNA sensitivity test to determine the optimal dosing of warfarin does not meet the *Group Health Medical Technology Assessment Criteria*.

## 10/18/2010: MTAC REVIEW

### Warfarin Sensitivity DNA Test

**Evidence Conclusion:** Analytic Validity There are several genotyping assays available to detect polymorphisms in the CYP2C9 and VKORC1 genes. King and colleagues compared the accuracy of four commercially available assays. All four methods evaluated had high accuracy compared to bi-directional sequencing (King 2009). Clinical Validity In 2008, based on the results from a meta-analysis and two cohort studies warfarin sensitivity DNA testing was found to have adequate clinical validity. Information from the 2008 review: A meta-analysis of observational studies found a statistically significant association between variants of the CYP2C9 gene and both a lower dose of warfarin and lower risk of bleeding. The meta-analysis did not study the VKORC1 gene (Sanderson 2005). Two cohort studies published after the meta-analysis (Schwartz 2008, Wadelius 2008) found significant associations between genetic variants of VKORC1 and efficacy outcomes (time to therapeutic INR or dose of warfarin). Associations with genetic variants of CYP2C9 were significant in one study but not the other. Both cohort studies were underpowered to assess the association between bleeding and genetic variants. New information since the 2008 review: A recent retrospective cohort study compared the accuracy of three different warfarin dosing algorithms. Results from this study suggest that the pharmacogenetic algorithm that included information on CYP2C9 and VKORC1 genotype produced initial warfarin dose recommendations that were significantly closer to the stable therapeutic dose than the clinical or fixed-dose algorithms. This analysis did not address whether a precise initial dose of warfarin would improve clinical endpoints, such as a reduction in the time needed to achieve a stable therapeutic INR, fewer INRs that are out of range, or a reduced incidence of bleeding (Klein 2009). Clinical Utility A recent cohort study compared the six month incidence of hospitalization in patients receiving warfarin genotyping versus historical controls. Compared to historic controls, patients who were genotyped for warfarin sensitivity had 31% fewer hospitalizations (P<0.001). Results from this study should be interpreted with caution. Patients were taking warfarin for a median of 32 days before the physician received the lab results. As there was no

further communication with the physician after the lab results were sent, it is unknown if the genotyping results were used to inform treatment. The main limitation of this study is the use of a historical control group. Because a contemporary control group was not selected the possibility that the benefits of genotype-guided warfarin therapy may be exaggerated due to confounding, either in the vigilance by the treating physicians or in the kinds of patients who agreed to participate, cannot be ruled out. Other limitations include the fact that the genotype of the control group was unknown and baseline differences in the prevalence of hypertension and diabetes between the control and intervention group (Epstein 2010). Conclusion: Analytic validity: There is fair evidence that the commercially available assays for determining warfarin genotype are accurate compared to bi-directional sequencing. However, there is insufficient evidence concerning the reproducibility of these tests. Clinical validity: Based on information for the 2008 review, the warfarin sensitivity DNA test was found to have adequate clinical validity. Clinical utility: There is insufficient evidence to determine whether patients managed with the genetic test had better outcomes compared to patients managed without the genetic test.

**Articles:** The literature search revealed several articles that addressed the analytic validity of warfarin genotyping assays. The study by King and colleagues was selected for review as it assessed the accuracy of four different commercial systems. In the 2008 review, warfarin sensitivity DNA testing passed criterion 3 (clinical validity), since then several studies were identified that evaluated the clinical validity of genetic testing to predict warfarin dose. One of the larger cohort studies was selected for review. The study by Epstein and colleagues was the only study identified that addressed the clinical utility of the warfarin sensitivity DNA test. The following studies were critically appraised: King CR, Porsce-Sorbet RM, Gage BF, et al. Performance of commercial platforms for rapid genotyping of polymorphisms affecting warfarin dosing. *Am J Clin Pathol* 2008; 129:876-883. See [Evidence Table](#). Klein TE, Altman RB, Erickson N, et al. Estimation of the warfarin dose with clinical and pharmacogenetic data. *N Engl J Med* 2009; 360:753-764. See [Evidence Table](#). Epstein RS, Moyer TP, Aubert RE, et al. Warfarin genotyping reduced hospitalization rates. *J Am Coll Cardiol* 2010; 55:2804-2812. See [Evidence Table](#).

The use of a DNA sensitivity test to determine the optimal dosing of warfarin does not meet all of the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Photodynamic Therapy (PDT)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service**

#### Criteria

##### For Medicare Members

National Coverage Determinations (NCD)

[Ocular Photodynamic Therapy \(OPT\) \(80.2\)](#)

National Coverage Article

[Ocular Photodynamic Therapy \(OPT\) with Verteporfin \(A52769\)](#)

##### For Non-Medicare Members

Service	Criteria Used
PDT with Visudyne for Pathologic Myopia	Medical necessity review no longer required
PDT for Advanced Esophageal Cancer and Barrett's Esophageal Disease	
PDT for Age-Related Wet Macular Degeneration	
PDT for Actinic Keratosis	
Photodynamic Laser Therapy for Tracheobronchial Cancer	Covered when the patient has obstructive tracheobronchial cancer as a palliative treatment.
PDT for Brain Tumors	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Photodynamic therapy (PDT) is a cancer treatment that destroys cancer cells selectively by an interaction between absorbed light and a retained photo-sensitizer. It is a two-part treatment using a photosensitizing drug, and red non-thermal laser light. The photosensitizing agent is a light activated chemical that selectively concentrates in malignant tissue. This agent is usually injected intravenously, and two days later it is activated by exposing the tissue to a laser light energy of a specific wavelength. For Photofrin, the FDA approved photo-sensitizer, the wavelength of light used for activation is 630 nm. The photo-sensitizer will absorb the light energy and produce toxic oxygen radicals that destroy the tumor and result in its necrosis in about 24 to 48 hours. The depth of penetration and tumor necrosis after PDT is limited to approximately 5-10 mm. This shallow depth of light penetration in the tumor provides a safety factor against perforation, but on the other hand it is a limiting factor to the effectiveness of the therapy for deeper tumors.

Photodynamic therapy is an outpatient procedure, performed with the patient sedated. It can be used together with other treatments, and can be repeated several times. It does not require anesthesia or pre-dilation of the esophagus.

The side effect most commonly associated with PDT is photosensitivity. This is usually manifested as sunburn or periorbital oedema. Patients are advised to avoid direct light for at least 4 weeks, after the treatment.

## Medical Technology Assessment Committee (MTAC)

### ***Photodynamic Therapy (PDT) for Advanced Esophageal Cancer and Barrett's Esophageal Disease***

#### BACKGROUND

Esophageal carcinoma is the seventh most common malignancy worldwide. Its incidence is increasing rapidly in the western world mainly due to adenocarcinoma of the lower third of the esophagus and gastro-esophageal junction, which usually arises from areas of Barrett's metaplasia (Lee 2001). Approximately 13,100 new cases of adenocarcinoma were diagnosed in the United States in 2002. The overall survival rate from esophageal cancer is 5-10% (Litle 2003). Most patients present with dysphagia, which usually occurs at an advanced stage of the disease. At that time, the lumen of the esophagus is often reduced by at least 50% of its diameter among most of the patients. Radical esophageal resection is still considered the therapeutic gold standard in patients with high-grade dysplasia or early cancer. For those not legible for surgical resection, treatment is palliative to reduce the esophageal obstruction and reduce the dysphagia. Different forms of palliative treatment include: external beam radiation therapy, brachytherapy, pneumatic dilatation, esophageal stenting, Nd: YAG laser, and photodynamic (PDT) therapy. Some of these therapies e.g. external radiation therapy may take several weeks to relieve the dysphagia, others like esophageal bypass have a longer recovery time, and still others are associated with severe side effects as stricture, perforation, reflux, fistula formation and others. PDT is a two-part treatment using a photosensitizing drug, and red non-thermal laser light (green light has been used in some studies). The photosensitizing agent is a light- activated chemical that is selectively retained in tumor cells, and interstitial tissue of the tumor. (McCaughan, 1996). This agent is usually injected intravenously, and two days later it is activated by exposing the tissue to a laser light energy of a specific wavelength. For Photofrin, the FDA approved photosensitizer, the wavelength of light used for activation is 630 nm. The photosensitizer will absorb the light energy and produce toxic oxygen radicals that destroy the tumor, and result in its necrosis in about 24 to 48 hours. The depth of penetration and tumor necrosis after PDT is limited to approximately 5-10 mm. This shallow depth of light penetration in the tumor provides a safety factor against perforation, but on the other hand it is a limiting factor to the effectiveness of the therapy for deeper tumors. Photodynamic therapy is an outpatient procedure, performed with the patient sedated. It can be used together with other treatments, and can be repeated several times. It does not require anesthesia or pre-dilation of the esophagus. Sensitivity of the patient body tissues to light always occurs once the agent is injected, and the patients should avoid direct light for at least four weeks. An important adverse effect of PDT is the potential formation of esophageal strictures due to fibrosis and scarring during the healing process. Barrett's esophagus is a condition where the squamous epithelium of the lower esophagus is substituted by specialized columnar mucosa. It is estimated to affect 700,000 adults in the United States (FDA 2003), and is believed to occur as a response to esophageal reflux of gastric contents especially gastric acid. Barrett's esophagus is regarded as a premalignant condition and is the most important risk factor for the development of adenocarcinoma (Spechler 2002). Non-dysplastic metaplasia can progress to low-grade dysplasia, high-grade dysplasia, and finally to invasive cancer (Conio 2005). Several investigators reported that the relative risk of the adenocarcinoma depends on several negative prognostic factors among which are metaplasia extension, length of the involved segment, dysplasia grading, and timing of diagnosis (Pagoni 2003). Esophageal adenocarcinoma is often diagnosed at an advanced stage of the disease, and thus has a poor prognosis with 5-year survival rates below 20% (Enzinger 2003). The increased availability of endoscopy and awareness of Barrett's esophagus and its associated cancer risk, have led to the increased detection of the condition in premalignant or early malignant stages. Partial or total esophagogastrectomy are considered the therapeutic gold standard in patients with high-grade dysplasia or early cancer. Surgical resection may however, be associated with high morbidity and mortality rates especially in low-volume surgical centers (Birkmeyer 2002). Moreover, some patients may be unfit for surgery. Other possible strategies have been proposed to destroy Barrett's mucosa. Among these techniques are photodynamic therapy (PDT), ablation therapy with Nd-YAG laser, Argon Plasma Coagulation (APC), and endoscopic mucosal resection (EMR). The objective of all these treatments is the complete destruction of the abnormal mucosa to reduce the cancer risk. The ideal treatment would destroy columnar metaplasia, and achieve regeneration of the squamous epithelium. PDT is a two-part treatment using a photosensitizing drug and red non-thermal laser light (green light has been used in some studies). The photosensitizing agent is a light- activated chemical that selectively concentrates in malignant

tissue. This agent is usually injected intravenously, and two days later it is activated by exposing the tissue to a laser light energy of a specific wavelength. The photosensitizer will absorb the light energy and produce toxic oxygen radicals that destroy the esophageal mucosa in about 24 to 48 hours. Photodynamic therapy is an outpatient procedure, performed with the patient sedated. It can be used together with other treatments, and may be repeated several times. It does not require anesthesia or pre-dilation of the esophagus. Sensitivity of the patient body tissues to light always occurs once the agent is injected, and the patients should avoid direct sunlight or any bright light for at least four weeks. An important adverse effect of PDT is the potential formation of esophageal strictures due to fibrosis and scarring during the healing process. Porfimer sodium (photofrin) was approved by the FDA in December 1995, to use in PDT for the palliation of patients with completely obstructing esophageal cancer, or patients with partially obstructing esophageal cancer who cannot be satisfactorily treated with Nd:YAG laser therapy. More recently, in August 2003 it was also approved for the ablation of precancerous lesions in Barrett's esophagus patients who do not undergo esophagectomy (FDA 2003).

## **02/06/2000: MTAC REVIEW**

### **Photodynamic Therapy for the Treatment of Advanced Esophageal Cancer**

**Evidence Conclusion:** Photodynamic therapy when compared to Nd:YAG thermal ablation for palliation of dysphagia from advanced esophageal cancer provides equivalent improvement in dysphagia, improved objective tumor response as measured by esophageal lumen diameter (ARR of 12% at one month in "complete response + partial response"  $P < 0.05$ ), and increased mild to moderate complications including sunburn in 19% of patients treated with PDT. Perforations from laser treatments or associated dilatations occurred in 1% of patients following PDT and 7% of patients following Nd:YAG treatment. ( $p < 0.05$ ) Termination of laser sessions due to adverse events occurred in 3% of patients receiving PDT and 19% receiving Nd:YAG. While this is an RCT, the high drop out rate and lack of blinding limit our ability to understand the difference in clinically important outcomes between Nd:YAG thermal ablation and PDT.

**Articles:** Articles were sorted on the basis of study type. Case series and cohort studies were not selected. Two randomized controlled trials were selected for review. One randomized controlled trial was selected (study by Heier SK et al. *Gastroenterology*. 1995;109:63-72) was excluded because of small study size: N=44; 20 in PDT group, 22 in Nd:YAG group). An evidence table was created for the best available evidence (Lightdale CJ, et al. *Gastrointestinal Endoscopy*. 1995;42:507-12.) Reference: Lightdale CJ, Heier SK, Marcon NE, et al. Photodynamic therapy with porfimer sodium versus thermal ablation therapy with Nd: YAG laser for palliation of esophageal cancer: a multicenter randomized trial. *Gastrointestinal Endoscopy*. 1995;42:507-12. See [Evidence Table](#).

The use of photodynamic therapy in treatment of esophageal cancer does not meet the *Group Health Medical Technology Assessment Criteria*

## **02/11/2004: MTAC REVIEW**

### **Photodynamic Therapy for the Treatment of Advanced Esophageal Cancer**

**Evidence Conclusion:** Barrett's esophagus: Ackroyd's study was a small RCT with valid methodology. It is randomized, controlled, double blind, and with sufficient power to detect the difference in the treatment response between the two groups despite the small sample size. The trial however compared PDT to placebo and not to an alternative treatment. The photosensitizer used was ALA not the commonly used porphyrin based agent, and the laser light used was the green light, not the red light described in the literature. Effect of the treatment on survival was not studied. Overall the results of the trial show that patients treated with PDT showed significantly more macroscopic and microscopic evidence of regression and reduction in Barrett's area, compared to those who received a placebo treatment. The response to treatment observed was maintained for the follow-up duration of 24 months. The other study reviewed (Overholt 2003) was a case series with long-term follow-up. The study, like all case series, has potential threats to its internal validity, and lacks a comparison or control group. Its results show that PDT was associated with a success rate (no dysplasia with or without Barrett's) ranging from 44.4% for cases with early stage carcinoma to 92.9% for cases with low-grade hyperplasia. PDT was not compared to an alternative treatment. In addition it was supplemented with Nd: YAG laser photoablation and continuous use of omeprazole, which may be responsible in part for the treatment success. Advanced esophageal cancer: Only case series data were available. The dysphagia scores seems to significantly improve after PDT treatment in the two series reviewed. There are no studies comparing the PDT with other treatments so the relative effectiveness cannot be determined. Moreover the case series studies are subject to selection and observation bias. A RCT (Lightdale, et al, 1995) with 218 patients randomized to receive either PDT or Nd:YAG was reviewed for MTAC in February 2000. It was not blinded, and had a high dropout rate, and did not provide sufficient evidence to determine the effect of the PDT on the treatment of esophageal cancer.

Conclusion: There is some weak evidence from one small RCT that PDT using ALA photosensitizer has more than a placebo effect on the regression of Barrett's area. There is insufficient evidence on the effect of PDT in the palliative treatment of advanced, and/ or inoperable esophageal cancer.

**Articles:** Barrett's esophagus: The search revealed 125 articles. The majority were reviews and tutorials. There was one RCT comparing the procedure to placebo, two other small RCTs comparing different methods for performing PDT, and several case series or case reports. The RCT and the case series with a relatively large sample size, and long-term follow-up were selected for critical appraisal. Ackroyd R, Brown JN, Davis MF, et al. Photodynamic therapy for dysplastic Barrett's oesophagus: a prospective, double blind, randomized, placebo-controlled trial. *Gut* 2000;47:612-617. See [Evidence Table](#). Overholt BF, Panjehpour M, Halberg D, et al. Photodynamic therapy for Barrett's oesophagus with dysplasia and/or early stage carcinoma: Long-term results. *Gastrointest Endosc* 2003;58:183-188. See [Evidence Table](#). Advanced esophageal cancer: The search on esophageal cancer in general revealed 94 articles, and that on advanced esophageal cancer revealed 21 articles the great majority of which were review articles. There were no RCTs comparing PDT to other modes of treatment. There were three case series with more than 50 patients each. One of these series compared PDT given in addition to radiotherapy. The other two were critically appraised. Luketich JD, Christie Na, Buenaventura PO, et al. Endoscopic photodynamic therapy for obstructive esophageal cancer. *Surg Endosc* 2000;14:653-657. See [Evidence Table](#). Moghissi K, Dixon K, Thorpe JA, et al. The role of photodynamic therapy (PDT) in inoperable oesophageal cancer. *Eur J Cardiothorac Surg* 2000;17:95-100. See [Evidence Table](#).

The use of photodynamic therapy in treatment of esophageal cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **06/06/2005: MTAC REVIEW**

##### **Photodynamic Therapy in Treatment of Barrett's Disease**

**Evidence Conclusion:** Kelty et al's RCT compared photodynamic therapy (PDT) and argon plasma coagulation (APC) for the ablation of Barrett's esophagus. The outcomes were the number of treatments required to achieve ablation, and the complete macroscopic reversal of the columnar epithelium. All patients had a biopsy proven Barrett's epithelium but none had any evidence of dysplasia. Thirty four patients were randomized to each treatment group, and followed for up to two years (range 6-24, median 12 months). 50% of the patients in the PDT group showed complete response to PDT, and 50% had only a partial regression. The APC therapy had significantly better outcomes with a complete response rate of 97%. Hage et al's trial was a smaller study (N=40) that also compared PDT with APC, and the primary outcome was the endoscopic reduction of the Barrett's esophagus surface. All patients had no or a low-grade dysplasia. They were randomized to receive APC therapy, single illumination (PDT 100), or a fractionated illumination (PDT 20+100), and followed for up to two years. The results of the trial show that patients who received a single illumination of PDT had a significantly lower rate of Barrett's esophagus surface reduction when compared to the PDT 20+100 group or the APC group (51%, 86% and 93% respectively). The difference between the latter two groups was insignificant. The two studies used 5-aminolevulinic acid (5-ALA); a more recent sensitizing agent and not the FDA approved photofrin (porfimer sodium). Both trials had generally valid methodology. However, they had relatively small sample sizes, and the follow-up duration of 2 years might be insufficient to study the effect of the therapy on reducing the risk of cancer. The outcome in these trials was the effect of the therapy on the reversal of the columnar epithelium and not on patient survival. Moreover, all study subjects had no or low-grade dysplasia, which might limit generalization of the results. The 2004 MTAC review only found weak evidence from one small RCT that PDT using ALA photosensitizer had more than a placebo effect on the regression of Barrett's area. The therapy failed the committee evaluation criteria. In conclusion, the studies reviewed provide some evidence that PDT may achieves complete clearance of Barrett's epithelium in at least 50% of the patients with no or low-grade dysplasia. They do not provide evidence on the effect of the therapy on higher-grade dysplasia, or its impact on cancer risk, and patient survival. Larger trials with long-term follow-up may be needed to establish these effects.

**Articles:** The search revealed 26 articles. The majority were review articles or opinion pieces. There were two randomized controlled trials and two case series. The two RCTs were selected for critical appraisal: Kelty CJ, Ackroyd R, Brown JN, et al. Endoscopic ablation of Barrett's esophagus: a randomized controlled trial of photodynamic therapy vs. argon plasma coagulation. *Aliment Pharmacol Ther* 2004;20:1289-1296. See [Evidence Table](#). Hage M, Siersema PD, van Dekken H, et al. 5-Aminolevulinic acid photodynamic therapy versus argon plasma coagulation for ablation of Barrett's oesophagus: a randomized trial. *Gut* 2004;53:785-790. See [Evidence Table](#).

The use of photodynamic therapy in treatment of Barrett's disease does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **Photodynamic Therapy for Brain Tumors**

##### **BACKGROUND**

Photodynamic therapy (PDT) refers to the use of photosensitizing agents to treat tumors. The only FDA-approved photosensitizing agent is porfimer sodium (Photofrin). The PDT process involves the infusion of photosensitizing

agents intravenously that are selectively retained within tumor cells. The photosensitizing agents are activated by exposure to light and cause oxidative damage to tumor tissues in which the drug has been retained.

The use of PDT to treat cerebral gliomas (brain tumors) was first investigated in 1972 using hematoporphyrin activated by white light on glioma cells in vitro and in rat tumors. Animal models have demonstrated the selective uptake of photosensitizers into cerebral gliomas. The first examination of PDT to treat human gliomas was reported by Perria in 1980. The ideal dose of photosensitizer and light for cerebral tumors has yet to be determined (Popovic). Other treatments for cerebral gliomas include surgical resection, postoperative whole-brain irradiation and chemotherapy. The effectiveness of these treatments is limited by inadequate local control of disease. It is hoped that PDT can improve local disease control and increase survival (Rosenthal).

#### **02/13/2002: MTAC REVIEW**

##### **Photodynamic Therapy for Brain Tumors**

**Evidence Conclusion:** There is insufficient evidence to determine the effect of PDT on health outcomes for patients with brain tumors. Much of the research appears to focus on developing the best methods for applying PDT to the treatment of brain tumors. Few clinical data are available. Popovic reported on a series of 120 patients; few methodological details were given and the intervention may not have been consistent. They found that the median survival among 38 patients with glioblastoma multiforme was 24 months; in a historical control group subject to selection bias, median survival in patients with a similar diagnosis was 8 months.

**Articles:** The search yielded 69 articles, most of which were review articles, laboratory studies, dealt with technical aspects of the procedures or addressed other, similar treatments. There were no randomized controlled trials or meta-analyses. There were several small case series, many of which did not report clinical outcomes. A recent review article with some case series data was reviewed: Popovic EA, Kaye AH, Hill JS. Photodynamic therapy of brain tumors. *J of Clin Laser Med & Surg* 1996; 14: 251-261. See [Evidence Table](#).

The use of photodynamic therapy in the treatment of brain tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

##### **Photodynamic Laser Therapy for Tracheobronchial Cancer**

###### **BACKGROUND**

Lung cancer is the leading cause of cancer deaths. It usually originates from bronchial cells, and grows in the bronchial lumen or peribronchially, thus, the term bronchial cancer is used synonymously with lung cancer. Resectional surgery is considered the treatment of choice, and the therapy with potential cure or long survival. However, the majority of patients diagnosed with lung cancer are at an advanced stage, and only 15-20% are surgical candidates at the time of diagnosis (Fry, 1996). There are several methods used for palliative treatment for bronchial obstruction including Nd: YAG laser therapy, brachytherapy, electrocautery, balloon dilatation, stent insertion, and photodynamic therapy (PDT). PDT is a cancer treatment that destroys cancer cells selectively by an interaction between absorbed light and a retained photosensitizer. It is a two-part treatment using a photosensitizing drug, and red non-thermal laser light. The photosensitizing agent is a light activated chemical that selectively concentrates in malignant tissue. This agent is usually injected intravenously, and two days later it is activated by exposing the tissue to a laser light energy of a specific wavelength. For Photofrin, the FDA approved photosensitizer, the wavelength of light used for activation is 630 nm. The photosensitizer will absorb the light energy and produce toxic oxygen radicals that destroy the tumor and result in its necrosis in about 24 to 48 hours. The depth of penetration and tumor necrosis after PDT is limited to approximately 5-10 mm. This shallow depth of light penetration in the tumor provides a safety factor against perforation, but on the other hand it is a limiting factor to the effectiveness of the therapy for deeper tumors. Of the potential advantages of the procedure is that may be technically easier and potentially safer than other procedures, and that it is repeatable and appears to be compatible with other treatments. The procedure does not require general anesthesia, and only requires a prolonged bronchoscopy. The side effect most commonly associated with PDT is photosensitivity. This is usually manifested as sunburn or periorbital oedema. Patients are advised to avoid direct light for at least 4 weeks, after the treatment. The risk of serious bronchial hemorrhage, which may be fatal is another important complication associated with the PDT therapy used for treating tumors invading bronchial walls, and big vessels. Other complications include cough, dyspnea, bronchitis, and pneumonia. PDT is approved by the FDA for the palliation of airway obstruction caused by malignant tumors in patients with advanced obstructive endobronchial disease, and as an alternative to surgery in selected patient with early-stage lung cancer. PDT use in the treatment of tracheobronchial cancer was reviewed by MTAC in February 2002, and failed the committee evaluation criteria.

#### **02/11/2004: MTAC REVIEW**

##### **Photodynamic Laser Therapy for Tracheobronchial Cancer**

**Evidence Conclusion:** There is insufficient new evidence to determine the effectiveness of photodynamic therapy in the treatment of tracheobronchial cancer.

**Articles:** The search yielded 25 articles. The majority were reviews and tutorials. There was a small longitudinal study (32 patients) on all bronchoscopic treatments of occult lung cancer, another retrospective study on all palliative measures for malignant airways including 8 patients receiving PDT treatment or stents, and a small trial with 16 patients comparing 2 photosensitizers used in PDT for the treatment of malignant bronchial stenosis. None of the studies was critically appraised.

The use of photodynamic therapy in the treatment of bronchial cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## 02/13/2002: MTAC REVIEW

### Photodynamic Laser Therapy for Tracheobronchial Cancer

**Evidence Conclusion:** Early-stage lung cancer: Only case series data were available. A large proportion of the patients studied appear to have complete remission following PDT (approximately 80%); there are no studies comparing remission rates with other treatments so the relative effectiveness cannot be determined. The case series reports are subject to selection and observation bias. The long-term effectiveness is difficult to determine because patients were permitted to have other treatments after PDT. Advanced lung cancer: The highest grade of evidence was an RCT. Diaz-Jimenez compared Nd-YAG to PDT in 31 patients. They found that patients who received PDT had a median of 12 days longer before treatment failure for any reason (50 vs. 38 days) and survived for a mean of 170 days longer (265 vs. 95 days) than the group receiving Nd-YAG. Because this is a small RCT, selection bias is likely. A greater proportion of patients assigned to the Nd-YAG group had advanced lung cancer that could at least partially explain the shorter time to treatment failure and shorter survival time. The existing evidence is insufficient to determine the effect of PDT on advanced lung cancer.

**Articles:** The search yielded 57 articles, many of which were review articles, opinion piece, dealt with technical aspects of the procedures or addressed other, similar treatments. Early-stage lung cancer: There were no randomized controlled trials (RCTs) or meta-analyses. The highest grade of evidence available was case series. The two largest case series were critically appraised: Furuse K, Fukoka M, Kato H, Horai T, Kubota K, Kodamo N et al. A prospective Phase II study on photodynamic therapy with photofrin II for centrally located early-stage lung cancer. *J Clin Oncol* 1993; 11: 1 852-57. See [Evidence Table](#). Kato H, Okunaka T, Shimatani H. Photodynamic therapy for early stage bronchogenic carcinoma. *J Clin Laser Med & Surg* 1995; 14: 235-238. See [Evidence Table](#). Advanced lung cancer: There were two RCTs. The remaining empirical articles were case series. One RCT had included only 11 patients and did not compare outcomes in the two randomized groups in analysis. One RCT was critically appraised: Diaz-Jimenez JP, Martinez-Ballerin JE, Llunell A, Farrero E, Rodriguez A, Castro MJ. Efficacy and safety of photodynamic therapy versus Nd-YAG laser resection in NSCLC with airway obstruction. *Eur Respir J* 1999; 14: 800-805. See [Evidence Table](#).

The use of photodynamic therapy in the treatment of bronchial cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### Photodynamic Therapy with Visudyne for Pathologic Myopia

#### BACKGROUND

Choroidal neovascularization (CNV) in patients with pathologic myopia is a condition in which there is an abnormal growth of blood vessels under the retina due to an elongation of the back of the eye associated with severe myopia. This condition can result in a progressive and serious loss of vision. There have not been effective treatments for this disease. Photodynamic therapy using Visudyne (verteporfin for injection) involves intravenous injection of verteporfin, a light activated or "photosensitive" drug. After infusion, verteporfin is activated by illumination with laser light shone into the patient's eye from a slit lamp of a microscope. The wavelength used corresponds to the wavelength at which peak absorption occurs, but is not so strong as to cause thermal damage. The light is directed to the area of neovascularization and damage to the retina is minimized. In April 2000, the FDA approved Visudyne for the treatment of the wet form of age-related macular degeneration. In August 2001, photodynamic therapy with Visudyne was additionally approved for the treatment of subfoveal choroidal neovascularization (CNV) due to pathologic myopia. Visudyne for age-related macular degeneration was found to meet MTAC review criteria in June 2000.

## 02/13/2002: MTAC REVIEW

### Photodynamic Therapy with Visudyne for Pathologic Myopia

**Evidence Conclusion:** One well done randomized controlled trial (VIP study group) was reviewed. This study provides evidence that photodynamic therapy with verteporfin is effective at decreasing vision loss 12 months after treatment. 28% of patients in the verteporfin group compared to 56% in the placebo group had at least an eight letter loss at 12 months, the study's primary outcome ( $p < 0.01$ , NNT=4). This finding is likely to be clinically

as well as statistically significant. The treatment appears to be safe. Ideally, the findings would be replicated in other studies and there would be longer-term follow-up. 24-month follow-up data will be available from the VIP study.

**Articles:** The search yielded 26 articles, many of which were review articles, opinion pieces, dealt with technical aspects of the procedures or addressed other, similar treatments. There was 1 randomized controlled trial (n=120) with and 1 case series (n=13). The case series included patients with choroidal neovascularization due to several conditions, e.g. pathologic myopia, ocular histoplasmosis syndrome, angioid streaks and idiopathic causes. *The RCT was critically appraised:* Verteporfin in photodynamic therapy (VIP) study group. Photodynamic therapy of subfoveal choroidal neovascularization in pathologic myopia with verteporfin: 1-year results of a randomized clinical trial: VIP report no. 1. *Ophthalmol* 2001; 108: 841-52. See [Evidence Table](#)

The use of photodynamic therapy in the treatment of pathologic myopia passed the *Group Health Medical Technology Assessment Criteria*.

**Visudyne with Photodynamic Therapy for Age-Related Wet Macular Degeneration**

**BACKGROUND**

Age-related macular degeneration (AMD) is the most common and most severe cause of vision loss in the U.S. and many developed countries. With increasing life expectancy, the prevalence of AMD (currently about 25%) in people aged 65 years and older will increase significantly, with an enormous social and financial cost. In spite of the significance of this problem, AMD's pathogenesis remains unclear and is essentially untreatable.

AMD is characterized by two forms: the "dry" and more severe "wet" form. The latter accounts for 15% of all AMD cases, but is responsible for 90% of the severe vision loss associated with this condition. Visual acuity loss usually results from choroidal neovascularization (CNV), the ingrowth of new vessels from the choriocapillaris.

These new vessels are accompanied by fibrous tissue that can destroy central visual function over months to years. Standard treatment of CNV has been with a thermal laser. The drawback of this laser is that in addition to destroying the CNV it destroys the surrounding retinal tissue with immediate vision loss. Photodynamic Therapy (PDT) utilizing verteporfin (Visudyne; CIBA Vision Corp, Duluth, GA) is a new technology which completed Phase III clinical trials last year and was recently recommended for FDA approval by the Ophthalmic Drugs Subcommittee of the FDA. Verteporfin therapy involves an intravenous administration of verteporfin, a light activated drug. Laser light at the specific wavelength absorbed by Visudyne is then directed to the area of neovascularization and causes preferential closure of these vessels while sparing the overlying retina.

The articles described below evaluate PDT as a treatment for choroidal neovascularization (CNV), the type of late AMD that is the most frequent cause of visual loss.

**06/14/2000: MTAC REVIEW**

**Visudyne with Photodynamic Therapy for Age-Related Wet Macular Degeneration**

**Evidence Conclusion:** The prospect of verteporfin (Visudyne) as a new therapy for subfoveal wet AMD is very promising, in light of the fact AMD is an important public health problem with no currently available treatment that spares destruction of the fovea itself. However, the efficacy and safety of verteporfin cannot be fully determined from the limited evidence provided by these two studies, which were conducted by the same investigators. The findings from the case series are threatened by small sample size and possible observation and selection biases. The findings from both studies are threatened by short length of follow-up, concerns about the generalizability of the findings, and the fact that the investigators would benefit financially from FDA approval of the drug. Further studies, preferably blinded, randomized controlled trials, such as the Verteporfin in Photodynamic Therapy (VIP) Trial (to be completed this Fall), will provide further evidence regarding whether photodynamic therapy with verteporfin can safely and effectively reduce the risk of vision loss in patients with age-related macular degeneration.

**Articles:** Miller JW, Schmidt-Erfurth U. Sickenberg M; Piurnaras CJ et al. Photodynamic Therapy with verteporfin for Choroidal Neovascularization caused by age-related Macular Degeneration. *Archives of Ophthalmology* 1999; 117:1167-1173. See [Evidence Table](#). TAP Study Group. Photodynamic Therapy of subfoveal choroidal neovascularization in age-related Macular Degeneration. *Archives of Ophthalmology* 1999; 117:1329-1345. See [Evidence Table](#).

The use of Visudyne with Photodynamic Therapy in the treatment of Age-related Macular Degeneration does meet the *Group Health Medical Technology Assessment Criteria*.

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Recent research suggests that inflammation plays a role in the development and progression of atherosclerosis. This observation, together with the advances in inflammatory biomarkers research, has led to the emergence of dozens of novel biomarkers that may potentially aid in predicting an individual's risk for cardiovascular disease. Among these novel biomarkers are C-reactive proteins, lipoprotein associated phospholipase A2 (Lp-PLA2), homocysteine, fibrinogen, plasminogen, interleukin-6 (IL-6), IL-18, and many others (Anderson 2008, Khakpour 2009, Packard 2009).

A novel biomarker for cardiovascular risk has clinical utility if it independently provides risk information above and beyond that provided by conventional risk factors, is easy to obtain and interpret in a primary care setting, is highly specific, accurately reproducible and contributes to patient management particularly through more accurate risk stratification and guidance in the choice of therapy (Oldgren 2007, Lerman 2008, Khakpour 2009).

Lp-PLA2, also known as platelet activating factor acetyl-hydrolase, has been proposed to be a more specific marker for vascular inflammation. It is an enzyme secreted by macrophages, monocytes, T-lymphocytes, and mast cells. Over two thirds of Lp-PLA2 circulate in the bloodstream bound to low-density lipoprotein cholesterol, and the rest travels bound to high-density and very low density lipoproteins. For several years there has been a lot of debate on whether the enzyme has a pro- or anti-atherogenic mechanism. One viewpoint suggests that it plays a role in the production of proinflammatory mediators including oxidized free fatty acids and lysophosphatidylcholine, and another view implies that that the enzyme could be protective by reducing inflammation and predisposition to thrombosis in blood through its hydrolysis of platelet activating factor (Anderson 2008, Wilensky 2009).

The diaDexus PLAC test is a second generation of the enzyme-linked immunoassay (ELISA) test used in many of the population studies that investigated the association of Lp-PLA2 with cardiovascular diseases. It is based on the standard principle of a sandwich enzyme immunoassay using two specific high affinity monoclonal antibodies directed against Lp-PLA2 that show no cross-reactivity with other phospholipases. A set of Lp-PLA2 calibrators is used to plot a standard curve of absorbance (y-axis) versus Lp-PLA2 concentration in ng/ml (x-axis) from which the Lp-PLA2 concentration in the test sample can be determined. This concentration of the enzyme in each

sample and control is then interpolated from the standard curve using a point-to-point curve fit with appropriate calibration curve fitting software. The test has a minimum detection limit of 1.3 ng/ml and the expected Lp-PLA<sub>2</sub> concentrations are 120-342 ng/ml for females and 131-376 ng/ml for males. PLAC test is classified under the Clinical Laboratory Improvement Amendments (CLIA) 88 as a high-complexity test and must be run in CLIA-certified-high-complexity laboratories (Hoogerveen 2005, FDA Website).

PLAC test, diaDexus, Inc, San Francisco, CA, was cleared by the FDA in 2003, for the quantitative determination of Lp-PLA<sub>2</sub> in human plasma to be used in conjunction with clinical evaluation and patient risk assessment as an aid for predicting risk for coronary heart disease, and ischemic stroke associated with atherosclerosis (FDA website).

## Medical Technology Assessment Committee (MTAC)

### PLAC Test in Detecting Risk of Coronary Heart Disease

#### 02/11/2004: MTAC REVIEW

**Evidence Conclusion:** Ballantyne et al's study was nested in a large prospective study. It included both men and women 45-64 years of age. In this sub-study CHD patients were compared to a random sample of 785 subjects (minus 45 cases with CHD), and not to the whole study population. The authors do not provide explanation why they selected such a design. There were several significant differences in the base-line characteristics between the cases, and non- cases. Adjustments were made for several of these variables, not for all. Other variables not adjusted for in the analysis may be potential confounders. Overall, it showed that the highest tertile of Lp-PLA<sub>2</sub> enzyme was associated with a higher CHD risk among patients with LDL cholesterol level <130 mg/dL. Packard's study was a case control nested in the WOSCOPS study. Participants were men 45-64 years of age, with baseline LDL cholesterol level 174 –232 mg/dL. Cases were those who developed a coronary event, and controls were men from the same cohort who did not develop a coronary event during the follow-up. Overall the results showed that lipoprotein-associated phospholipase A<sub>2</sub> was significantly associated with coronary events, independent of the other variables studied. Blake's study on the other hand did not detect a significant association between the enzyme and the risk of cardiovascular events among women. It was also a case control nested in a large trial, "Women's Health Study" that only enrolled women 45 years of age or older. The case control study was small, and the power might have been insufficient to detect a significant association. The different findings between the two studies may also indicate that lipoprotein-associated phospholipase levels may be predictive of coronary events in men but not women. The three studies reviewed examined Lp-PLA<sub>2</sub> as a marker or risk predictor for coronary events, but did not study the implication of identifying this risk factor on the management of the patients or in improving the net health outcome.

**Articles:** The search yielded 25 articles, the majority of which were news, review articles, and tutorials. The search did not reveal any RCTs. The studies embedded in larger prospective cohort studies were identified. All three were critically appraised: Ballantyne CM, Hoogerveen RC, Bang H, et al. Lipoprotein-associated phospholipase High sensitivity C-reactive protein, and risk incident coronary heart disease in middle-aged men and women in the atherosclerosis risk in communities (ARIC) study. *Circulation* 2004;109:837-842. See [Evidence Table](#). Packard CJ, O'Reilly DS, Caslake MJ, et al. Lipoprotein-associated phospholipase A<sub>2</sub> as an independent predictor of coronary heart disease. *N Engl J Med* 2000;343:1148-1155. See [Evidence Table](#). Blake GJ, Dada N, Fox JC, et al. A prospective evaluation of lipoprotein-associated phospholipase A<sub>2</sub> levels and the risk of future cardiovascular events in women. *J Am Coll Cardiol* 2001;38:1302-1306. See [Evidence Table](#).

The use of PLAC Test in detecting risk of coronary heart disease does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 10/05/2009: MTAC REVIEW

### PLAC Test in Detecting Risk of Coronary Heart Disease

**Evidence Conclusion:** *Lp-PLA<sub>2</sub> as a marker for predicting future CVD risk* In the last decade, a number of epidemiologic studies investigated the association between plasma Lp-PLA<sub>2</sub> and the cardiovascular disease risk. The majority were nested case-cohort studies, and the blood samples were taken only once at baseline and stored at ~ -70oC for up to 10 years before its analysis. The results were mainly presented in hazard ratios comparing the lowest with the highest tertile, quartile or quintile values. Several studies including West of Scotland Coronary Prevention Study (WOSCOPS), the Atherosclerosis Risk in Communities (ARIC) Study, and MONICA study found an association between elevated levels of Lp-PLA<sub>2</sub> and increased risk for cardiovascular events in certain groups of patients. In the ARIC study however, the relative risk associated with the upper tertile of Lp-PLA<sub>2</sub> became statistically insignificant when adjustments were made for traditional risk factors. Other studies including the Women's Health Study, GUSTO and FRISC did not show a significant association between Lp-PLA<sub>2</sub> and CVD risk. A meta-analysis (Garza 2007) that pooled the results of 14 studies, showed a significant independent association between Lp-PLA<sub>2</sub> and CVD risk. The results however, do not provide evidence that measurement of

Lp-PLA2 levels would improve risk stratification for CVD or add to the predictive value of the traditional risk factors and scoring systems used e.g. Framingham Risk Score. An analysis of the ARIC study (Folsom 2006) showed that the addition of Lp-PLA2 to the basic risk model increased the area under the receiver operating curve (AUC) from 0.774 to 0.780. Due to the large sample size, this small difference was statistically significant, but is of minor clinical significance. A statistically significant, independent association of a marker to CVD does not necessarily indicate that it improves the risk prediction beyond the traditional variables. Lp-PLA2 as therapeutic target There are no long-term published RCTs to date provide evidence that measuring LP-PLA2 would lead to meaningful changes in patient management, or improvement in clinical outcomes. In a multicenter placebo-controlled trial, Mohler and colleagues 2008 investigated the effect of darapladib, a selective Lp-PLA2 inhibitor, on the enzyme activity as well as on another panel of biomarkers. The study randomized 959 participants with stable CHD or risk equivalent, to receive a placebo or one of three doses of darapladib (40, 80, or 160mg daily), for 12 weeks, together with atorvastatin 20 or 80mg/day. The trial did not have hard clinical outcomes, instead Lp-PLA2 and other select biomarkers were used as surrogates of atherosclerosis risk, to assess the efficacy of the therapy. The results showed that darapladib given together with atorvastatin was associated with lower Lp-PLA2 activity, which appeared to be dose-dependent (darapladib 40,80, and 160 mg significantly inhibited Lp-PLA2 activity by 43%, 55%, and 66% respectively compared to placebo). This was observed in the two atorvastatin groups but without affecting the LDL levels. The study duration was too short to determine the long-term adverse events of the therapy, and its effect on CVD risk. (i.e. whether inhibition of Lp-PLA2 leads to accumulation of proinflammatory or prothrombotic factors). Intervention trials investigating the effect of LP-PLA2 inhibitors on coronary disease events are in progress. These include STABILITY trial on the effect of darapladib on CHD and FRANCIS-ACS trial that evaluates varespladib in patients with acute coronary syndrome. Diagnostic accuracy of PLAC test: The literature did not identify any study that examined the diagnostic accuracy, predictive values, or likelihood ratios of PLAC test in measuring LP-PLA2 among patients at different levels of cardiovascular disease risk. *Conclusion:* The current evidence suggests that Lp-PLA2 may be associated with vascular disease risk, but it is insufficient to show the association is causal, that measuring the enzyme level improves risk stratification for CVD, would have any impact on managing patients at high risk, or that inhibition therapy of Lp-PLA2 enzyme would improve health outcomes.

**Articles:** The search yielded around 33 articles. There was a meta-analysis, and a number of case control studies examining the association between Lp-PLA2 and CVD. The search also identified one randomized controlled trial on the effect of a selective Lp-PLA2 inhibitor of the enzyme activity (darapladib) in patients with CHD or risk equivalent, and another small RCT on the effect of the drug on the atherosclerotic plaque. The literature search did not reveal any published studies on the clinical benefits of screening for Lp-PLA2 in optimizing therapy and reducing cardiovascular risk, and/or events. There were also no studies on the diagnostic accuracy of PLAC test in assessing the Lp-PLA2 levels. The meta-analysis on the association between Lp-PLA2 and CVD risk, the ARIC study (FDA approval), and the RCT on the effect of darapladib on the enzyme activity in patients with CHD or risk equivalent were selected for critical appraisal: Garza CA, Montori VM, Connell JP, et al. Association between lipoprotein-associated phospholipase A2 and cardiovascular disease: a systematic review . Mayo Clin Proc.2007;82:159-165. See [Evidence Table](#). Ballantyne CM, Hoogeveen RC, Bang H, et al. Lipoprotein-associated phospholipase High sensitivity C-reactive protein, and risk incident coronary heart disease in middle-aged men and women in the atherosclerosis risk in communities (ARIC) study. Circulation 2004;109:837-842. See [Evidence Table](#). Mohler ER, Ballantyne CM, Davidson MH, et al. The effect of darapladib on plasma lipoprotein - associated phospholipase A2 activity and cardiovascular biomarkers in patients with stable coronary heart disease or coronary heart disease equivalent. The results of a multicenter, randomized double-blind, placebo-controlled study. J Am Coll Cardiol 2008;51:1632-1641. See [Evidence Table](#).

The use of PLAC Test in detecting risk of coronary heart disease does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Plethysmography

- Lower Limb Deep Vein Thrombosis (DVT)
- Occlusive Peripheral Arterial Disease (PAD)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### Non-Medicare Members

Clinical review is no longer required for this service.

#### PADnet System for the Detection of Peripheral Vascular Disease

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Plethysmography (PG) is a noninvasive method used to measure changes in blood flow or air volume within an organ or the whole body. The term plethysmography is a combination of the ancient Greek words plethysmos, which means increase, and grapho which means write (Alnaeb 2007). Total body plethysmography measures intrathoracic gas volume and volume change, pulmonary plethysmography measures the volume of air that can be voluntarily inhaled or exhaled, limb plethysmography measures changes in the volume of a limb in response to change in blood volume, and genital plethysmography measures blood flow in the genitals.

There are several types of plethysmographic systems that measure blood flow and velocity in the carotid artery and peripheral vascular system. These include electrical impedance plethysmography, segmental plethysmography, oculoplethysmography, strain gauge plethysmography, photoelectric plethysmography, air plethysmography, and several others. These instruments indirectly detect and quantify vascular disease based in alterations in pulse wave contour, blood pressure, or arterial or venous blood flow (Barnes 1991, Graham 1996).

Oculoplethysmography indirectly measures the hemodynamic significance of internal carotid artery stenosis or occlusion by demonstration of an ipsilateral delay in the arrival of ocular pressure transmitted from branches of the ophthalmic artery. It detects only severe narrowing or blockage, and is incapable of directly measuring the flow or demonstrating anatomic information or quantifying percent of stenosis. Other tests (ultrasound or angiography) are required to confirm the diagnosis and have largely replaced this technique (Graham 1996).

Photoplethysmography (PPG) is a technique based on the determination of optical properties of the underlying tissue. It uses an optical light-emitting diode in a sensor that is attached to the skin and transmits light through the dermis into the subcutaneous tissue. A photoelectric cell captures the reflected light to detect changes in blood volume. Changes in the beam wavelength are measured by a microcomputer and a plethysmogram representing the blood flow of the limb is produced. PPG is not strictly a plethysmographic technique as its operation is based on the principles of light densitometry and photon diffusion theory. Both PPG and light reflection rheography (also known as quantitative PPG), have been used in the detection of varicose veins, venous insufficiency, phlebothrombosis, and other peripheral venous disease (Higgins 1986, Keechi 2008, Khandanpour 2009).

Strain-gauge plethysmography (SPG) uses the technique of filling the distal veins of the lower limbs by inflation of a tourniquet around the thigh, causing occlusion of the veins, then indirectly measuring the changes in venous outflow and capacitance in response to release of tourniquet by a strain gauge placed around the calf. The strain-gauge plethysmography may also be used to assess the effectiveness of different types of compression devices

on the legs of patients with venous deficiency (Siau 2010).

Impedance plethysmography is performed by placing two sets of electrodes around the patient's calf and an oversized blood pressure cuff around the thigh. The electrodes sense a change in blood volume and record it on a strip chart. Changes in venous filling are produced by inflating the thigh cuff to obstruct venous return, then deflating the cuff to re-establish blood flow. The time required for the venous volume in the calf to return to baseline is recorded. A clot in the popliteal or proximal veins will delay venous emptying. In water plethysmography, an extremity is enclosed in a water-filled chamber where volume changes can be detected. Air plethysmography is based on the same principle but uses an air-filled long cuff. As indicated these techniques depend on detecting alterations in venous outflow and capacitance in the presence of thrombi in the deep veins. Extrinsic compression of the proximal veins by pregnancy tumor, or poor venous outflow in cases of severe edema, all may lead to false positive results. It was also reported that plethysmographic techniques are inaccurate in detecting deep vein thrombosis in vessels in which the venous outflow has not been significantly impeded by the thrombus (Graham 1996, Locker 2006, Mosti 2010).

Segmental plethysmography (or pulse volume recording [PVR]) is a noninvasive hemodynamic measurement that can potentially provide an initial assessment of the location and severity of peripheral arterial disease. Segmental limb plethysmography waveform analysis is based on evaluation of waveform shape and signal amplitude. Standardized criteria relating waveform changes to anatomic site and hemodynamic severity of disease are used in the diagnostic interpretation. The test involves placing cuffs around the leg at selected locations, and connecting them to a plethysmograph to detect and graphically record changes in limb volume. Normally, a single, large thigh cuff is used along with regular-sized calf and ankle cuffs, plus a brachial cuff that reflects the undampened cardiac contribution to arterial pulsatility. Once the cuff is inflated to 60–65 mmHg (a pressure sufficient to detect volume changes without resulting in arterial occlusion), pulse volume recordings are obtained. These PVRs have the potential of detecting and localizing significant occlusive lesions. The tests can also be repeated over time to follow disease progression. Segmental plethysmography is an indirect examination of the artery and may not detect multiple stenoses located at or above the level of the cuff (Gerhard-Herman 2006, Clements, TASC).

Plethysmography have the potential of providing rapid and non-invasive diagnosis of deep vein thrombosis, and peripheral arterial diseases, and was once considered to be the primary diagnostic test for noninvasive detection of deep vein thrombosis (Stevens 2007, Abbara 2010). However, it has been reported that due to its inaccuracy and with the improvements in both direct real-time ultrasonic imaging and Doppler ultrasonic flow detection and color-flow mapping, plethysmography as well as other indirect techniques are assuming a less important role in vascular diagnosis ( Barnes 1991, Stevens 2007).

Several plethysmographic devices have received FDA clearance as Class II medical devices to assist in the diagnosis of vascular disease. PADnet System for the detection of peripheral vascular disease was previously reviewed by MTAC in 2005 and did not meet its evaluation criteria due to lack of evidence on the system. The current review focuses on the use of plethysmography in the diagnosis of deep vein thrombosis and occlusive peripheral arterial disease.

The PADnet lab, manufactured by BioMedix, is a noninvasive cardiovascular blood flow monitor intended for use by trained medical professionals for the early detection of peripheral vascular disease (FDA Home page). The manufacturer claims that it detects blockages in arteries and the quality of blood flow using pulse volume recording and oscillometer segmental blood pressure measurement. It is used with a pressure cuff that is applied, and inflated to shut off the flow in the artery. When deflated the device records the oscillations and assigns a systolic pressure value and the results sent to the vascular specialists (BioMedix Web site). The device includes a laptop computer and a color printer on a medical grade car.

The FDA cleared PADnet for marketing in October 2004 based on its equivalence to legally marketed predicate devices.

## Medical Technology Assessment Committee (MTAC)

### **PADnet system**

#### **08/01/2005: MTAC REVIEW**

**Evidence Conclusion:** There is no published data to date on the PADnet system other than the marketing information provided by BioMedix, the manufacturer of the device, on their web site.

**Articles:** The search did not reveal any studies or articles on the PADnet system.

The use of PADnet system in the evaluation for early detection of peripheral vascular disease does not meet the *Group Health Medical Technology Assessment Criteria*.

## **PADnet system**

### **06/20/2011: MTAC REVIEW**

**Evidence Conclusion:** Use of plethysmography for detecting deep vein thrombosis. The published studies showed variable accuracies for the different plethysmographic techniques. The sensitivity ranged from 20-100% and specificity from the lower 60s to the upper 90s. The negative predictive value was as high as 100% for some systems such as digital photoplethysmography (D-PPG) used for screening asymptomatic patients at high risk for developing DVT. It performed better for proximal vs. distal (calf) DVTs. In a meta-analysis of 78 studies, Locker and colleagues (Evidence table 1) evaluated the performance of plethysmography and rheography in the diagnosis of DVT. Sensitivity and specificity were 75% and 90% respectively for impedance plethysmography, 83% and 81% for strain-gauge plethysmography, 85% and 91% for air plethysmography, and 91% and 71% for light-reflex rheography. The authors concluded that the accuracy of these techniques is insufficient to use them as stand-alone tests for screening for DVT. Siau and colleagues, 2010 (Evidence table 2) examined the accuracy of Well's clinical predictive tool, D-dimer analysis, and computerized strain-gauge plethysmography (CSGP) in the assessment of patients with suspected DVT, using imaging as a gold standard. The results showed that CSPG had a poor sensitivity and relatively low negative predictive value. CSPG performed better for above knee DVT vs. calf DVT, but still had an insufficient accuracy. Its use with D-Dimer did not add value to D-Dimer testing alone. Williams and colleagues (2005) also assessed the clinical utility of D-Dimer, strain-gauge plethysmography and a combination of both in the diagnosis of DVT in 243 patients with low, moderate, and high clinical pretest probability (PTP) of DVT. A definitive diagnosis of the disease was made based on a compression ultrasound. The results of the study showed that the plethysmography had lower negative predictive values than those of D-dimer test for patients with low, moderate, or high PTP. The addition of strain-gauge plethysmography did not improve clinical decision making in any of the groups. Sharif-Kashani, et al (Evidence table 3) evaluated the role of digital photoplethysmography (D-PPG) in screening asymptomatic patients at high risk for developing DVT. They examined 337 lower limbs of 169 patients and showed that D-PPG had 100% sensitivity in detecting DVT in these patients at high risk. It also had a 100% negative predictive value, i.e. it is a good test for excluding the disease. However, it had a lower specificity indicating that patients with abnormal results will need further investigations. It is to be noted that all detected DVTs were proximal and the results cannot be generalized to distal vein thrombosis. There is insufficient published evidence evaluate the accuracy of plethysmography in the diagnosis of clinically suspected upper extremity DVT. Use of plethysmography for detecting occlusive peripheral artery disease (PAD). The majority of published studies on the use plethysmography for detecting lower limb peripheral occlusive disease examined the accuracy and predictive values of photoplethysmography (PPG) and/ or agreement with other standard measures of ankle brachial pressure index (ABPI). In a study of selected 131 patients diagnosed with PAD, Khandanpour and colleagues, 2009 (Evidence table 4) found a significant agreement between ankle brachial pressure index (ABPI) derived from photoplethysmography (PPG) or continuous wave Doppler (CW-Doppler). Allen et al, 2008 (Evidence table 5) assessed the diagnostic accuracy of novel bilateral photoplethysmography toe pulse measurement techniques for the detection of significant lower limb PAD. The study included 111 subjects of whom 48 (43%) had a significant disease. The study results show high accuracy and significant agreement between bilateral PPG and ankle-brachial pressure index in detecting higher grade peripheral artery disease in the lower limbs. With the pulse measurement techniques studied PPG was found to have high negative predictive value when used to screen population with low prevalence of the disease, and a high positive predictive value among high disease prevalence patients referred to a vascular laboratory. Other published small studies evaluated different algorithms and devices based on PPG for the assessment of PAD, and concluded that the technology may be used as a noninvasive screening tool for early detection of the disease. It was reported however, that the technology may not provide valid measurements for patients with very high systolic arterial pressure, obesity, edema, or those with stiff arteries e.g. in diabetes mellitus, hypercholesterolemia, end-stage renal disease, and advanced age (Alnaeb 2007). The effect of using plethysmography vs. other standard techniques on clinical decision making and outcome of patients diagnosed with early or significant peripheral artery disease was not studied.

**Articles:** The following studies were selected for critical appraisal based on their population sizes and methodological quality: Allen J, Overbeck K, Nath AF, et al. A prospective comparison of bilateral photoplethysmography versus the ankle-brachial pressure index for detecting and quantifying lower limb peripheral arterial disease. *J Vasc Surg.* 2008;47:794-802. See [Evidence Table](#). Khandanpour N, Armon MP, Jennings B, et al. Photoplethysmography, an easy and accurate method for measuring ankle brachial pressure index: can photoplethysmography replace Doppler? *Vasc Endovascular Surg.* 2009;43:578-582. See [Evidence Table](#). Locker T, Goodacre S, Sampson F, et al. Meta-analysis of plethysmography and rheography in the diagnosis of deep vein thrombosis. *Emerg Med J* 2006;23:630-635. See [Evidence Table](#). Sharif-Kashani B, Behzadnia N, Shahabi P, et al. Screening for deep vein thrombosis in asymptomatic high-risk patients: a comparison between digital photoplethysmography and venous ultrasonography. *Angiology.* 2009;60:301-317. Medical necessity review is not required for all dx's except prevention of post-operative deep vein thrombosis, below.

##### Prevention of Post-Operative Deep Vein Thrombosis

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Thromboembolic disease is a common complication following surgery particularly total joint replacement arthroplasty. It has been reported that without prophylaxis the rate of deep vein thrombosis (DVT) is as high as 88% after total knee arthroplasty and as high as 50% after total hip arthroplasty. It is also reported that lower extremity DVT is the origin of 90% of symptomatic pulmonary embolism (PE). Prophylaxis for DVT has become the standard of care for total joint arthroplasty. Chemical prophylaxis with warfarin or low-molecular weight heparin effectively reduces the incidence of DVT, but carries a risk of bleeding. Orthopedic surgeons thus often use mechanical methods of prophylaxis as an alternative to chemoprophylaxis in patients with higher bleeding risk. Other surgeons also use it in standard risk patients in conjunction with the anticoagulant-based prophylaxis (Edwards 2008, Zywiell 2010).

Graduated compression stockings (GCSs) and intermittent pneumatic compression (IPC) are the two predominant mechanical methods used for DVT prevention. These have quite different methods of action; graduated compression stockings apply a constant pressure to the limb with the aim of maintaining a reduced venous caliber and preventing the static accumulation of blood. Intermittent pneumatic compression actively empties the deep veins of the limb in a predetermined cycle of pressure, producing a pulse of blood that travels proximally preventing stasis. On deflation of the cuff, the veins will refill, the intermittent nature of the system will insure periodic blood flow through the deep veins, as long as there is a supply. The IPC cuffs are normally wrapped around a limb, secured by velcro, and attached with tubes to an electric pump to regulate the pressure applied (Morris 2004, Morris 2010, Sobieraj-Teague 2011).

GCSs do not require attachment to any device and allow the patient to move freely. They come in a range of sizes and the limb has to be measured accurately to prevent incorrect pressure gradients, which may increase the risk of DVT. Intermittent compression devices are available in different forms; the cuff can cover the whole leg, the

calf, or just the feet, it may inflate uniformly or sequentially with graded pressure; and can have rapid or moderate inflation rates. These characteristics may influence patient compliance which is critical as the longer the device is used, the better is the protection. The major disadvantages for standard IPC devices used in hospitals are their size, weight, and reliance on external power source, all of which result in poor patient compliance and in turn limit the efficacy of the device (Morris 2004, Froimson 2009).

In an attempt to overcome the problem of poor patient compliance with traditional mechanical compression systems, several lightweight, portable, battery-powered devices were developed to allow their use by the patient while ambulating in the hospital or at home after discharge. Many of these devices have received FDA clearance.

## Medical Technology Assessment Committee (MTAC)

### *Portable Compression Devices for Prevention of Post op DVT*

#### **4/16/2012: MTAC REVIEW**

**Evidence Conclusion:** The published trials on the use of portable compression devices for the prophylaxis against DVT mainly compared the devices to chemoprophylaxis. Generally, patients randomized to the portable compression devices also received chemoprophylaxis, and in one study they also used graduated compression stockings (GCS). There were no head-to-head trials that compared the portable devices to the GCS. The trials reviewed were randomized and controlled, but were not blinded, used different definitions of major bleeds, and were financially supported by the manufacturers of the devices. Colwell and colleagues, 2010 (Evidence table 1) compared a new portable intermittent calf compression device (Continuous Enhanced Circulation Therapy plus Synchronized Flow Technology [CEPT+SFT]) versus a low molecular weight heparin (LMWH), for the prevention of thromboembolic disease after total hip replacement in 410 patients. The compression device was applied preoperatively and the LMWH was started the morning after the surgery. Patients in the compression group were allowed to receive 81mg of aspirin daily after surgery according to the surgeon's discretion. Both treatments were continued for 10 days, and the patients were followed-up clinically for 10 weeks. Bleeding was the primary outcome of the trial and rate of thromboembolic events was a secondary outcome. Overall, the results of the trials showed that the rate of major bleeds was significantly lower among the patients randomized to the portable compression group. There was no difference in the rate of thromboembolic events, but this was a secondary outcome and the study was not designed to determine equivalence. Edwards and colleagues, 2008 (Evidence table 2) compared an earlier version of the portable intermittent calf compression device (CEPT) given together with LMWH versus LMWH alone in the prevention of VTE in patients undergoing either total hip or total knee arthroplasty. Patients randomized to the CEPT group had the device applied in the operating room and continued during hospitalization, and the two groups received a LMWH for 7-8 days after surgery. The results of the study showed a significantly lower rate of DVT in patients in the portable compression device plus LMWH after a total knee arthroplasty compared to those using chemoprophylaxis alone, with a NNT of 8. No such significant difference was observed among those who underwent total hip replacement. In a similar trial Gelfer and colleagues (2006) compared prophylaxis with the CEPT and aspirin versus LMWH and showed significant reduction in the incidence of DVT in the compression group vs. the LMWH group. In a more recent RCT, Sobieraj-Teague and colleagues, 2012 (Evidence table 3) examined the efficacy and tolerability of a new portable intermittent calf compression device (Venowave) in high risk neurosurgical patients. Patients were randomized to usual care alone or in addition to the portable compression device, and all participants in the two groups were prescribed below the knee graduated compression stockings. They could also receive pharmacological prophylaxis (aspirin, LMWH, or unfractionated heparin) according to the discretion of the neurosurgeon. The overall results indicate the rate of DVT was significantly lower in the study group that used a portable compression device in addition to the graduated compression stocking and chemoprophylaxis as needed in this high risk neurosurgical patients. The portable devices used in the trials had an average compliance rate around 80%, and the associated side effects were mainly discomfort especially at night, pruritis, and sweating.

**Articles:** The literature search revealed a number of earlier RCTs that compared the graduated compression stockings to intermittent compression therapy. However, IPC systems used in these studies were the standard devices used in the hospitals and not the portable IPCs which are the focus of this review. There were three RCTs that compared the use chemoprophylaxis given alone or with IPC using portable devices after total joint arthroplasty, and one trial that evaluated the efficacy of using a portable compression device in addition to graduated compression stockings and chemoprophylaxis in high risk neurosurgical patients. The following studies were selected for critical appraisal;

Colwell CW Jr, Froimson MI, Mont MA, et al. Thrombosis prevention after total hip arthroplasty: a prospective, randomized trial comparing a mobile compression device with low-molecular-weight heparin. *J Bone Joint Surg Am.* 2010 ;92:527-535. See [Evidence Table](#)

Edwards JZ, Pulido PA, Ezzet K A, et al. Portable compression device and low-molecular-weight heparin compared with low-molecular-weight heparin for thromboprophylaxis after total joint arthroplasty. *J Arthroplasty.* 2008;23:1122-1127. See [Evidence Table](#)

Sobieraj-Teague M, Hirsh J, Yip G, Gastaldo F, et al. Randomized controlled trial of a new portable calf compression device (Venowave) for prevention of venous thrombosis in high-risk neurosurgical patients. *J Thromb Haemost.* 2012;10:229-235. See [Evidence Table](#)

The use of portable compression devices does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Portable Compression Devices**

#### **BACKGROUND**

Thromboembolic disease is a common complication following surgery particularly total joint replacement arthroplasty. It has been reported that without prophylaxis the rate of deep vein thrombosis (DVT) is as high as 88% after total knee arthroplasty and as high as 50% after total hip arthroplasty. It is also reported that lower extremity DVT is the origin of 90% of symptomatic pulmonary embolism (PE). Prophylaxis for DVT has become the standard of care for total joint arthroplasty. Chemical prophylaxis with warfarin or low-molecular weight heparin effectively reduces the incidence of DVT, but carries a risk of bleeding. Orthopedic surgeons thus often use mechanical methods of prophylaxis as an alternative to chemoprophylaxis in patients with higher bleeding risk. Other surgeons also use it in standard risk patients in conjunction with the anticoagulant-based prophylaxis (Edwards 2008, Zywiell 2010). Graduated compression stockings (GCSs) and intermittent pneumatic compression (IPC) are the two predominant mechanical methods used for DVT prevention. These have quite different methods of action; graduated compression stockings apply a constant pressure to the limb with the aim of maintaining a reduced venous caliber and preventing the static accumulation of blood. Intermittent pneumatic compression actively empties the deep veins of the limb in a predetermined cycle of pressure, producing a pulse of blood that travels proximally preventing stasis. On deflation of the cuff, the veins will refill, the intermittent nature of the system will insure periodic blood flow through the deep veins, as long as there is a supply. The IPC cuffs are normally wrapped around a limb, secured by velcro, and attached with tubes to an electric pump to regulate the pressure applied (Morris 2004, Morris 2010, Sobieraj-Teague 2011). GCSs do not require attachment to any device and allow the patient to move freely. They come in a range of sizes and the limb has to be measured accurately to prevent incorrect pressure gradients, which may increase the risk of DVT. Intermittent compression devices are available in different forms; the cuff can cover the whole leg, the calf, or just the feet, it may inflate uniformly or sequentially with graded pressure; and can have rapid or moderate inflation rates. These characteristics may influence patient compliance which is critical as the longer the device is used, the better is the protection. The major disadvantages for standard IPC devices used in hospitals are their size, weight, and reliance on external power source, all of which result in poor patient compliance and in turn limit the efficacy of the device (Morris 2004, Froimson 2009). In an attempt to overcome the problem of poor patient compliance with traditional mechanical compression systems, several lightweight, portable, battery-powered devices were developed to allow their use by the patient while ambulating in the hospital or at home after discharge. Many of these devices have received FDA clearance.

#### **04/16/2012: MTAC REVIEW**

##### **Portable Compression Devices**

**Evidence Conclusion:** The published trials on the use of portable compression devices for the prophylaxis against DVT mainly compared the devices to chemoprophylaxis. Generally, patients randomized to the portable compression devices also received chemoprophylaxis, and in one study they also used graduated compression stockings (GCS). There were no head-to-head trials that compared the portable devices to the GCS. The trials reviewed were randomized and controlled, but were not blinded, used different definitions of major bleeds, and were financially supported by the manufacturers of the devices. Colwell and colleagues, 2010 (Evidence table 1) compared a new portable intermittent calf compression device (Continuous Enhanced Circulation Therapy plus Synchronized Flow Technology [CECT+SFT]) versus a low molecular weight heparin (LMWH), for the prevention of thromboembolic disease after total hip replacement in 410 patients. The compression device was applied preoperatively and the LMWH was started the morning after the surgery. Patients in the compression group were allowed to receive 81mg of aspirin daily after surgery according to the surgeon's discretion. Both treatments were continued for 10 days, and the patients were followed-up clinically for 10 weeks. Bleeding was the primary outcome of the trial and rate of thromboembolic events was a secondary outcome. Overall, the results of the trials showed that the rate of major bleeds was significantly lower among the patients randomized to the portable compression group. There was no difference in the rate of thromboembolic events, but this was a secondary outcome and the study was not designed to determine equivalence. Edwards and colleagues, 2008 (Evidence table 2) compared an earlier version of the portable intermittent calf compression device (CECT) given together with LMWH versus LMWH alone in the prevention of VTE in patients undergoing either total hip or total knee arthroplasty. Patients randomized to the CECT group had the device applied in the operating room and continued during hospitalization, and the two groups received a LMWH for 7-8 days after surgery. The results of the study showed a significantly lower rate of DVT in patients in the portable compression device plus LMWH after a total

knee arthroplasty compared to those using chemoprophylaxis alone, with a NNT of 8. No such significant difference was observed among those who underwent total hip replacement. In a similar trial Gelfer and colleagues (2006) compared prophylaxis with the CECT and aspirin versus LMWH and showed significant reduction in the incidence of DVT in the compression group vs. the LMWH group. In a more recent RCT, Sobieraj-Teague and colleagues, 2012 (Evidence table 3) examined the efficacy and tolerability of a new portable intermittent calf compression device (Venowave) in high risk neurosurgical patients. Patients were randomized to usual care alone or in addition to the portable compression device, and all participants in the two groups were prescribed below the knee graduated compression stockings. They could also receive pharmacological prophylaxis (aspirin, LMWH, or unfractionated heparin) according to the discretion of the neurosurgeon. The overall results indicate the rate of DVT was significantly lower in the study group that used a portable compression device in addition to the graduated compression stocking and chemoprophylaxis as needed in this high risk neurosurgical patients. The portable devices used in the trials had an average compliance rate around 80%, and the associated side effects were mainly discomfort especially at night, pruritis, and sweating.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Esophageal achalasia (EA) is an uncommon motility disorder involving the smooth muscle layer of the esophagus and the lower esophageal sphincter (LES) located at the junction of the esophagus and stomach. Most commonly affecting middle-aged and older adults, the disorder can occur at any age and is characterized by incomplete LES relaxation, increased LES tone and lack of peristalsis of the esophagus, ultimately preventing the passage of food into the stomach. Symptoms include difficulty swallowing, regurgitation, chest pain and heart burn, as well as unintentional weight loss. Extreme complications may include aspiration of solids and liquids and perforation of the esophagus (Mayberry, 2001).

Diagnosis of EA relies on esophageal manometry or radiographic imaging and treatment options aim to disrupt or weaken the LES although no treatment option effectively cures the condition. Conservative options, such as pharmaceutical therapies, have LES muscle relaxing effects which may help to relieve symptoms in early stages, however, long term drug therapy is inconvenient, ineffective, and associated with a variety of unpleasant side effects. Alternative treatment options require the mechanical weakening of the LES via procedures that tear or cut the muscle. Laparoscopic Heller myotomy (LHM) has long been regarded as the standard treatment option for patients who are good surgical candidates (Campos, Vittinghoff et al. 2009). The technique involves cutting the muscles at the end of the esophagus and at the top of the stomach allowing the valve between the esophagus and stomach to remain open. In total, the procedure requires five small incisions on the abdomen wall.

Advances in the surgical field have allowed surgeons to improve practice offering alternative entry routes. Per oral endoscopic myotomy (POEM), for example, is a less invasive alternative to LHM. First described in human subjects in 2008, the technique, nearly analogous to LHM, allows the surgeons to enter via a natural orifice thus eliminating the need for skin incision. Further to this, when compared to LHM, the POEM technique allows surgeons to isolate the inner circular muscles for myotomy and offers better access to the mediastinal esophagus without disrupting the crura of the diaphragm. The technique is reported to minimize pain and blood loss (Inoue, Minami et al. 2010; Costamagna, Marchese et al. 2012).

The United States Food and Drug Administration (FDA) ensures the safety and effectiveness of drugs and medical devices. As a surgical procedure for the treatment of achalasia, POEM does not fall under the authority of the FDA. The Medical Technology and Assessment Committee (MTAC) has not previously addressed POEM for the treatment of achalasia and is currently reviewing it due to provider request to support a coverage decision.

## Medical Technology Assessment Committee (MTAC)

### Per Oral Endoscopic Myotomy

**12/15/2014:** Bhayani and colleagues compared the experience of 101 patients from a single institution undergoing either LHM or POEM. Swallowing outcomes at one and six months were assessed via objective measures (manometry and pH levels). In addition, the investigators collected information regarding operative time, complications and postoperative gastro-esophageal reflux disease (GERD). Manometry indicated that there were decreases in pressure across both groups, however, the postmyotomy resting pressures were higher for the POEM group than for LHMs (16 vs. 7 mm Hg, P=0.006). The same effect was not seen between groups for relaxation pressure (9 vs. 4). Both groups experienced relief of symptoms with the POEM group showing significantly lower Eckhardt scores when compared with the LHM group at one month (0.8 vs. 1.8, P<0.0001). At six months, however, the difference was no longer significant (1.7 vs. 1.2, P=0.1). Ultimately, the investigators conclude that POEM is comparable with LHM for safe and effective treatment of EA (Bhayani, Kurian et al. 2014). While POEM appears to be comparable to LHM, the technique is still evolving. At this particular point in time, the body of evidence only reports on the success of POEM in highly select populations with short-term follow-up. To add to this, the study is not randomized and relies on a small sample of subjects. Ultimately, the literature does not support the safety and effectiveness of POEM for the treatment of achalasia when compared to LHM. Conclusions: There is insufficient evidence to support the effectiveness of POEM compared to LHM for the treatment of EA. There is insufficient evidence to support the safety of POEM compared with LHM for the treatment of EA.

**Articles:** The literature search revealed over 200 studies relating to the use of POEM for the treatment of achalasia. The literature was dominated by publications that introduce and describe the technique as well as studies from individual centers describing their experience with POEM with short-term follow-up. A search of the clinicaltrials.gov website revealed several ongoing studies with the aim to evaluate of the clinical utility and safety of POEM (NCT01832779). For the purposes of this review, one of the larger and more recent nonrandomized comparison studies was identified for critical appraisal. The following articles were selected for critical appraisal: Bhayani NH, Kurian AA, Dunst CM, et al. A comparative study on comprehensive, objective outcomes of laparoscopic Heller myotomy with per-oral endoscopic myotomy (POEM) for achalasia. *Annals of Surgery*. 2014; 259(6): 1098-1103. [See Evidence Table 1](#).

The use of Per Oral Endoscopic Myotomy does not meet the *Group Health Medical Technology Assessment Criteria*.

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Colorectal cancer is the second leading cause of death from cancer in the United States. Most colorectal cancers begin with the development of benign adenomatous polyps. It is believed that cells acquire genetic changes as adenomatous polyps develop into an adenocarcinoma, a process that can take 10-20 years.

EXACT Sciences Corporation (Marlborough, MA) has developed tests that analyze patient stool samples to see whether they contain genetic markers associated with colorectal cancer. The PreGen-Plus, the topic of the current review, is a test for the early detection of colorectal cancer in an average-risk population. It uses a multitarget assay panel that incorporates 21 point mutations in *K-ras*, adenomatous polyposis coli (*APC*) and *p53* genes, a microsatellite instability marker (BAT-26) and a proprietary marker, the DNA Integrity Assay (Tagore, 2003). A similar test, PreGen-26, is intended to detect colorectal cancer in high-risk patients. The BAT-26 is the basis of the PreGen-26 test (manufacturer's website).

According to a review article on emerging technologies for colorectal cancer screening (Levin, 2003), it may be possible to identify cancer at an earlier stage with DNA tests such as the PreGen-Plus than with fecal occult blood test (FOBT), the standard non-invasive test. Other potential advantages of the PreGen-Plus test may be a reduced false-positive rate because the test targets mutations specific to colorectal cancer, and the need for only a single stool sample since DNA is shed continuously from colorectal cancer and precursor polyps. A potential disadvantage is that the most appropriate markers for DNA detection of colorectal cancer are not known and clinical evaluation of the tests is limited.

The FDA has determined that approval of the PreGen-Plus test is not required.

### Medical Technology Assessment Committee (MTAC)

#### Fecal DNA Testing

02/11/2004: MTAC REVIEW

**Evidence Conclusion:** The Tagore study provides preliminary data on the sensitivity of the PreGen-Plus test in a population with known colorectal neoplasia (47-85% depending on the stage of disease) and specificity in normal individuals (96%). This is not an accurate assessment of how the screening test would perform in a general population sample. Studies that include a blinded comparison of PreGen-Plus to a gold standard in a screening population are needed. In addition, head-to-head comparisons with the standard noninvasive test for colorectal cancer, fecal occult blood testing, would strengthen the evidence.

**Articles:** The manufacturer's website had an announcement dated October, 2003 stating that a study comparing the sensitivity of the PreGen-Plus test and FOBT had been conducted and would be submitted to a peer-reviewed journal when data analysis was finished.

One was on the sensitivity and specificity of a multitarget assay panel labeled as PreGen Plus using colonoscopy as the gold standard (Tagore, 2003). The second article was on a plasma DNA test, not a stool test. The broader search on DNA testing for colorectal cancer yielded 49 articles. There was an empirical study demonstrating the successful extraction of DNA from the stool of colorectal cancer patients (Dong, 2001). Another empirical study extracted DNA from stool and evaluated the sensitivity and specificity of the DNA analysis compared to colonoscopy (Ahlquist, 2000). The PreGen-Plus test was not mentioned, although analysis for the Ahlquist study was done by Exact Laboratories. The Tagore study was critically appraised because it clearly used the PreGen-Plus test and had a larger sample size than the Ahlquist study (n=292 vs. n=61). The citation is as follows: Tagore KS, Lawson MJ, Yucaitis JA. et al. Sensitivity and specificity of a stool DNA multitarget assay panel for the detection of advanced colorectal neoplasia. *Clin Colorectal Cancer* 2003; 1: 47-53. See [Evidence Table](#)

The use of PreGen-Plus in screening of colorectal cancer does not meet the *Group Health Medical Technology Assessment Criteria*

### **Fecal DNA Testing**

#### **10/20/2014: MTAC REVIEW**

**Evidence Conclusion:** In an effort to establish the accuracy of the Cologuard™ test, Imperiale et al. compared the tests performance to the gold standard, colonoscopy. As a secondary endpoint, the investigators also compared the tests performance to the FIT. The cross-sectional study evaluated 9,989 asymptomatic averaged-risk adults between the ages of 50 and 84 years who were scheduled to undergo screening colonoscopy. All participants provided a stool specimen before routine bowel preparation for colonoscopy. Stool specimens were analyzed in three laboratories and colonoscopy results were evaluated by independent local pathologists and further confirmed and categorized by a central independent pathologist. The gold standard identified CRC in 65 participants and advanced adenomas (AA) in 757 participants. The Cologuard™ was able to accurately detect 60 cancers and 321 AA (sensitivities 92.3% and 42.4%, respectively) while the FIT identified 48 cancers and 180 AA (sensitivities 73.8% and 23.8%, respectively). The Cologuard™ had a lower specificity for detecting all nonadvanced adenomas or negative results when compared with FIT (86.6% vs. 94.9%, respectively) (Imperiale, Ransohoff et al. 2014). Risks of Diagnostic Test In terms of risk, the Cologuard™ test itself presents low risk to the patient as it is noninvasive, requires no bowel preparation or dietary restrictions and allows for collection during normal bowel movements in the toilet. The study reported four mild adverse events and one death. The death occurred prior to colonoscopy and was deemed to be unrelated to the study. Of particular concern, however, is the indirect risk as it relates to false positives and negatives. Although the Cologuard™ test yields a high sensitivity, that came at the cost of a lower specificity which could lead to additional colonoscopies as well as unnecessary stress and anxiety.

Table 1. Number Needed to Screen (NNS) to detect one CRC

	Colonoscopy	Cologuard	FIT
Any CRC (156-286)	154 (120-200)	166 (130-217)	208
Stage I to III CRC (169-313)	166 (130-217)	178 (140-238)	227
Advanced precancerous lesion (65)	13 (12-24)	31 (28-35)	55 (48-65)

Conclusions from the last review of multitarget stool DNA testing in MTAC did not live up to genetic test evaluation criteria citing the need for additional research that includes blinded comparison with the gold standard in a screening population as well as, head-to-head comparison with the current standard noninvasive test. Since then, the Cologuard™ has undergone several evolutions reflected throughout the literature with the most current version validated by a large cross-sectional study including comparisons with the gold standard, colonoscopy, as well as the FIT. Generally speaking, the study, which was financially supported by the manufacturer Exact Sciences Inc., appears to be well-designed and well-conducted including almost 10,000 participants in 90

centers across the United States and parts of Canada. The investigators, who are also the developers of the device, fail to describe the baseline characteristics of the study population but do identify the significant differences between the participants whose results could be fully evaluated and those whose results could not. Further to this, recruitment was weighted towards the older age of the eligible age spectrum which might limit the generalizability of the results. The design of the study was the primary limiting factor. While it is typical to use a cross-sectional study design to compare diagnostic tests, the results provide only a snap shot of the situation at one given time, failing to provide adequate follow-up to demonstrate how the Cologuard™ might function in clinical practice. Further to this, the sensitivity and specificity is based on stool samples collected at one point in time limits the ability to provide an interval at which the Cologuard™ would be applied. Exact Sciences has provided the protocol for a longitudinal post-market approval study that will likely address these limitations. Conclusions: There is evidence to establish the analytic validity of the Cologuard™ test, that is, the test accurately identifies the particular gene variant.

There is evidence to establish the clinical validity of the Cologuard™ test, that is, how well the test is related to the presence, absence or risk of a disease. There is insufficient evidence to conclude that the test is not harmful to patients. There is insufficient evidence to establish the clinical utility of the Cologuard™ test, that is, the test is reasonably expected to lead to more appropriate patient management than if the test were not available.

**Articles:** The literature search for multitarget stool DNA testing for CRC screening yielded numerous publications. Among them were various editorials addressing the recent FDA approval, as well as commentary recognizing the Cologuard™ as the first product to be reviewed through the joint FDA-CMS parallel review pilot program. In addition, several publications that mirror the evolution of the device over the years were identified. The FDA's current approval relied on one clinical trial to establish the safety and effectiveness of the Cologuard™ test. This article was selected for review. See [Evidence Table](#)

The use of Stool DNA Testing for Colorectal Cancer Screening does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Preimplantation Genetic Diagnosis (PGD)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Non-Medicare Members

Preimplantation genetic diagnosis (PGD) is performed on single cells removed from an embryo. Standard prenatal diagnosis is customarily performed on multiple cells obtained by chorionic villous sampling (CVS) or amniocentesis. PGD on single, embryonic cells is considered medically necessary only when there is a need to diagnose a specific, detectable single gene mutation in an embryo at risk due to an identified deleterious genetic mutation in one or both genetic parents, as defined below:

- I. In order to meet medically necessary criteria for PGD, **both 1 and 2 must be met:**
  - A. There must be documentation confirming that PGD is medically necessary to detect a single gene disorder or chromosomal abnormality whose expression in the fetus or child would be expected to have a significant adverse medical impact and that detection in the pre-implantation period would directly affect reproductive decisions.
  - B. **One of the following** clinical circumstances must be documented:
    1. One genetic parent has a balanced, reciprocal translocation or Robertsonian translocation
    2. One genetic parent has a single gene autosomal dominant disorder
    3. Both genetic parents are known carriers of the same single gene autosomal recessive disorder
    4. The female genetic parent is a known carrier of a single gene X-linked recessive disorder

*The procedure to obtain a cell sample from an embryo for PGD is covered when the above criteria for PGD are met. However, the procedures and services (such as IVF) required to create the embryos to be tested and the transfer of embryos to the uterus after testing, are covered only for members with advanced reproductive technology (ART) benefits and who meet medical necessity criteria for IVF (in vitro fertilization).*

- II. The following are not covered for preimplantation screening:
  - A. Aneuploidy screening, including in the setting of recurrent miscarriage or repeated failure of IVF (e.g. screening for Down Syndrome, in women over the age of 35)
  - B. Screening for chromosomal abnormalities in the absence of a known, clinically significant genetic or chromosomal defect in a genetic parent
  - C. Selecting against conditions or disorders in the absence of a known and identifiable genetic or chromosomal defect in a genetic parent
  - D. Gender selection or selection of nonmedical trait to determine an embryo's carrier status
  - E. Screening for autosomal recessive disorders when the embryos are created using donor egg or sperm
  - F. Detecting genetic or chromosomal abnormalities contributed by donor egg or sperm
  - G. Screening for adult-onset disorders or for genetic predisposition to adult-onset disease
  - H. HLA typing of an embryo to identify a future suitable stem cell, tissue or organ transplantation donor.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Historically, couples at high risk of transmission of a genetic disorder have had limited reproductive options, forced after prenatal diagnosis to choose between either termination of affected pregnancies or acceptance of the emotional and financial burden of having a child with severe disability and early mortality. Preimplantation genetic diagnosis (PGD) was introduced to enhance efficiency in assisted conception. It is a technique for reducing the burden of genetic disease performed on couples who are at risk of a specific inherited disorder and used to identify genetic defects present in embryos created through in vitro fertilization (IVF) before transferring them to the uterus.

PGD is performed in conjunction with IVF and is offered to both fertile and infertile couples. Introduced in 1990 as an experimental procedure, PGD has now become an established clinical option in reproductive medicine (Handyside, Kontogianni et al. 1990; Verlinsky, Ginsberg et al. 1990). Because only unaffected embryos are transferred to the uterus for implantation, PGD can provide an alternative to current postconception diagnostic procedures such as amniocentesis or chorionic villus sampling which are sometimes followed by pregnancy termination when results are unfavorable (Verlinsky, Cohen et al. 2004). PGD techniques are now also being utilized for preimplantation genetic screening (PGS) with the intent to identify potential genetic abnormalities in conjunction with IVF for couples without specific known inherited disorders.

With single gene disorders and inherited chromosomal abnormalities being the main indicators for PGD, the technique is available for most known genetic mutations. With that said, PGD can be considered a rapidly evolving technique. Put simply, PGD requires egg extraction, IVF, cell biopsy, genetic analysis and embryo transfer (Handyside, Kontogianni et al. 1990). At present, there are three different procedures utilized for cell biopsy, each with its own advantages and disadvantages, including polar body biopsy, cleavage-stage embryo biopsy and blastocyst biopsy. Depending on the whether the characteristic being tested for is associated with chromosomes or DNA, the sample can be analyzed in one of three ways including polymerase chain reaction (PCR), fluorescence in situ hybridization (FISH) and comparative genomic hybridization with new technologies emerging rapidly. Regardless of the methods, the results are used by parents and providers to select which embryos are transferred back to the uterus with the ultimate goal of establishing an unaffected pregnancy.

The accuracy and reliability of PGD are key issues and exploring these matters requires consideration of the technical challenges and risks inherent in the genetic test itself and in the IVF procedure that it entails. Any PGD strategy has to deal with the detection and avoidance of misdiagnosis from the onset with the risk and outcome relating directly to the type of genetic disorder for which testing is performed. Although PGD has been suggested as an alternative for current post conception diagnostic procedures, the amount of DNA available for testing is limited. Due to this risk, prenatal diagnosis by amniocentesis or chronic villus sampling testing is strongly recommended upon established pregnancy to confirm genetic health.

National Coverage Determinations (NCD)	<a href="#">Prolotherapy, Joint Sclerotherapy, and Ligamentous Injections with Sclerosing Agents (150.7)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Back pain is the most prevalent musculoskeletal condition encountered in primary care and is estimated to affect 65-80% of people during their life. The majority of back pain is benign, self-limiting and requires symptomatic therapy only. Back pain is often related to muscular, tendon or ligament strain or injury. Common treatments include physical therapy, steroidal and nonsteroidal anti-inflammatory drugs and chiropractic manipulation. One proposed treatment for chronic low back pain, which is resistant to other treatments, is the injection of sclerosing compounds into back tissue to produce scarring and potentially stabilize soft tissue in the area of the injury.

Prolotherapy, also called sclerotherapy and proliferative injection therapy, has been used as a treatment for chronic low-back pain since the 1950s (Dechow). Sclerosing agents are injected into the fibro-osseous junctions of the lower back. The rationale for using prolotherapy is that the injection of irritant solutions into a pain site will initiate local inflammation. The inflammation then begins a cascade of wound healing which results in the deposition of new collagen and stronger ligaments (Banks).

### Medical Technology Assessment Committee (MTAC)

#### Prolotherapy/Sclerotherapy for Low Back Pain

06/09/1999: MTAC REVIEW

**Evidence Conclusion:** The published evidence consists of two randomized trials, one showing a 1.5 point improvement (7.5 point visual analogue scale) in pain and a 4.9 point improvement (33 item scale) in disability between the proliferant and placebo groups at 6 months. The experimental regimen also included injectable steroids, forceful spinal manipulation and different anesthetic volumes, therefore differences between experimental and placebo groups cannot be attributed only to proliferant. The second trial reports a less than 1 point difference in pain and disability scores between proliferant and placebo at 6 months. Overall, there is weak evidence that an intensive intervention (including proliferant) produces a statistically and clinically significant improvement in pain and disability. When proliferant and placebo are directly compared, there is weak evidence that proliferant provides no additional benefit compared to placebo.

**Articles:** Ongley, MJ, et al, A New Approach to the Treatment of Chronic Low Back Pain, 1987, *Lancet*, ii: 143-148. See [Evidence Table](#). Klein, RG, et al, A Randomized Double-Blind Trial of Dextrose-Glycerine-Phenol Injections for Chronic Low Back Pain, *Journal of Spinal Disorders*, 1993, 6:23-33 See [Evidence Table](#).

The use of prolo/sclerotherapy in the treatment of low back pain does not meet the *Group Health Medical Technology Assessment Criteria*.

**04/10/2002: MTAC REVIEW**

**Prolotherapy/Sclerotherapy for Low Back Pain**

**Evidence Conclusion:** One new RCT was identified on prolotherapy/sclerotherapy for low back pain (Dechow). This was a valid RCT that compared three, once-weekly injections with sclerosing agents to placebo injections. The authors did not find statistically significant differences in pain, disability or spinal flexion between groups. There was clearly no effect of the intervention on disability but it is possible that there could be smaller, yet clinically significant differences in pain or spinal flexion that this study was unable to detect. Prolotherapy/sclerotherapy was previously reviewed by MTAC in April 1999. In the first MTAC review, two RCTs were critically appraised. Both were limited in that the treatment group received multiple interventions so the effectiveness of prolotherapy itself could not be determined. In summary, there is insufficient evidence that prolotherapy/sclerotherapy as a stand-alone intervention is effective for reducing low back pain. The results of one RCT powered to detect a 50% reduction in pain levels between groups suggest that it may be an ineffective intervention.

**Articles:** The search yielded six articles. There were two empirical studies, one of which was included in the initial MTAC review in 1999. The other study, an RCT, was evaluated. No additional empirical studies were identified from the appeal materials. The following article was critically appraised: Dechow E, Davies RK, Carr AJ, Thompson PW. A randomized, double-blind, placebo-controlled trial of sclerosing injections in patients with chronic low back pain. *Rheumatology* 1999;38:1255-59. See [Evidence Table](#).

The use of prolo/sclerotherapy in the treatment of low back pain does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Extracorporeal Immunoabsorption Using Protein A Columns

- **Prosorba Columns**

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

See [NCD for Extracorporeal Immunoabsorption \(ECI\) Using Protein A Columns \(20.5\)](#)

##### For Non-Medicare Members

Medical necessity review is no longer required for this service.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The ProSORBA column is a plastic cylinder that contains protein A bound to an inert silica matrix. Protein A, a component derived from several strains of the *staphylococcus* bacterium, has a strong affinity for high molecular weight IgG and IgM complexes such as rheumatoid factors and circulating immune complexes. The ProSORBA device is used with a plasmapheresis machine. Blood is withdrawn from the patient and the plasma is separated and passed through the ProSORBA column. Afterwards, the plasma is recombined with the cells and returned to the patient. Treatment generally involves 12 weekly therapy sessions. The rationale for ProSORBA treatment is that it reduces harmful antibodies or immune complexes that are present in auto-immune diseases and does not result in systemic immunosuppression (Felson et al., 1999; Levy & Degani, 2003).

ProSORBA is most commonly used for treating rheumatoid arthritis (RA), a chronic condition involving inflammation of the lining of the joints (synovium). RA can lead to the destruction of the synovium and the underlying joint, and is associated with chronic pain, loss of function and disability. Other treatments for RA include medication treatment (nonsteroidal anti-inflammatories, analgesics, glucocorticoids or prednisone, disease modifying antirheumatic drugs (DMARDs), and biologic response modifiers such as etanercept, physical therapy, splinting and surgery to correct deformities.

The FDA has approved the use of ProSORBA columns for the treatment of idiopathic thrombocytopenic purpura (ITP) in patients with platelet counts less than 100,000 mm<sup>3</sup> and in patients with moderate to severe rheumatoid arthritis who have failed or are intolerant to DMARDs.

Medicare approved the use of ProSORBA columns for the treatment of ITP in 1987. Effective January 1, 2001, Medicare also covers this treatment for RA for use in patients meeting certain conditions. Medicare's approval of ProSORBA for the treatment of RA was based on preliminary findings of the ProSORBA Trial Investigators study published in *Arthritis and Rheumatism* (Felson et al., 1999).

#### Medical Technology Assessment Committee (MTAC)

##### 02/14/2001: MTAC REVIEW

##### ProSORBA Column

**Evidence Conclusion:** The RCT data reported on in Felson et al., 1999 and Furst et al., 2000 are insufficient to draw conclusions on the effectiveness of ProSORBA at treating rheumatoid arthritis. Limitations of this trial are that it had a small sample size, included patients with severe RA only, had only a 69% completion rate, was funded by the manufacturer of the ProSORBA column, and compared ProSORBA treatment to sham treatment without including

a control group that did not receive apheresis. This trial provides fair data that ProsoRba treatment has a high rate of adverse effects.

**Articles:** The search yielded 16 articles. 11 were review articles, opinion pieces or were not directly relevant. There were three case series studies, all with small sample sizes (fewer than 25 patients). There were two reports of the same randomized controlled trial conducted by the ProsoRba Trial Investigators (Furst et al., 2000 and Felson et al., 1999). An evidence table was created on the Felson study in May 2000 by Brian Budenholzer, MD, Director, Clinical Enhancement and Development, Group Health Cooperative Network Services Division. For this review, an evidence table was created for the newer, Furst et al. study. References for the articles on the ProsoRba Trial Investigators' RCT are as follows: Furst D, Felson D, Thoren G, Gendreau for the ProsoRba Trial Investigators. Immunoadsorption for the treatment of rheumatoid arthritis: Final results of a randomized trial. *Ther Apher* 2000; 41: 363-373. See [Evidence Table](#). Felson, DT, LaValley MP, Baldassare AR, Block JA, Caldwell JR, Cannon GW et al. The ProsoRba column for treatment of refractory rheumatoid arthritis. *Arthritis Rheum* 1999; 42: 2153-2159. See [Evidence Table](#).

The use of ProsoRba Column for treatment of arthritis does not meet the *Group Health Medical Technology Assessment Criteria*.

**06/06/2005: MTAC REVIEW**

**ProsoRba Column**

**Evidence Conclusion:** One new empirical study on ProsoRba treatment, a case series, was identified since the previous literature search. The case series (Roth, 2004) found that 54% of study completers had a positive response to treatment. However, only 91 out of 131 enrolled patients (69%) completed the study, and the study was uncontrolled and non-blinded. Study duration was 24 weeks, similar to the length of the previously published sham-controlled RCT. To date, no long-term follow-up data are available for ProsoRba treatment. Conclusions from the 2001 MTAC review are as follows: "The RCT data reported on in Felson et al., 1999 and Furst et al., 2000 are insufficient to draw conclusions on the effectiveness of ProsoRba at treating rheumatoid arthritis. Limitations of this trial are that it had a small sample size, included patients with severe RA only, had only a 69% completion rate, was funded by the manufacturer of the ProsoRba column, and compared ProsoRba treatment to sham treatment without including a control group that did not receive apheresis. This trial provides fair data that ProsoRba treatment has a high rate of adverse effects."

**Articles: Rheumatoid arthritis:** There was one additional publication (Gendreau, 2001<sup>1</sup>) on the same randomized controlled trial previously reported on by Felson (1999) and Furst (2000). The Gendreau article did not appear to present new substantive data and was therefore not reviewed. The only other empirical study was a recent case series, conducted by Fresenius HemoCare (Redmond, WA) as part of post-marketing surveillance. This study was critically appraised: Roth S. Effects of ProsoRba column apheresis in patients with chronic refractory rheumatoid arthritis. *J Rheumatol* 2004; 31: 2131-5. See [Evidence Table](#).

The use of ProsoRba Column for treatment of arthritis does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Proton Radiation Therapy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

##### Local Coverage Determination (LCD)

[Stereotactic Radiosurgery \(SRS\) and Stereotactic Body Radiation Therapy \(SBRT\) \(L34151\).](#)

##### For Non-Medicare Members

Group Health has elected to use the Proton Beam Therapy (GHC-0389) MCG\* for medical necessity determinations.

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Most recent medical oncology notes
- Most recent radiation oncology notes
- Most recent imaging (i.e. CT/MRI)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Proton beam therapy (PBT) is a form of stereotactic radiosurgery that delivers a focused dose of radiation energy to the targeted area while surrounding normal tissue receives minimal radiation. PBT releases its highest percentage of energy at the end of its path (i.e., Bragg peak), depositing 100% of the dosage at the targeted tissue.

Prostate cancer is one of the most common cancers, and the second leading cause of cancer death in men in the US. The standard management options for a localized disease include surgery, radiotherapy, and watchful waiting. The optimal treatment however, is not well defined; both surgery and radiation therapy are reported to have equivalent outcomes, and each approach has its advantages and side effects. Researchers have reported that for intermediate and high risk disease, radical external beam treatment is the standard treatment, and that there is a dose response for biochemical relapse-free survival. The success of radiation therapy depends on the dose delivered to the tumor and the accuracy of delivery. However, dose escalation to >70 Gy is associated with an increase in genitourinary and gastrointestinal side effects. Several techniques have been developed to deliver high doses of radiation to the prostate while sparing surrounding normal tissue. Among these are the three dimensional conformal radiotherapy external beam radiotherapy (EBRT), intensity modulated radiation therapy (IMRT), brachytherapy, and proton therapy (Vordermark 2006, Hoskin 2007, Rades 2007).

Proton therapy, like other forms of radiotherapy, works by aiming ionizing particles onto the target tumor. Theoretically proton radiation therapy has the benefit of more localized delivery of radiotherapy than that achieved with photons produced by a linear accelerator. Unlike X-ray beams, a single proton beam can be shaped to deliver a homogeneous radiation dose to irregular three dimensional volumes. Due to their relatively large size, protons scatter less easily in the tissue with very little lateral dispersion. They follow a predetermined track and stop abruptly at any prescribed depth. The proton beam energy is at its minimum at entry to the body, and maximum, known as 'Bragg-peak', near the end of the range of the proton beam. Beyond the Bragg-peak, the dose falls practically to zero. By choosing appropriate proton beam energies, the depth of the Bragg-peak can be adjusted

according to the depth and extent of the target volume. The improved dose distribution can potentially allow higher doses of radiotherapy to the tumor without increasing the normal tissue toxicity (Slater 1999, Brada 2007, Olsen 2007). There is a concern however, that proton beam radiotherapy exposes healthy tissue to stray radiation emitted from the treatment unit and secondary radiation produced within the patient. These exposures may potentially increase a patient's risk of developing a radiogenic second cancer (Taddei 2008).

Proton therapy was initially used for the treatment of choroidal malignant melanomas, and tumors of the skull base. Currently there is a growing interest in the use of proton therapy for the treatment of tumors where conventional radiation therapy would damage surrounding radiosensitive tissues to an unacceptable level as brain tumors, lung cancers, and other tumors in the neck, vicinity of the spinal cord, liver, upper abdomen and pelvis. Proton therapy is also favored for pediatric patients where long-term side effects, as occurrence of secondary tumors resulting from overall radiation dose to the body, are of concern.

Some investigators have questioned the ability of proton therapy to limit morbidity, and others have questioned its value relative to the cost. In addition, concerns have been raised about a potential risk for secondary malignancies.

### **National Cancer Institute Clinical Trials**

Two Phase III trials are comparing photon versus carbon ion radiation therapy in patients with low and intermediate grade chondrosarcoma of the skull base ([NCT01182753](#)) and chordoma of the skull base ([NCT01182779](#)).

A Phase III trial is comparing hypofractionated proton radiation versus standard dose for prostate cancer ([NCT01230866](#)).

### **National Comprehensive Cancer Network (NCCN) Guidelines**

**Prostate Cancer:** NCCN guidelines for [prostate cancer](#) (v 3.2012) state that "proton beam therapy can be added as an alternative radiation sources. However, proton therapy is not recommended for routine use at this time since clinical trials have not yet yielded data that demonstrates superiority to, or equivalence of, proton beam and conventional external beam for the treatment of prostate cancer". (1)

**Bone Cancer:** NCCN guideline for [bone cancer](#) (v 2.2012) states that "proton and/or photon beam RT may be useful for patients with chondrosarcomas of the skull base and axial skeleton with tumors in unfavorable location not amenable to resection." (3)

The FDA cleared several medical devices designed to produce and deliver a proton beam for the treatment of patients with localized tumors and other conditions susceptible to treatment by radiation.

## **Medical Technology Assessment Committee (MTAC)**

### ***Proton Radiation Therapy***

#### **12/01/2008: MTAC REVIEW**

**Evidence Conclusion:** No randomized clinical trials, to date, have directly compared the efficacy of protons and conventional radiation therapy using photons in the treatment of clinically localized prostate cancer. The only two published RCTs involving proton therapy were evaluating the effect of dose escalation on cancer control. Both studies used protons as a boost to photon irradiation and neither was intended to compare the efficacy of protons versus the conventional photon radiation therapy. Zietman et al's (2005) trial randomized 393 patients with early stage (T1B-T2B) prostate cancer to a proton dose of 19.8 GyE or 28.8 GyE followed by photon irradiation to 50.4 Gy. All patients in the two arms of the study received both photons and protons. The results showed no significant difference in 5-year survival (96% vs. 97%) between the two proton doses, but there was an improvement in 5-year biochemical total control rate from 61.4% for the low-dose group to 80.4% to the high dose group (p<.001). The higher radiation dose was however associated with an increase in acute and late grade 2 rectal toxicity. The largest published case series on proton therapy (Slater 2004) was retrospective, had selection bias, and no comparison or control group. Patients with localized prostate cancer who received proton therapy in the early 1990s were treated with a combination therapy of both protons and photons. Later, after the proton treatment capacity increased, the patients were selected to receive either proton therapy alone or in combination with photon therapy. Therapy was selected based on the patient's risk of lymph node micrometastases as calculated by Partin nomogram. The study does not allow making any conclusion on the comparative efficacy of protons versus photon therapy. There is insufficient evidence to determine whether the use of protons for the treatment of patients with localized prostate cancer would improve survival, and reduce biochemical failure rate compared with the highly conformal photon therapy currently used. There is insufficient evidence to determine

whether the use of protons for treating patients with localized prostate would reduce acute or late rectal and urinary toxicity compared with the highly conformal photon therapy currently used.

**Articles:** The literature search revealed over 170 published articles on proton therapy for prostate cancer. The majority were review articles on the technical aspects of the therapy. No randomized controlled trials that directly compared proton therapy to any other conventional radiation therapy were identified. There were two published RCTs on dose escalation (Shipley 1995, and Zietman 2005) using a combination of photon and proton therapy for localized prostate cancer, and several case series with historical, or no controls. Shipley's trial (1995) used inadequate photon doses and techniques compared to the current standards. Zietman and colleagues' trial as well as the largest published case series on proton therapy were selected for critical appraisal. Zietman AL, Desilvio ML, Slater JD, et al. Comparison of conventional-dose vs. high-dose conformal radiation therapy in clinically localized adenocarcinoma of the prostate. A randomized controlled trial. JAMA 2005; 294:1233-1239. See [Evidence Table](#). Slater JD, Rossi CJ, Yonemoto LT, et al. Proton therapy for prostate cancer.: The initial Loma Linda University experience Int J Radiat Oncol Biol Phys 2003;59:348-352. See [Evidence Table](#).

The use of Proton radiation therapy for the treatment of prostate cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## Codes

CPT: 77520, 77522, 77523, 77525

## Clinical Review Criteria

### LASIK (Laser Assisted In-situ Keratomileusis) PTK (Phototherapeutic Keratectomy)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

##### National Coverage Determination (NCD)

[Refractive Keratoplasty \(80.7\)](#)

##### For Non-Medicare Members

Lasik is covered when all of the following conditions are met:

- 1) Astigmatism and/or anisometropia have been surgically induced.
- 2) Patient is unable to wear glasses or contact lenses after surgery due to anisometropia (eyes having unequal refractive power) and/or high astigmatism.
- 3) Documented attempts to correct the surgical error with historical means of refraction and/or contact lens fitting.
- 4) There must be 2.5 diopter or more increase in astigmatism and/or anisometropia from the pre to the postoperative state.
- 5) Patient must express some functional disability due to the increased astigmatism and the surgeon must have a reasonable expectation that the laser will improve the patient's function.
- 6) The patient's primary problem is not corneal graft rejection or multiple failures when comfort may be the goal, not vision improvement.
- 7) The equipment used is FDA approved and the procedure is performed by an ophthalmologist trained to use the equipment.

Relative contraindications include:

- a) Poorly controlled autoimmune disease
- b) Immunosuppressive medications
- c) Keratoconus and other corneal ectasias
- d) History of keloid formation
- e) Coexisting ocular disease
- f) Unstable refractive error
- g) Underlying systemic disease affecting wound healing

Phototherapeutic keratectomy (PTK) is covered when the **ALL** following criteria are met:

- 1) It is being used to remove damaged and/or diseased tissue from the anterior surface of the cornea.
- 2) **ONE** of the following is true:
  - a) The proposed treatment area is up to 300 microns thick or the cornea is at least 250 microns thick after ablation and other less invasive treatments are not possible or have failed (such as stromal puncture)
  - b) The treatment of anterior corneal dystrophies, removal of scars and other opacities in the anterior third of the cornea, and smoothing of irregular corneal surfaces to improve visual acuity and reduce pain associated with the corneal condition or improve the patient's ability to wear or tolerate spectacles or contact lenses.
- 3) And none of the following conditions exist:
  - a) Active infections of the cornea
  - b) Bullous keratopathy
  - c) Deep pathology extending beyond the anterior third of the cornea
  - d) Depressed scars
  - e) Unstable keratometry
  - f) Existing hyperopia

Photorefractive keratectomy (PRK) is considered cosmetic and is not covered.

**Note:** Phototherapeutic keratectomy (PTK) should not be confused with photorefractive keratectomy (PRK). Although technically the same procedure, PTK is used for the correction of particular corneal diseases; PRK involves use of the excimer laser for correction of refractive errors (e.g., myopia, hyperopia, astigmatism, and presbyopia) in persons with otherwise non-diseased corneas.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

In 1995 the FDA approved the use of Excimer 193nm laser as an effective tool for performing phototherapeutic (PTK=correcting corneal pathology) and photorefractive (PRK=correcting visual abnormalities) keratectomy of PRK and PTK. In early 1996 Group Health evaluated the use of this technology and its efficacy. Following that evaluation it was recommended that Group Health would provide PRK/LASIK as a non-covered service. However, in a few cases where traditional treatment options, including surgery, have failed and the only option available is PRK/LASIK.

## Evidence and Source Documents

On March 13, 1996, The GHC Committee on Medically Emerging Technology (COMET) reviewed key articles and concluded that the recently FDA approved Excimer 193nm laser is an effective tool for performing phototherapeutic (PTK=correcting corneal pathology) and photorefractive (PRK=correcting visual abnormalities) keratectomy. In the case of photorefractive keratectomy, its use should be restricted to patients with low to moderate myopia (1 to 8 diopters of visual correction) until efficacy data becomes available for PRK in high myopes. For GHC patients, it was recommended that PTK for corneal pathology should be a covered service and that PRK for refractive errors should be a non-covered service.

## Clinical Review Criteria

### Pulmonary Rehabilitation

- COPD
- Chronic Pulmonary Lung Disease
- Emphysema

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

#### National Coverage Determination (NCD)

[Pulmonary Rehabilitation Services \(240.8\)](#)

#### For Non-Medicare Members

- I. Medically supervised outpatient pulmonary rehabilitation will be considered medically necessary when **ONE of the following** (either A or B) are met:
  - A. Pulmonary rehabilitation may be indicated when **ALL of the following** are present:
    1. Member does not have a recent history of smoking or has quit smoking for at least 3 months; and
    2. Member has a reduction of exercise tolerance that restricts the ability to perform activities of daily living (ADL) and/or work; and
    3. Member has chronic pulmonary disease (including alpha-1 antitrypsin deficiency, asbestosis, chronic obstructive asthma, emphysema/COPD, chronic airflow obstruction, chronic bronchitis, cystic fibrosis, fibrosing alveolitis, pneumoconiosis, pulmonary alveolar proteinosis, pulmonary fibrosis, pulmonary hemosiderosis, radiation pneumonitis), or other conditions that affect pulmonary function such as ankylosing spondylitis, bronchopulmonary dysplasia, Guillain-Barre' syndrome or other infective polyneuritis, muscular dystrophy, myasthenia gravis, paralysis of diaphragm, sarcoidosis, or scoliosis.
    4. Respiratory dysfunction, as indicated by **ONE or more of the following**:
      - i. FEV1( forced expiratory volume in 1 second) < or = to 65% of predicted
      - ii. DLCO (single breath diffusion capacity of CO<sub>2</sub>) < or = to 65%
    5. Patient ambulatory able to comply with exercise requirements of the program
    6. Member does not have any concomitant medical condition that would otherwise imminently contribute to deterioration of pulmonary status or undermine the expected benefits of the program to include **ALL of the following**:
      - a. No dementia or disabling stroke
      - b. No symptomatic coronary artery disease,
      - c. No ejection Fraction < 20%
      - d. No untreated or unstable dysrhythmias
      - e. No active joint disease
      - f. No claudication
      - g. No metastatic cancer
      - h. No active pulmonary infection
      - i. No unstable pulmonary hypertension
      - j. No severe psychiatric disease
      - k. No significant neurologic disease that prevents participation in the exercise component of the program
  - B. Patient has been referred to or is enrolled in a lung transplant program or is status-post operative for a lung transplant or lung volume reduction surgery

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

The American Thoracic Society and the European Respiratory Society define pulmonary rehabilitation as “an evidence-based, multidisciplinary, and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities. Integrated into the individualized treatment of the patient, pulmonary rehabilitation is designed to reduce symptoms, optimize functional status, increase participation, and reduce health care costs through stabilizing or reversing systemic manifestations of the disease. Comprehensive pulmonary rehabilitation programs include patient assessment, exercise training, and psychosocial support”.

Individuals with chronic obstructive pulmonary disease (COPD) constitute the largest population of those referred for pulmonary rehabilitation. COPD is defined as a slowly progressive disease of the airways characterized by airflow limitation and loss of lung function that is not fully reversible. Pulmonary rehabilitation may also be of value for other patients who have respiratory symptoms associated with reduced functional capacity or health-related quality of life (Celli 2008; Nici 2006).

The American Academy of Chest Physicians and the American Association of Cardiovascular and Pulmonary Rehabilitation updated their guideline on pulmonary rehabilitation in 2007. The new guideline accepts the above definition of pulmonary rehabilitation. This guideline considers the three most important features of a successful pulmonary rehabilitation program to be: a multidisciplinary approach, individual assessment and goal-setting, and paying attention to physical functioning and social functioning. The guideline recommends at least 6 weeks of pulmonary rehabilitation; however, no specific combination of program components is recommended (Ries 2007).

## Medical Technology Assessment Committee

### ***Pulmonary Rehabilitation***

#### **05/01/2000: MTAC REVIEW**

**Evidence Conclusion:** Although there is some evidence that specific pulmonary rehabilitation programs have lasting benefits for selected patients (Guell et al., Griffiths et al.), conclusions cannot be drawn about the effectiveness of pulmonary rehabilitation in general for the following reasons: Each pulmonary rehabilitation program has different components (see attached table): study methodologies do not permit conclusions about which component or components affect outcomes. Each pulmonary rehabilitation program is a different length and has a different intensity (see attached table): it is not possible to draw conclusions about what length or intensity is necessary to improve outcomes. Study methodologies do not permit conclusions about whether the pulmonary rehabilitation program itself or other factors such as the social support provided by program participation affects outcomes. Most programs have small sample sizes and results may be unreliable. Replications of individual programs are not available. The results of programs are not necessarily generalizable to other populations. For example, the Guell et al. study was conducted only with men and results may not be generalizable to women. Most of the early studies examining the effectiveness of PR were of poor quality (as reported in the meta-analysis by Cambach et al.) The ideal evidence, which does not currently exist, would be well conducted RCTs that examine different combinations of PR program components (e.g. education alone, education+exercise, exercise alone, etc.). In addition, there needs to be sufficient numbers of participants and data for the entire population of interest (i.e. both men and women).

**Articles:** The literature search yielded 73 articles. There were 8 randomized controlled trials (RCTs) and 2 meta-analyses. Five RCTs were excluded because of one of the following reasons: The groups compared were not directly relevant to this review (in-patient vs. out-patient PR, PR vs. lung surgery); had a small sample size (total n < 50); or were included in the meta-analysis that was selected for review.

Articles selected for critical appraisal include: The more recent meta-analysis: Cambach, W, Wagenaar, RC, Koelman, TW, van Keimpema, T, Kemper, HCG. The long-term effects of pulmonary rehabilitation in patients with asthma and chronic obstructive pulmonary disease: A research synthesis. Arch Phys Med Rehabil 1999; 80: 103-111. See [Evidence Table](#). Griffiths, TL, Burr, ML, Campbell, IA et al. results at one year of outpatient multidisciplinary pulmonary rehabilitation: a randomized controlled trial. Lancet 2000; 355: 362-8. See [Evidence Table](#). Guell, R, Casan, P, Belda, J et al. Long-term effects of outpatient rehabilitation of COPD: a randomized trial. Chest 2000; 117: 976-83. See [Evidence Table](#). Wedzicha, JA, Bestall, JC, Garrod, R et al. Randomized controlled trial of pulmonary rehabilitation in severe chronic obstructive pulmonary disease patients, stratified with the MRC dyspnoea scale. Eur Respir J 1999; 12: 363-9. See [Evidence Table](#).

The evidence failed MTAC evaluation criteria due to the lack of a standard definition of pulmonary rehabilitation and the paucity of rigorous studies.

### **Pulmonary Rehabilitation**

#### **12/01/2008: MTAC REVIEW**

**Evidence Conclusion:** The best evidence on the efficacy of pulmonary rehabilitation for COPD is a Cochrane review of randomized controlled trials (Lacasse et al., 2006). PR was defined as a program of at least 4 weeks' duration that included exercise therapy, with the optional addition of education or psychosocial support. The meta-analysis did not specify whether programs included individualized assessment or a multidisciplinary team, so it is not clear how many programs met the criteria defined for this review. Pooled analyses in the Cochrane report found significantly better functional exercise capacity, maximal exercise capacity and quality of life in patients randomized to PR compared to usual care. Limitations of the evidence included in the Cochrane review include: Most of the published RCTs were small, and of low-quality. None were rated by the Cochrane reviewers as high-quality. No data were reported on long-term effectiveness of PR. Most studies reported findings at the end of the active intervention. The outcomes reported were exercise capacity and quality of life. There are insufficient data on the impact of PR on the rate of exacerbations and hospitalizations. The comparison intervention in the Cochrane review was usual care, the content of which varied from study to study. Thus, we cannot draw conclusion on which components of PR might be effective. Another limitation of the body of evidence is that RCTs comparing PR to sham PR programs are not available. Therefore, we cannot determine whether PR programs per se are effective or whether there is a 'placebo effect' of participating in a program believed by patients to be beneficial. One RCT (Sewell et al., 2005) suggests that an individually tailored exercise program, a key feature of pulmonary rehabilitation, may not be any more effective than a general exercise program in which all participants perform the same exercise. The Sewell study did not find statistically significant differences in functional ability or exercise performance in patients with COPD randomly assigned to receive a 7-week PR program of education plus a general or individualized exercise program. The Sewell study is not conclusive—sample size calculations were not reported and it may have been underpowered. In conclusion: The evidence on pulmonary rehabilitation for COPD has important limitations. RCTs were small and of low quality, outcome data are short-term and are only available for exercise capacity and quality of life, and a placebo effect of participating in a PR program cannot be ruled out. There are no RCTs comparing a PR program meeting criteria established for this review and a less-intensive intervention. It is important to know whether a comprehensive PR program that includes individualized assessment and involves a multi-disciplinary team is more effective than a less resource-intensive intervention such as an exercise program. There is insufficient evidence on the effectiveness of pulmonary rehabilitation for conditions other than COPD.

**Articles:** The ideal study is a double-blind randomized controlled trial comparing pulmonary rehabilitation to a sham rehabilitation program (i.e. a program of similar intensity without the therapeutic content under evaluation). No studies meeting these criteria were identified. However, there was one relatively large RCT (Sewell et al., 2005) that compared an individualized exercise program to a general exercise program for COPD. The general exercise program could be considered a type of sham and could allow for blinding of participants. Other than a sham-controlled trial, the next best design is a study comparing two PR programs with a different combination of components, especially if one of the PR programs met the definition for this review. One small RCT was identified that compared exercise only, exercise plus activity training and exercise plus didactic education (Norweg et al., 2005). This study, however, was excluded due to the small number of participants. A third type of comparison intervention is "usual care". Since the previous MTAC review, a Cochrane review of randomized controlled trials comparing pulmonary rehabilitation to usual care for patients with COPD has been published (Lacasse et al., 2006). No large, well-conducted RCT on PR versus any comparison intervention published after the Cochrane review was identified. The search did not yield any randomized controlled trials or meta-analyses that evaluated pulmonary rehabilitation for any lung condition other than COPD. The Cochrane review and one RCT were critically appraised: Lacasse Y, Goldstein R, Lasserson TJ, Martin S. Pulmonary rehabilitation for chronic obstructive pulmonary disease. Cochrane Database of Systematic Reviews 2006. Issue 4. See [Evidence Table](#). Sewell L, Singh SJ, Williams JEA et al. Can individualized rehabilitation improve functional independence in elderly patients with COPD? Chest 2005; 128: 1194-1200. See [Evidence Table](#).

The use of pulmonary rehabilitation in the treatment of COPD, chronic pulmonary lung disease and emphysema does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Pulmonary Rehabilitation**

#### **12/20/2010: MTAC REVIEW**

**Evidence Conclusion:** A recent meta-analysis that evaluated the effectiveness of pulmonary rehabilitation after an acute exacerbation of COPD found that compared to usual care, subjects in the pulmonary rehabilitation intervention had fewer hospital admissions. However, only 3 studies with a total of 93 subjects were included in the meta-analysis (Puhan 2009).

### Pulmonary Rehabilitation vs. Usual Care

Outcome	# of studies	# of subjects	Odds Ratio (95% CI)	NNT (95% CI)
Hospital admission	3	93	0.13 (0.04 to 0.35)	3* (2 to 4)

\*NNT over 34 weeks

Conclusion: Evidence from a meta-analysis that included small studies of moderate quality suggests that pulmonary rehabilitation is effective at reducing hospital admissions in patients with an acute exacerbation of COPD.

**Articles:** Only randomized controlled trials, meta-analyses, and clinical trials were included in the review. Studies were excluded if they were: community based; if they did not have sufficient statistical power to detect a difference in one of the main outcomes; or if they did address one of the main outcome measures (hospitalizations or emergency department visits). The following study was critically appraised: Puhan M, Scharplatz M, Troosters T, Walters ED and Steurer J. Pulmonary rehabilitation following exacerbation of chronic obstructive pulmonary disease. *Cochrane Database Syst Rev.* 2009, Issue 1. Art No.: CD005305. DOI: 10.1002/14651858.CD005305.pub2. See [Evidence Table](#).

The use of pulmonary rehabilitation in the treatment of COPD, chronic pulmonary lung disease and emphysema does not meet the *Group Health Medical Technology Assessment Criteria*.

#### For Non-Medicare Members

Group Health has elected to use the Facet Neurotomy (A-0218) MCG\* for medical necessity determinations.

\*The MCG are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider &/or specialist (Neurology, physiatrist, anesthesia, orthopedics)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Radiofrequency (RF) neurotomy is a treatment for various conditions, including certain types of back and neck pain. It is based on the premise that severing the nerve supply to a painful structure may reduce pain and allow a restoration of function. It was first described by Shealy in 1975 and the technique has been modified since that time (Niemisto, 2003). Generally, in order to use RF neurotomy, two criteria must be fulfilled: 1) the structure responsible for the pain must be at or near the spinal facet joints and 2) the painful structure must be identified with a diagnostic block of local anesthesia causing temporary relief of pain. Due to the high false-positive rate of single local anesthetic blocks, placebo-controlled blocks are recommended, particularly for the lumbar spine (Lord and Bogduk, 2002).

The RF neurotomy procedure consists of inserting a radiofrequency electrode percutaneously under fluoroscopy guidance to the targeted area. A small amount of electrical stimulation is initially used to identify the nerve position. A regional anesthetic is then injected. After that, RF current is applied to the tissue. RF current is low energy, high frequency alternating current. When applied to biological tissue, the current causes charged molecules to oscillate and the resulting friction produces heat. A RF lesion is made by raising the temperature of the electrode to 70-90°C for 60-90 seconds. The size of the lesion varies with the size of the electrode; the maximum width of the lesion is 3-4 times the width of the electrode tip. Since the lesions are small, accurate placement of the electrode requires knowledge of the topography of the target nerve tissues and surgical precision (Lord and Bogduk, 2002)

Documentation should include:

- Pre-procedural documentation must include a complete initial evaluation including history and an appropriately focused musculoskeletal and neurological physical examination. There should be a summary of pertinent diagnostic tests or procedures justifying the possible presence of facet joint pain.

- A procedure note must be legible and include sufficient detail to allow reconstruction of the procedure. Required elements of the note include a description of the techniques employed, nerves injected and sites(s) of injections, drugs and doses with volumes and concentrations as well as pre and post-procedural pain assessments. With RF neurotomy, electrode position, cannula size, lesion parameters, and electrical stimulation parameters and findings must be specified and documented.
- Facet joint interventions (diagnostic and/or therapeutic) must be performed under fluoroscopic or computed tomographic (CT) guidance. Facet joint interventions performed under ultrasound guidance will not be reimbursed.
- A hard (plain radiograph with conventional film or specialized paper) or digital copy image or images which adequately document the needle position and contrast medium flow (excluding RF ablations and those cases in which using contrast is contra-indicated, such as patients with documented contrast allergies), must be retained and submitted if requested.
- In order to maintain target specificity, total IA injection volume must not exceed 1.0 mL per cervical joint or 2 mL per lumbar joint, including contrast. Larger volumes may be used only when performing a purposeful facet cyst rupture in the lumbar spine.
- Total MBB anesthetic volume shall be limited to a maximum of 0.5 mL per MB nerve for diagnostic purposes and 2ml for therapeutic. For a third occipital nerve block, up to 1.0 mL is allowed for diagnostic and 2ml for therapeutic purposes.
- In total, no more than 100 mg of triamcinolone or methylprednisolone or 15 mg of betamethasone or dexamethasone or equivalents shall be injected during any single injection session.
- Both diagnostic and therapeutic facet joint injections may be acceptably performed without steroids.

## Medical Technology Assessment Committee (MTAC)

### Back/Neck Pain

#### 07/14/2004: MTAC REVIEW

**Evidence Conclusion: Back Pain** There is insufficient evidence to conclude that RF neurotomy improves health outcomes among patients with back pain. Two of the three RCTs on back pain that were reviewed (LeClaire; Barendse) did not find a significant benefit of RF neurotomy compared to a sham intervention in the primary analysis. Barendse may have been underpowered to detect a clinically significant difference between groups. The third study (van Kleef, 1999), which included patients with low back pain originating from the lumbar zygapophysial joint, found significantly more clinical successes in the RF neurotomy group. The latter study (n=32), which included a multivariate analysis to adjust for baseline differences, had imprecise estimates with large confidence intervals and only an 8-week follow-up period. All of the studies were limited by small sample sizes. In addition, all of the studies used non-blinded diagnostic blocks and there may have been false positive findings of the location of pain. Long-term safety and efficacy of RF neurotomy for treating back pain was not evaluated.

**Evidence Conclusion: Neck pain** There is insufficient evidence to conclude that RF neurotomy improves health outcomes among patients with neck pain. One of the two RCTs reviewed (Lord) was well designed but had a biased presentation of study results. The authors did not report their primary outcomes, pain and impact of pain on activities of daily living, at the end of the double blind follow-up period at 3 months. The results they did report were confounded by rescue treatment. The other RCT (van Kleef, 1996) found a significant benefit of RF neurotomy compared to sham intervention for patients with cervicobrachial pain. The study is limited by its short (8-week) follow-up period and small sample size (n=20), which can result in baseline differences between groups. Also, the van Kleef, 1996 study used non-blinded diagnostic blocks and some patients may have been falsely identified with cervicobrachial pain. Long-term safety and efficacy of RF neurotomy for treating neck pain was not evaluated.

**Articles:** The search yielded 23 articles. There was a Cochrane library review from 2003 that reviewed the randomized controlled trials on the topic, but did not conduct a quantitative meta-analysis to evaluate the overall effectiveness of the treatment. Seven double-blind sham-controlled RCTs met the inclusion criteria for the Cochrane review. One additional small RCT published after the Cochrane review was identified in the Medline search, but this study was excluded because the patient population had already failed intradiscal electrothermal annuloplasty (IDET). The Cochrane investigators assigned a methodological quality score to each RCT they included. Studies that received a quality score of at least 7 out of 10 were selected for this review. The LeClaire and Barendse articles were by the same research groups, but included different study populations. **Back pain:** There were four RCTs on the treatment of back pain. One RCT that had a low methodology score in the Cochrane review was not reviewed. The remaining three RCTs were critically appraised: LeClaire R, Fortin L, Lambert R et al. Radiofrequency facet joint denervation in the treatment of low back pain. *Spine* 2001; 26: 1411-1418. See [Evidence Table](#) van Kleef M, Barendse GAM, Kessels A et al. Randomized trial of radiofrequency lumbar facet denervation for chronic low back pain. *Spine* 1999; 24: 1937-1942. See [Evidence Table](#) Barendse GAM, van den Berg SGM, Kessels AHF et al. Randomized controlled trial of percutaneous intradiscal radiofrequency thermocoagulation for chronic discogenic back pain. *Spine* 2001; 26: 287-292. See [Evidence Table](#) Lord SM,

Barnsley L, Wallis BJ et al. Percutaneous radio-frequency neurotomy for chronic cervical zygapophyseal-joint pain. *N Engl J Med* 1996; 335: 1721-1726. See [Evidence Table](#)

The use of radiofrequency neurotomy in the treatment of chronic neck and back pain does not meet the *Group Health Medical Technology Assessment Criteria*.

**07/29/2005: MTAC REVIEW**

**Back Pain/Neck Pain**

**Evidence Conclusion:** A PubMed search (2004 to present) yielded 6 articles. Four were review articles and one was a study of electrode placement, not effectiveness. There was one new RCT (Stovner et al. *Cephalalgia* 2004; 24: 821). The study was not worth critically appraising because it only included 12 patients. It did not find a significant benefit of radiofrequency neurotomy vs. sham treatment for neck pain, but they almost certainly did not have sufficient statistical power.

This review was not taken to the Medical Technology Assessment Committee. The information was not sufficient to warrant a review by the committee.

## Clinical Review Criteria

### Radioimmunoscintigraphy

- ProstaScint (Indium In 111 Capromab Pendetide, Capromab)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

National Coverage Determinations (NCD)

[Nuclear Radiology Procedure \(220.8\)](#)

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Prostate cancer is the most frequently diagnosed malignancy in the US, and second leading cause of death in men. In the era of prostate specific antigen (PSA) testing, prostate cancer is detected at an earlier stage, and about 85% of newly diagnosed patients have a localized disease that may be treated with definitive radical prostatectomy or radiation therapy. Though these are considered definitive treatments, 15-40% of the patients will develop biochemical PSA relapse within 10 years. The disease may recur locally in the prostatic fossa, in the regional lymph nodes, or at distant sites (Nagda 2007, Raj 2001, Pukar 2008).

The appropriate management of prostate cancer is highly dependent on accurate information about the location and extent of the disease. Surgical resection of the prostate is not indicated for patients whose disease has spread outside the prostatic bed. Although a rising PSA level may be indicative of prostate cancer and a residual or recurrent disease after radical prostatectomy, it is not specific and cannot determine the stage of the disease or discriminate between local cancer and metastatic involvement. Normograms, or clinical algorithms (e.g. that developed by Partin and colleagues in the early 1990s), use a combination of serum PSA level, Gleason score, and clinical stage to predict the likelihood of extraprostatic disease in order to help with treatment decisions. The normograms offer a statistical probability of disease organ confinement for populations of patients with similar clinical variables, but sometimes do not apply to the individual patient, who may need to be evaluated further. Traditionally patients undergo transrectal ultrasound with biopsy to assess local tumor, chest x-ray to look for any lung metastases, bone scan to determine the presence of osseous metastases, and CT scan or MRI of the abdomen, and pelvis to evaluate lymph node for disease involvement. After definitive treatment of the cancer, patients are followed up with periodic measurement of PSA levels and digital rectal examination (DRE). Imaging is performed if there are suspicious findings on DRE, PSA relapse, or if the patients have symptoms such as bone pain. Distinguishing between local versus systemic extent of the disease in patients with a PSA relapse is crucial for determining the salvage treatment modality. Salvage radiation therapy is used for local recurrence in the prostatic fossa, and systemic therapy is considered for those with a disease outside the fossa.

Conventional CT scans and MRI may be helpful in evaluating patients who have advanced disease with adjacent organ invasion and distant lymph adenopathy, but have limited clinical value in local staging or detecting early recurrence of the tumor. CT and MRI classify metastatic nodes strictly by size; they are classified as normal if they are one centimeter or less in diameter, and as abnormal if larger. The majority of patients presenting with clinically localized prostate carcinoma and occult lymph node metastases have either microscopic involvement or a disease volume less than 1 cm<sup>3</sup>, which would go undetected. On the other hand, inflammatory or hyperplastic nodes

grater than one centimeter in diameter might be erroneously classified as neoplastic (Polascik 1999, Raj 2002, Bander 2006, Nagda 2007).

In contrast to anatomic imaging, radioimmunoscintigraphy is a functional imaging modality which acquires images through the use of a radiolabeled antibody that selectively recognizes malignant tissue. One antigen of interest for prostate cancer is prostate-specific epithelial cell membrane antigen (PSMA) which is expressed at high levels in prostate cancers. The expression increases as the tumor grade increases, and in metastatic deposits. It increases further as the tumor becomes androgen-independent.

Capromab pendetide (ProstaScint) is a murine monoclonal antibody that reacts with PSMA. Immunoscintigraphy is accomplished by labeling the antibody with indium 111. After infusion of the antibody, whole body planar and single-photon emission CT images are obtained. ProstaScint images can potentially aid in patient management by helping identify when the cancer has spread outside the prostatic bed to regional lymph nodes or to distant soft tissue sites. Capromab however, recognizes a molecular site that is masked in viable cells, and detects antigenic sites on the intracellular portion of PSMA, a site not accessible to circulating antibody. It thus cannot adequately image bone metastases, which are the most common and earliest site of metastatic spread in prostate cancer (Haseman 2007, Akin 2007).

Indium-capromab pendetide (ProstaScint, Cytogen, Princeton, NJ) was approved by the FDA in 1996 as an immunoscintigraphic diagnostic imaging agent for newly diagnosed patients with biopsy-proven prostate cancer, who are at high risk for pelvic lymph node metastases, and in patients with a rising PSA levels after prostatectomy.

## Medical Technology Assessment Committee (MTAC)

### *Radioimmunoscintigraphy for the Diagnosis of Prostate Cancer*

#### **06/12/2009: MTAC REVIEW**

**Evidence Conclusion:** As indicated earlier, 111Indium capromab pendetide (ProstaScint) scan was studied in two clinical settings. 1. Presurgical staging of prostate cancer, and 2. Post prostatectomy biochemical failure. Presurgical staging of prostate cancer: Polascik and colleagues (1999) compared the accuracy and predictive values of ProstaScint with various algorithms/normograms used to predict lymph node involvement prior to surgery, and Manyak and colleagues (1999) compared it with CT scan and MRI results. The gold standard was pathological results of surgically resected lymph nodes. Bone metastases were not evaluated. These, as well as other published studies, included patients at high risk of extraprostatic disease. The overall results show that ProstaScint had sensitivity around 62%, specificity ranging from 72-80%, and a positive predictive value ranging from 62-66% in detecting lymph node involvement. The observed ProstaScint sensitivity in predicting lymph node metastases was higher than CT and MRI but lower than the various clinical algorithms based on a PSA level, biopsy Gleason score, and clinical stage. The predictive value of Partin's normogram was not improved when combined with ProstaScint scan. There are no published follow-up studies to indicate that high-risk patients with a negative capromab pendetide scan have a lower failure rate after surgery. Biochemical failure after prostatectomy: There were no randomized controlled trials that compared outcomes of salvage radiation therapy in patients with and without ProstaScint imaging. The published studies retrospectively examined the association of negative and positive ProstaScint scans on PSA regression and/ or survival after salvage radiotherapy to the prostate fossa. The studies had their limitations, potential biases and confounding, and had conflicting results. Nagda and colleagues (2007), Wilkinson and Chodak ( 2004), and Thomas et al (2003) study results all indicated that ProstaScint scans has limited value in making clinical decisions. Nagda et al's study showed no significant difference in relapse free survival between patients who showed or did not show a positive capromab pendetide uptake. Wilkinson and Chodak 2004, found that less than half of the patients with a localized uptake of ProstaScint scan had a durable response after salvage radiation therapy. Thomas and colleagues 2003 found no statistically significant association between ProstaScint scan findings and the response to salvage radiotherapy. On the other hand other the results of other studies (Haseman 2007, Proano 2006, Kahn 1998, and Levesque 1998) suggested that ProstaScint scan might be useful in selecting patients for salvage radiotherapy therapy. Haseman et al study (2007) showed that overall death, and prostate cancer specific death rates were significantly higher among patients with central abdominal ProstaScint uptake. Praono and colleagues 2006, found that patients with negative ProstaScint scans had significantly lower PSA progression rate after salvage radiotherapy than those with a positive scan. They however indicated that the finding might be dependent on the pre-radiotherapy PSA level. Kahn et al 1998, and Levesque and colleagues 1998, also suggested that ProstaScint scan might be useful in selecting patients for salvage radiotherapy therapy. RCTs comparing salvage radiation therapy in patients with and without ProstaScint imaging would help determine the role of the scan in predicting success of salvage radiation therapy after failed definitive treatment. **Conclusion:** There is insufficient evidence to determine that ProstaScint would improve presurgical

staging of prostate cancer, differentiate between local and distant spread in patients with biochemical failure after definitive treatment, or predict success of salvage radiation therapy.

**Articles:** The literature search revealed around 110 articles on Capromab pentetide (ProstaScint). The published studies examined the utility of ProstaScint/ radioimmunosciintigraphy in two settings: 1. Presurgical staging 2. PSA biochemical failure after prostatectomy. Presurgical staging: There were five studies that used surgical pathology results of resected lymph nodes as a gold standard. The three larger studies (N=195, N=152, and N= 51) were conducted by the same study group and most probably with overlapping populations. The other two were very small (N=19, and N=22). The study with the largest population size, as well as the study that compared the accuracy of ProstaScint vs. CT and MRI were selected for critical appraisal. PSA biochemical failure after prostatectomy: The utility of radioimmunosciintigraphy in patients with biochemical failure after definitive therapy was examined for: Its ability to differentiate between local and distant recurrence of the disease: There were 2 retrospective case series with no comparison group, and a very small study that compared the detection of metastatic disease by capromab vs. CT which have limited utility for detecting early recurrence of the disease. The search also revealed a small study on the impact of fusion of capromab pentetide data with those from MRI or CT in patients with recurrent prostate cancer. Due to the small size, design and quality of the studies, none was selected for critical appraisal. Its ability to predict response to salvage therapy: The literature search did not reveal any randomized controlled trials comparing outcome of salvage radiation therapy in patients with and without ProstaScint. There were seven retrospective studies; four examined the association between ProstaScint and PSA progression rate in patients after salvage radiotherapy, and three with survival/mortality outcomes. Two studies with mortality outcomes and one on PSA progression were selected for critical appraisal, based on methodology, size, and duration of follow-up. The following studies were critically appraised: Haseman MK, Rosenthal SA, Kipper SL, et al. Central abdominal uptake of indium-111 capromab pentetide (ProstaScint) predicts for poor prognosis in patients with prostate cancer. Urology 2007;70:303-308 See [Evidence Table](#). Manyak MJ, Hinkle GH, Olsen JO, et al. Immunoscintigraphy with indium-111-capromab pentetide: evaluation before definitive therapy in patients with prostate cancer. Urology 1999;54:1058-1063 See [Evidence Table](#). Nagda SN, Mohideen N, Lo SS, et al. Long-term follow-up of 111In-capromab pentetide (ProstaScint) scan as pretreatment assessment in patients who undergo salvage radiotherapy for rising prostate-specific antigen after radical prostatectomy for prostate cancer. Int J Radiation Oncol Biol Phys 2007;67:834-840. See [Evidence Table](#). Polascik TJ, Manyak MJ, Haseman MK, et al, Comparison of clinical staging algorithms and 111indium-capromab pentetide immunoscintigraphy in the prediction of lymph node involvement in high risk prostate carcinoma patients. Cancer 1999;85:1586-92 See [Evidence Table](#). Proano JM, Sodee B, Resnik MI, et al. The impact of a negative (111) indium-capromab pentetide scan before salvage radiotherapy J of Urol.2006;175: 1668-1672. See [Evidence Table](#).

The use of Radioimmunosciintigraphy for the diagnosis of prostate cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Reduction Mammoplasty Surgery

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	<a href="#">Medicare Benefit Policy Manual Chapter 16 120 Cosmetic Surgery.</a>
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	See <a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	None

##### For Non-Medicare Members

Group Health has elected to use the Reduction Mammoplasty (Mammoplasty) (GHC-0274) MCG\* for medical necessity determinations.

\*The MCG are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

##### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider &/or specialist (primary care physician)
- Physical Therapy notes if applicable
- Plastic surgery consultation
- Most recent height & weight

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Reduction mammoplasty surgery is a covered benefit under Group Health benefit packages when it is determined to be for medical rather than cosmetic reasons. This benefit was added by Group Health on 11/1/83. Over the years several modifications have been made to the criteria. The main purpose of the criteria is to differentiate cosmetic from medical indications for the procedure.

#### Evidence and Source Documents

##### 10/2012

Baasch M, Nielsen SF, Engholm G, Lund K Breast cancer incidence subsequent to surgical reduction of female breast. Br J Cancer April 1990; 73 (7): 961-961 1240 patients w surgical intervention for breast hypertrophy. Followed between 1943 and 1971. 32 cases of cancer identified by 1990. Expected number was 52.55 yielding a relative risk factor (RR) of 0.61. The greatest reduction was seen in women who had 600 or more grams or more of breast tissue. In the group who had the operation before the age of 20, 4 cases of breast cancer developed, compared to the expected 2.23, to give an RR of 1.79.

Dabbah A, Lehman J, Parker M, Tantri D, Wagner D Reduction Mammoplasty: An outcome analysis. Ann of P Surg October 1995; 35(4): 337-341

Survey of 285 consecutive female patients who had reduction mammoplasty between 1988 - 1993. Also Chart reviews were conducted. Mean age was 40 and average follow-up was 37 months. 185 returned completed surveys and were included in the analysis. The most common complains were: shoulder grooving (90%), back

pain (82%), shoulder pain (78%), and neck pain (65%). The average amount of breast tissue removed was 855 gm from each breast (range 148 - 3,717 gm total). Most patients (97%) had improvement of symptoms. No statistically significant difference between obese and non-obese patients in outcomes or symptom relief and put into question the use of weight guidelines or bra-cup size reduction validation. The amount of breast tissue removed did not alter the outcome of surgery or relief of symptoms. The amount of breast tissue removed to relieve symptoms will vary with height, weight and bra-cup size for each patient. This puts into question the requirement of a maximum amount of breast tissue to be removed. Increase in complications when greater than 1,000 gm was removed from each breast. Overall patient satisfaction was high (95%, happy or very happy). McMahan JD, Wolfe JA, Cromer BA, Ruberg RL. Lasting success in teenage reduction mammoplasty. Ann of P Surg September 1995; 35(3): 227-231

86 female patients less than 20 years of age. 48 contacted and returned questionnaire. Primary questions were: does the breast tissue grow back, what are the effects of future pregnancies and weight gain, and do the potential consequences of surgery overshadow the early pain relief. Patient age range:15 - 19.9. Average range of follow-up was 5.9 yr (range 1.4-20.4). 72% reported regrowth of tissue. 11 patients had been pregnant since their surgery: 5 did not breast feed, 3 were unable to and 2 were still pregnant. The greatest improvements were seen in their presurgical symptoms, ability to increase their physical activity, and improvement in their self-esteem. None seemed to have problems with sexual pleasure from their breasts.

Davis GM, Ringler SL, Short K, Sherrick d, Bengtson BP. Reduction Mammoplasty: Long-term efficacy, morbidity and patient satisfaction Plast Recon Surg 96: 1106-1110

780 female patients who had reduction mammoplasties between 1981 and 1992. 406 responded to a retrospective questionnaire. The mean age was 38yr. Follow-up average 4.7 yr. 60% of the study population was 5-10 kg over their ideal body weight as determined by the Metropolitan Life Insurance Company Statistical Bulletin (1985). Average reduction was 676 gram per breast (range 120-4200 gm). Conclusion was that women found that their preoperative symptoms were corrected by the surgery. Major complications are uncommon. Minor complications (50% of the women) are tolerated by the women. Thirty-seven women became pregnant following their operation. Of this population 68 % (25) successfully breast-fed their infants. Patients who lost nipple sensitivity were most likely to be dissatisfied with the procedure.

Seitchik MW. Reduction Mammoplasty: Criteria for insurance coverage. Plast Recon Surg May 1995: 1029-1032 The guidelines by which insurer determine eligibility for coverage of reduction mammoplasty must rely largely on subjective materials: reported patient symptoms, interpretation of photographs, determination of the amount of breast mass to be removed surgically. The author has attempted to find relationships between body weight and resected specimen weight that may be more objective.

100 consecutive reduction mammoplasties beginning 1991 recorded pre-op weight and height. The weight of resected breast tissue was obtained in the OR. Reduction planned for 46 to 70 kg body weight bra size of mid-B to small C. Above 70kg sizes ranged to a small D. Follow-up questionnaire 6 months postoperative. Based on his analysis he was unable to develop a model which would accurately predict preoperatively the amount of breast mass required to be removed to achieve the target bra size. He also felt that insurance company excise breast weight to determine eligibility for coverage was arbitrary.

## Clinical Review Criteria

### ReliefBand® Device

#### To Treat:

- Morning Sickness
- Chemotherapy Nausea
- Post-Operative Nausea

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies (and/or) provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

The Relief Band (Woodside Biomedical, Inc, Carlsbad, CA) is a non-invasive nerve stimulation device that resembles a wristwatch. The battery-powered device emits an electrical stimulus, similar to a TENS unit, and is adjustable for pulse frequency and intensity. The electrical stimulation is targeted to the Nei-Guan P6 acupoint on the underside of the wrist which in traditional Chinese medicine is believed to relieve nausea and vomiting. There are other techniques for stimulating the P6 point including acupuncture (needling) and acupressure (e.g. elasticized wrist bands with a protruding button centered over the P6 point).

The Relief Band (Woodside Biomedical, Inc) received initial FDA approval in February, 1999 as a Class II device to relieve nausea and vomiting due to motion sickness. In March, 2000 newer Relief Band models received FDA approval for the treatment of nausea and vomiting associated with motion sickness, pregnancy and chemotherapy, as an adjunct to antiemetics for post-operative nausea. Over-the-counter Relief Band models were approved in March, 2002 for nausea and vomiting due to motion sickness and for mild to moderate nausea and vomiting during pregnancy.

### Medical Technology Assessment Committee (MTAC)

#### ReliefBand® Device

#### 10/10/2003: MTAC REVIEW

**Evidence Conclusion:** Pregnancy-related nausea and vomiting: The single RCT on the use of the Relief Band to relieve morning sickness found significantly greater improvement in nausea and vomiting symptoms among women who used the Relief Band for 21 days in early pregnancy compared to those who used a sham device. The primary outcome was the Rhodes Index of Nausea and Vomiting. The Relief Band group had a mean score at follow-up that was 1.83 points lower on the Rhodes Index (out of a total of 32 possible points); the clinical significance of this degree of difference is unclear. The study had some methodological limitations including lack of intention to treat analysis with a 80% study completion rate. Chemotherapy-induced nausea and vomiting: The single RCT on the use of the Relief Band to relieve chemotherapy-induced nausea and vomiting did not find any statistically significant differences in nausea and vomiting outcomes among patients who used a Relief Band compared to an acupressure band or no band following chemotherapy. Post-operative nausea and vomiting (PONV): There were 3 RCTs on this topic, one addressed prevention of PONV following plastic surgery, one addressed prevention of PONV following laparoscopic surgery and one addressed treatment of established PONV after laparoscopic surgery. Of the two studies on prophylactic use of the Relief Band, the plastic surgery study found significant reduction of PONV with the relief band plus ondansetron compared to ondansetron alone at 24 hours post-discharge (but not 72 hours discharge). The laparoscopy study found significantly less PONV with the Relief Band compared to an inactive device at most time points during the 9 hour post-operative observation period. In the study of treatment of patients with PONV, there was less use of rescue medication prior to

discharge among patients who received the Relief Band plus ondansetron compared to ondansetron alone (but not at the 24 and 72 hour follow-ups). The two studies that included a group that received treatment with ondansetron only found benefit with a combination of the Relief Band and ondansetron compared to ondansetron alone: there was no head-to-head comparison the Relief Band and ondansetron. Studies were limited by multiple statistical comparisons without adjustment of the p-value and unclear specification of the primary outcomes. In addition, all three PONV studies included the same corresponding author (PF White) who was a paid consultant to Woodside Biomedical, the manufacturer of the Relief Band.

**Articles:** The search yielded 14 articles including review articles, opinion pieces and empirical studies. The following randomized controlled trials were identified: 1 RCT on the use of Relief Bands during pregnancy. This study was critically appraised: Rosen T, deVeciana M, Miller HS et al. A randomized controlled trial of nerve stimulation for relief of nausea and vomiting in pregnancy. *Obstet Gynecol* 2003; 102: 129-135. See [Evidence Table](#).

The use of ReliefBand® Device in the treatment of morning sickness, chemotherapy nausea and post-operative nausea does not meet the *Group Health Medical Technology Assessment Criteria*.

Behavioral Health (treatment resistant depression)	MCG* B-801-T
Migraine Headaches (eNeura)	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
Other diagnoses	Require medical review

**\*The MCG\* are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Major depressive disorder is a common health condition, and is associated with substantial morbidity, mortality and health care costs. No single approach is uniformly effective at treating depression. Antidepressant treatment with SSRIs is currently a common first step. Approximately, two-thirds of patients respond to an initial course of antidepressants (O'Reardon et al., 2000). One alternative for non-responders is to switch to a different antidepressant, in the same or another class of medications. Findings from a recent RCT indicate that approximately 1 in 4 individuals who failed an initial course of SSRIs respond to a second one (Rush et al., 2006). Adding psychotherapy is another option for non-responders.

Interest in alternative treatment options, such as transcranial magnetic stimulation (TMS), has grown in recent years. TMS is a non-invasive method of modulating the brain's electrical environment by using magnetic fields. The technique involves applying alternating electrical currents through an insulated coil on the scalp which, ultimately, produces an electrical field in the brain, which in turn induces depolarization of nerve cells and results in the stimulation or disruption of brain activity. Changes in brain activity with TMS can be detected through various imaging techniques (PET, SPECT, or MRI). TMS can be delivered in either individual or repetitive pulses (the latter known as rTMS). Most studies of TMS for depression use repetitive pulses, and target the left dorsal lateral prefrontal cortex (DLPFC). Reported side-effects of TMS are generally mild including headache, local discomfort, and transient change in auditory threshold, which can be prevented by the use of earplugs. Instances of mania and epileptic seizure, however, have been known to occur (Fitzgerald and Daskalakis 2008; George 2010; Shelton, Osuntokun et al. 2010; Slotema, Blom et al. 2010).

Several TMS devices, including the NeuroStar TMS system (Neuronetics, Atlanta, GA) and the Brainsway Deep TMS system (Brainsway Ltd., Jerusalem, Israel), have received 510(k) clearance by the United States Food and Drug Administration (FDA). The devices are indicated for the treatment of major depressive disorder (MDD) in adult patients who have failed one prior antidepressant medication at or above the minimal effective dose and duration. The medical technology and assessment committee (MTAC) previously reviewed TMS technology in 2009, and subsequently in 2011. In each case, the evidence failed to satisfy MTAC criteria due to inappropriate comparators and lack of established long term efficacy.

## Medical Technology Assessment Committee (MTAC)

### Repetitive transcranial magnetic stimulation (rTMS)

#### 06/01/2009: MTAC REVIEW

##### **Evidence Conclusion:** Active rTMS vs. sham treatment for treatment-resistant depression

**Efficacy:** There is insufficient evidence on the long-term efficacy of rTMS for treatment-resistant depression. In the RCTs, patients were generally evaluated at the end of the treatment period, 4 weeks or less. A pooled analysis of the 4 studies that followed patients for an additional 1-2 weeks also found a significantly higher response rate with rTMS vs. sham treatment. There is sufficient evidence from a meta-analysis of 21 RCTs (Lam et al., 2008) that there is a higher short-term clinical response rate with rTMS compared to sham treatment (NNT=6). **Safety:** In the Lam meta-analysis, there was a low rate of withdrawals due to adverse effects overall, 2% of patients in the active rTMS group and 1.5% in the sham group. Janicak et al. (2008), in a study funded by Neuronetics, compiled safety data from one sham-controlled RCT and two unpublished open-label studies, and found few treatment-related adverse effects. No deaths or seizures were reported among the 218 patients receiving active treatment. A total of 41 serious adverse events were reported. 36 of the 41 were assessed by study investigators as unrelated to the study device. The 5 related events included 3 related to a manufacturing defect in a component of the study device, 1 was left-sided facial numbness and the fifth, deemed probably related, was not specified.

**rTMS vs. other established treatment for treatment-resistant depression:** There is insufficient evidence to draw conclusions about the safety and efficacy of rTMS for treatment-resistant depression compared to electroconvulsive therapy. One RCT comparing rTMS to ECT in this population was identified (Rosa et al., 2006). The study did not find a significant difference in the rate of clinical remission with rTMS compared to ECT. There were a relatively small number of patients enrolled, a relatively high drop-out rate and no analysis of statistical power, so conclusions can not be made about equivalence of the treatments. There is insufficient evidence to draw conclusions about the safety and efficacy of rTMS for treatment-resistant depression compared to additional trials of antidepressants. No trials were identified comparing monotherapy with rTMS or antidepressants in this population. One RCT compared the combination of rTMS and escitalopram to escitalopram (plus sham rTMS) (Bretlau et al., 2008). The study, which included patients who failed at least one previous trial of antidepressants, used the difference in depression scores as the primary outcome, rather than the more clinically significant outcomes, clinical response or remission. With an appropriate statistical analysis, adjusting for multiple comparisons, there was a significant benefit of the combined active treatment group at the end of the three-week rTMS period, but no difference after an additional 9 weeks of medication treatment.

##### **Articles:** Active rTMS vs. sham treatment for treatment-resistant depression

The Pubmed search yielded three meta-analyses of RCTs comparing rTMS for major depression to sham treatment. Only one of the three meta-analyses (Lam et al., 2008) focused on treatment-resistant depression, the FDA-approved indication and was critically appraised. No major sham-controlled RCTs were published after the meta-analysis literature search date (May 15, 2008). The search of the Cochrane database yielded a systematic review of rTMS for depression but this review had not been updated since 2001 and was therefore excluded. A study that compiled safety data from several trials (Janicak et al., 2008) was reviewed, but an evidence table was not created. rTMS vs. other established treatment for treatment-resistant depression. One RCT comparing rTMS to ECT for patients with treatment-resistant depression (Rosa et al., 2006) was identified and critically appraised. Another RCT comparing rTMS and ECT had as its entry requirement, referral for ECT. The investigators did not specify that patients needed to have failed at least one treatment, so this study was excluded from further review. One RCT comparing rTMS to antidepressants for medication-resistant depression (Bretlau et al., 2008) was identified and critically appraised. Two other RCTs that evaluated the combination of rTMS and antidepressants as first-line treatment were excluded. The references for the studies that were reviewed are as follows: Bretlau LG, Lunde M, Uden M et al. Repetitive transcranial magnetic stimulation (rTMS) in combination with escitalopram in patients with treatment-resistant major depression. *Pharmacopsychiatry* 2008; 41: 41-47. See [Evidence Table 1](#). Janicak PG, O'Rearson JP, Sampson SM et al. Transcranial magnetic stimulation in the treatment of major depressive disorder: A comprehensive summary of safety experience from acute exposure, extended exposure and during reintroduction treatment. *J Clin Psychiat* 2008; 69: 222-232. Lam RW, Chan P, Wilkins-Ho M et al. Repetitive transcranial magnetic stimulation for treatment-resistant depression: A systematic review and meta-analysis. *Can J Psychiatr* 2008; 53: 621-631. refractory depression: a randomized, single-blind study. *Int J Neuropsychopharm* 2006; 9: 667-676. See [Evidence Table 1](#).

The use of Repetitive transcranial magnetic stimulation (rTMS) for the treatment of treatment-resistant major depression does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 04/18/2011: MTAC REVIEW

##### **Repetitive Transcranial Magnetic Stimulation (rTMS)**

**Evidence Conclusion:** *rTMS vs. sham rTMS:* A recent RCT evaluated the safety and efficacy of daily left prefrontal cortex rTMS compared to sham rTMS for the treatment of antidepressant medication resistant depression in 190 patients with unipolar depression. The primary outcome was remission defined as a Hamilton Scale for Depression (HAM-D) score  $\leq 3$  or 2 consecutive HAM-D scores less than 10. Thirteen patients in the active rTMS group and five patients in the sham rTMS group experienced remission [Odds ratio 4.18, 95% CI (1.32-13.24), NNT=12]. There was no significant difference in adverse events by treatment arm. Results from this trial suggest that rTMS is more effective than placebo at treating medication resistant depression; however, this trial does not address the duration of the effect (George 2010). *rTMS vs. venlafaxine ER* The efficacy of rTMS over the right prefrontal dorsolateral cortex versus venlafaxine ER for the treatment of resistant depression was assessed in a recent RCT that followed 60 patients for 4-weeks. The primary outcome measure was change in Montgomery-Åsberg Depression Rating Scale (MADRS) score. Clinical response (more than a 50% reduction of the MADRS score) and remission (MADRS score  $\leq 10$  points) were also evaluated. There was no significant difference in mean change in MADRS score, clinical response, or remission rates between the two groups (Bares 2009).

**Conclusion:** There is insufficient evidence to determine the long-term safety and efficacy of rTMS for the treatment of depression in patients who have failed at least one prior antidepressant medication. Results from one RCT suggest that rTMS may be effective at treating medication resistant depression; however, this trial does not address the durability of the effect. Additionally, studies addressing the efficacy of rTMS differ with regards to the duration of treatment and treatment parameters. More research is necessary to identify the ideal duration of treatment and treatment parameters.

**Articles:** Studies were selected for review if they included at least 25 subjects and assessed either the safety or efficacy of transcranial magnetic stimulation for the treatment of depression. Studies were excluded if they addressed the safety or efficacy of TMS for the treatment of conditions other than depression; if they compared different TMS applications to each other; or if they lacked a valid comparison group. Two recent meta-analyses were also identified, but not selected for review. One meta-analysis that examined the efficacy of slow-frequency ( $\leq 1$  Hz) rTMS for the treatment of depression was not selected as the trials included were all published before the 2009 review (Schutter 2010). The other meta-analysis was not selected for review because of methodological limitations (Slotema 2010). Additionally, the majority of the articles included in these meta-analyses were also included in a previously reviewed meta-analysis. Two RCTs were selected for review. The following studies were critically appraised: Bares M, Kopecek M, Novak T, et al. Low frequency (1-Hz), right prefrontal repetitive transcranial magnetic stimulation (rTMS) compared with venlafaxine ER in the treatment of resistant depression: A double-blind, single-center, randomized study. *J Affect Disord* 2009; 118:94-100. See [Evidence Table](#). George MS, Lisanby SH, Avery D, et al. Daily left prefrontal transcranial magnetic stimulation therapy for major depressive disorder: a sham-Controlled randomized trial. *Arch Gen Psychiatry* 2010; 67:507-516. See [Evidence Table](#).

The use of Repetitive transcranial magnetic stimulation (rTMS) for the treatment of treatment-resistant major depression does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 08/17/2015: MTAC REVIEW

##### **Repetitive Transcranial Magnetic Stimulation (rTMS)**

**Evidence Conclusion:** The BCBS TEC assessment, published in January of 2014, established that the available evidence on the use of TMS therapy for depression does not meet the TEC criteria. More specifically, the TEC assessment was not able to make conclusions with regard to the effect of TMS on health outcomes, net health outcomes, and, as a result, was unable demonstrate that the technology was as beneficial as any established alternative and that results were attainable outside the investigational setting (BCBS 2014). Subsequent to the TEC assessment, a group of European experts made a conflicting conclusion regarding the efficacy of TMS for the treatment of depression. In their analysis of the literature, the European experts made a level A recommendation establishing the efficacy of high frequency rTMS of the left DLPFC in depression (Lefaucheur, André-Obadia et al. 2014).

**Effectiveness:** In the first meta-analysis, Gaynes and colleagues pooled data from 18 trials with the overall aim to evaluate the efficacy of rTMS in patients with treatment resistant depression. In all three primary outcomes (severity of depression symptoms, response rate, and remission) the investigators reported that rTMS was superior to sham leading to the conclusion that rTMS is a reasonable, effective treatment option in patients with

treatment-resistant depression (Gaynes, Lloyd et al. 2014). The second meta-analysis, carried out by Kedzior and colleagues, focused more on the durability of the antidepressant effect. In their analysis, data from 16 studies involving 495 patients demonstrated only a small antidepressant effect during follow up (Kedzior, Reitz et al. 2015). [Evidence Table 1](#) **Safety:** The literature reports several common events to be associated with TMS therapy including problems at the site of coil placement, tension like headaches and light-headedness with the most serious event reported being seizure. Overall, however, the technique appears to be relatively safe and reasonably well tolerated. Collectively, the body of published evidence relating to TMS therapy for depression is plagued with heterogeneity with a wide range of aims, outcomes and varying populations. To add to this, the technology is inherently limited by the lack of any established consensus regarding both the frequency and intensity of stimulation. Historically, TMS therapy for depression has failed MTAC criteria due to insufficient evidence. The current evidence remains conflicting and does not provide clear and convincing evidence that rTMS therapy is an effective and sustainable treatment option for depression. **Conclusion:** There is insufficient evidence to support the superiority of rTMS over antidepressants. There is evidence to support the short term efficacy of rTMS over sham therapy. rTMS appears to be a relatively safe and well tolerated treatment.

**Articles:** The literature search identified an evidence based guidelines on the therapeutic use of rTMS in a variety of different conditions. (Lefaucheur, André-Obadia et al. 2014). In addition, a 2014 TEC (technology evaluation center) assessment produced by the Blue Cross and Blue Shield (BCBS) Association in association with Kaiser Permanente was identified (BCBS 2014). As a result, the literature search focused on updating the evidence base established by the guideline and TEC assessment (March 2014 through July 2015). The search yielded just over 200 publications including a variety of case series/reports, clinical trials, review articles, and meta-analyses. No studies were identified comparing rTMS as a monotherapy with antidepressants. The following studies were selected for critical appraisal: Gaynes BN, Lloyd S, Lux L, et al. Repetitive transcranial magnetic stimulation for treatment-resistant depression: a systematic review and meta-analysis. *J Clin Psychiatry*. 2014; 75(5):477-489. [See Evidence Table 1](#). Kedzior KK, Reitz SK, Azorina V, et al. Durability of the antidepressant effect of the high-frequency repetitive transcranial magnetic stimulation (rTMS) in the absence of maintenance treatment in major depression: a systematic review and meta-analysis of 16 double-blind randomized, sham-controlled trials. *Depression and Anxiety*. 2015;32:193-203. [See Evidence Table 1](#).

The use of Repetitive transcranial magnetic stimulation (rTMS) for the treatment of major depression does not meet the *Group Health Medical Technology Assessment Criteria*.

**MCG 19<sup>th</sup> Edition: A-0240 \*note removed in 20<sup>th</sup> Edition  
Transcranial Magnetic Stimulation – for migraine headaches**

For migraine headaches, evidence is insufficient, conflicting, or poor and demonstrates an incomplete assessment of net benefit vs harm; additional research is recommended. (RG B) A systematic review and meta-analysis concluded that in the absence of replicated, large controlled studies, no recommendations could be made for the use of any protocol of repetitive transcranial magnetic stimulation in the treatment of migraine headaches.(11) (EG 1) A randomized, double-blinded, parallel-group, sham-controlled study of 164 patients investigated the use of single-pulse transcranial magnetic stimulation for treatment of migraine with aura; active treatment was found to increase freedom from pain at 2 hours, as well as at 24 and 48 hours after treatment.(24) (EG 1) A double-blind randomized sham-controlled study involving 100 patients reported a significantly greater reduction in frequency of headaches with high-frequency repetitive transcranial magnetic stimulation as compared with sham stimulation at 1 month follow-up.(25) (EG 1) A technology assessment concluded that the efficacy and long-term safety of transcranial magnetic stimulation for the treatment or prevention of migraine headaches was limited and recommended its use only within a controlled clinical trial setting.(26) (EG 2)

And for facility-based services billed using a UB form, see [Local Coverage Determination \(LCD\): Non-Covered Services \(L34886\)](#)

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Retinitis pigmentosa (RP) comprises a group of hereditary eye diseases characterized by progressive degeneration of retinal photoreceptors; usually starting in the midperiphery of the fundus and advancing towards the macula and fovea. This field loss is progressive and usually does not reduce central vision until late in the disease resulting in severe visual loss that may lead to legal blindness. Like other areas of the mammalian central nervous system, neurons of the retina are not replaced following degeneration (Musarelle 2011, Petrs-Silva 2014, Rayapudi 2013)

Currently, there is no proven therapy for retinitis pigmentosa. However, there are worldwide efforts to develop new therapies for preserving or improving the retinal function. Therapeutic strategies that may potentially restore vision to patients who only retain light perception, or even no light perception vision, include optogenetics and retinal chip implants. Transcorneal electrostimulation is another technique that might help patients with retinitis pigmentosa who still have functional vision. Optogenetics uses light sensors to induce some cells to be reactive to light. The activated light sensor creates an electric current that can stimulate or inactivate a particular cell. Retinal chips on the other hand, use transducers to create electricity to replace the electrical stimulation that would normally be created by the photoreceptors. Eyes with retinitis pigmentosa respond to electrical stimulation from the retinal chip because the disease destroys the photoreceptors but leaves a significant percentage of inner retinal cells (ganglion and bipolar cells) intact and functional. The chip implants stimulate these remaining functional cells, thus bypassing the need for functioning photoreceptor cells. In order to restore visual function, chip implants have to detect light, convert light energy into electrical signal and deliver it to retinal neurons other than photoreceptors to elicit activity that is interpreted as vision (Garg 2013, Wieland 2011).

Retinal implants or prosthesis can be categorized according to the location of the stimulating electrodes. In clinical trials the electrodes were placed epiretinally, subretinally, suprachoroidally, or inside the optic nerve. In earlier feasibility studies the stimulating electrodes were placed temporarily (acute implantation). Chronic implantation on the other hand, refers to leaving the device in the subjects for a length of time. This requires considerable engineering to manufacture the device. Chronic retinal prosthesis can be divided into uncontrolled/passive stimulation devices or controlled /active stimulation devices, based on whether the electrical stimulation pattern can be controlled via software or just by light activation without the need for an external power source. Some of the major challenges for bioelectronic implants include long-term stable performance of the implanted electronics as well as a safe surgical implantation procedure (Weiland 2011).

Argus II retinal prosthesis system (Second Sight Medical Products Inc.) consists of an implantable device that is surgically implanted on and in the eye, and an external unit worn by the user. The implanted portion consists of a receiving and transmitting coil, a sealed electronic case fixed to the sclera outside the eye, and an electrode array (a 6 x 10 array of 60 electrodes) that is secured to the surface of the retina (epiretinally) inside the eye by a retinal

tack. The electrode array is connected to the electronics by a metalized polymer cable that penetrates the sclera in the pars plana. The external unit consists of a small camera and transmitter mounted on a pair of sunglasses and a video processing unit (VPU) and battery that can be worn on a belt or shoulder strap. The camera captures a video and sends the information to the processor, which converts the image to electronic signals that are then sent to the transmitter on the glasses. The implanted receiver wirelessly receives these data and sends the signal to the electrode array via a small bus, where electric stimulation pulses are emitted. The controlled electrical stimulation of the retina induces cellular responses in retinal ganglion cells that travel through the optic nerve to the visual cortex and results in visual percepts. It is reported that positioning of the epiretinal array remains a challenge, since poor positioning was shown to lead to higher stimulus thresholds. In addition, object recognition including letter reading tasks generally requires head movement to move the camera. An implanted or an external camera coupled to eye movement may allow a more natural viewing experience for users (Weiland 2011, Lauritzen 2012, Dorn 2013).

Epiretinal implants have the advantage of their direct attachment to the ganglion cells which are the cells that need to be stimulated to generate a visual signal that is sent to the brain. A potential disadvantage of this however, is the unwanted stimulation for the retinal ganglion cells that can result in less distinct and /or wanted visual stimuli (Garg 2013).

## Medical Technology Assessment Committee (MTAC)

### Argus II Retinal Prosthesis System

#### 04/21/2014: MTAC REVIEW

**Evidence Conclusion:** There is insufficient published evidence to determine the safety and efficacy of Argus II retinal prosthesis system in patients with profound visual loss due to retinitis pigmentosa. Argus II retinal prosthesis was evaluated in a small, multicenter, case series with no control group (evidence table1). The study enrolled 30 patients between June 2007 and August 2009. The primary performance endpoint was visual function as assessed by several visually guided tasks and orientation and mobility tasks. The primary safety endpoint was the number, severity, and relation of all adverse events. The study enrolled 30 blind patients 50 years or older (18 or older in some clinical sites) with a diagnosis of retinitis pigmentosa (or other outer retinal degeneration at some sites), with remaining vision of bare or no light perception in both eyes, and with a history of useful form vision. All participants received an Argus II implant, and were regularly evaluated for a duration of 36 months. 28 of the 30 participants were available for testing. The results indicate that all 28 were able to perceive light during the postoperative stimulation of the implant. 57% were able to see the motion of a white bar moving across a black background, and many were able to identify some 3-4.5 cm letters on a high contrast background. The best vision was 20/1262. Adverse events associated with the Argus II system included conjunctival dehiscence or erosion over the extraocular implant in 16% of cases, endophthalmitis (10%), and hypotony (10%). There was one intraoperative retinal tear, and two postprocedural retinal detachment. The adverse effects were treated in all patients except for one in whom the device had to be explanted.

**Articles:** The literature search revealed only one small observational study with no control or comparison group. The study was published in a number of journal articles, and was critically appraised.

**Evidence Table.** Ahuja AK, Dorn JD, Caspi A, et al. Blind subjects implanted with the Argus II retinal prosthesis are able to improve performance in a spatial-motor task. *Br J Ophthalmol.* 2011;95:539-543. da Cruz L, Coley BF, Dorn J, et al. The Argus II epiretinal prosthesis system allows letter and word reading and long-term function in patients with profound vision loss. *Br J Ophthalmol.* 2013;97:632-636. Dorn JD, Ahuja AK, Caspi A, et al. The Detection of Motion by Blind Subjects with the Epiretinal 60-Electrode (Argus II) Retinal Prosthesis. *JAMA Ophthalmol.* 2013;131:183-189. ## Clinical Review Criteria

### Radiofrequency Ablation

- Barrett's Esophagus
- Lung Cancer
- Renal Tumors
- Primary HCC and Metastatic Liver Cancer
- Vertebral Augmentation for Painful Spinal Metastases

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	Lung Cancer: <a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	None

*\*Covered without review: Esophagus, liver tumors, and renal tumors*

#### For Non-Medicare Members

Service	Criteria Used
Barrett's Esophagus	Radiofrequency ablation is considered medically necessary for the treatment of members with Barrett's esophagus (BE) who have histological confirmation of low-grade dysplasia by two or more endoscopies three or more months apart.
Lung Cancer	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
Renal Tumors Primary HCC and Metastatic Liver Cancer	Medical necessity review is no longer required for this service.
Vertebral Augmentation for Painful Spinal Metastases	See criteria for <a href="#">Vertebroplasty</a>

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## **Radiofrequency Ablation for the Treatment of Barrett's Esophagus**

### **BACKGROUND**

Barrett's esophagus is a disease wherein the stratified squamous epithelium lining the esophagus gets replaced by metaplastic columnar epithelium. The disease affects more Caucasians than Blacks and is diagnosed around 55 years (Spechler & Goyal, 1996) and its prevalence varied widely from 0.4% to 20% (Gerson, Shetler, & Triadafilopoulos, 2002; Ormsby et al., 2000; Ward et al., 2006). Barrett's esophagus is caused by chronic gastro esophageal reflux disease (GERD). While Body mass index (BMI), is believed to be associated with increased risk of Barrett's esophagus (Kamat, Wen, Morris, & Anandasabapathy, 2009), studies have found that abdominal obesity is a risk factor for Barrett's esophagus (Corley et al., 2007; Edelstein, Farrow, Bronner, Rosen, & Vaughan, 2007; Kramer et al., 2013). It is not well known if germline mutations are associated with the disease.

Initially, Barrett's esophagus manifests with no symptoms or patients show signs of GERD. The most common symptoms of GERD are pyrosis (heart burn), regurgitation and dysphagia. Other manifestations of GERD are chronic cough, bronchospasm and laryngitis, chest pain resembling angina pectoris. GERD is complicated by erosive esophagitis, esophageal ulceration, stricture and hemorrhage (Spechler & Goyal, 1996), and Barrett's esophagus. The annual cancer incidence varied from 0.1 to 0.4% (Desai et al., 2012; Hvid-Jensen, Pedersen, Drewes, Sørensen, & Funch-Jensen, 2011; Rugge, Fassan, Cavallin, & Zaninotto, 2012; Shakhathreh et al., 2014). Studies have shown that the risk of developing cancer is proportional to dysplasia status and length of Barrett's esophagus (Pohl et al., 2016; Sikkema et al., 2011; Thota et al., 2015; Van der Veen, Dees, Blankensteijn, & Van Blankenstein, 1989). Patients with high-grade dysplasia have higher risk (4-8%) of progression to adenocarcinoma while patients with Barrett's esophagus, low-grade dysplasia and indefinite for dysplasia have a risk ranging from 0.2 to 1.2% (Singh et al., 2014; Verbeek et al., 2012). However, mortality due to esophageal adenocarcinoma is lower than that of other causes (Sikkema, De Jonge, Steyerberg, & Kuipers, 2010). Diagnostic is based on endoscopy and biopsy showing columnar epithelium and intestinal metaplasia respectively. Histology classification has described four types of Barrett's esophagus (BE); these include non-dysplastic (ND), low-grade for dysplasia (LGD), indefinite for dysplasia (ID), high-grade dysplastic (HGD).

General management includes proton pump inhibitor (PPI). Fundoplication may be an alternative for PPI resistance. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit cyclooxygenase (COX) have been described; however, these drugs have potential side effects. Surveillance has been promoted by many guidelines (Association, 2011; Fitzgerald et al., 2014; Shaheen, Falk, Iyer, & Gerson, 2016) but its benefit is not well documented. In addition, surveillance modality depends on the type of dysplasia. Treatment of dysplasia is of greatest importance. Several approaches have been described and include endoscopic ablative therapies, endoscopic resection or the combination of both, and esophagectomy. Endoscopic resection encompasses removal of both mucosa and submucosa (Pech, May, Gossner, Rabenstein, & Ell, 2004) and can lead to stricture. Endoscopic ablative therapies consist of radiofrequency ablation (RFA), photodynamic therapy, and endoscopic spray cryotherapy.

RFA uses radiofrequency energy and produces thermal injury to destroy the mucosa. Energy used comes from a balloon equipped with a series of electrodes to ablate the mucosa (Sharma et al., 2007). The radiofrequency energy can either be delivered circumferentially or focally. There are two different devices and accessories, both manufactured by BARRX. The balloon based HALO360 device is used to treat circumferential areas of BE. The system includes a high-power energy generator, a sizing balloon catheter and several balloon based ablation catheters. There are 60 tightly spaced, bipolar independent electrodes encircling the balloon through which the energy is delivered. A preselected amount of energy is delivered in less than a second at 350 W. This allows for full thickness ablation of the epithelium without damage to the submucosa. The HALO [90] ablation system is used to treat more focal areas and uses a radiofrequency generator and an endoscope mounted electrode. Both procedures can be done on an outpatient basis. Barrx90 ULTRA, Barrx60, and Channel RFA device are alternative options for focal ablations.

### **02/01/2010: MTAC REVIEW**

#### **Radiofrequency ablation for the treatment of Barrett's Esophagus**

**Evidence Conclusion:** The literature search revealed only one published randomized controlled trials (Shaheen et al, 2009) that compared radiofrequency ablation of Barrett's esophagus to a sham endoscopic procedure. The trial had valid design and analysis; it was multicenter, appropriately randomized, controlled, blinded, had sufficient statistical power, and with low dropout rate. However, radiofrequency ablation was compared to a sham procedure and not to another established alternative procedure with a curative intent for BE with dysplasia e.g. endoscopic resection, esophagectomy, or photodynamic therapy. Moreover, the trial had only one year of follow-up which is insufficient to determine the long-term efficacy, and safety of the procedure. Due to the short follow-up duration, the authors used neoplastic progression and eradication of dysplasia and metaplasia as surrogates for death from

cancer. The trial randomized 127 patients (in a 2:1 ratio) with low or high grade dysplasia to undergo either radiofrequency ablation or sham endoscopic therapy. Randomization was stratified according to grade of dysplasia (LGD or HGD) and length of BE lesion (<4 or 4-8cm). Those in the ablation group underwent step-wise circumferential and focal ablation using HALO 360 and HALO 90 systems (BARRX Medical Inc, Sunnyvale, CA). Patients in the two groups underwent endoscopic surveillance for the study period; biopsies were obtained throughout the BE length every 3 months in patients with HGD or 6 months among those with LGD. After 12 months of follow-up, the results of the trial showed that more than three fourths of patients treated with radiofrequency ablation had complete eradication of intestinal metaplasia and dysplasia (77 % of all BE was completely reversed into normal epithelium among those who received RFA, vs. 2% in the control; 90% of patients with LGD, and 81.5% with HGD had complete eradication of the dysplasia vs. 23% and 19% of the controls respectively). The ablation therapy was also associated with a significant decrease in the risk of cancer but, as acknowledged by the authors this should be interpreted with caution due to the small number of cases. RFA therapy was not without risk as 5 (6%) cases developed esophageal stricture that required endoscopic dilatation, and 3 (3.5%) had other serious events as bleeding and chest pain.

Conclusion:

- There is fair evidence from one RCT with short-term follow-up that radiofrequency ablation using the HALO systems is superior to sham therapy (no therapy) in the treatment of BE with dysplasia.
- There is insufficient evidence to determine that RFA has better outcomes and less harms than alternative therapies with curative intent for BE with dysplasia.
- There is insufficient evidence to determine the long-term efficacy, and safety of radiofrequency ablation therapy in the management of patients with Barrett's esophagus with dysplasia, and whether the risk of ablation is less than the risk of progression of BE.
- There is insufficient evidence to determine that radiofrequency ablation therapy eliminates the necessity for of further endoscopic surveillance of patients with Barrett's esophagus with dysplasia.
- There is insufficient evidence to determine that radiofrequency ablation therapy reduces or eliminates cancer risk in patients with Barrett's esophagus with dysplasia.

**Articles:** The search yielded around forty articles. Many were reviews, letters, and editorials. There was one randomized controlled trial and number of case series and reports. The RCT and the majority of the case series were conducted by the same group of investigators. The RCT with the following citation was critically appraised. Shaheen NJ, Sharma P, Overholt B, et al. Radiofrequency ablation in Barrett's esophagus with dysplasia. *N Engl J Med* 2009;360:2277-2288. See [Evidence Table](#)

The use of Radiofrequency ablation for the treatment of Barrett's esophagus with dysplasia does not meet the *Group Health Medical Technology Assessment Criteria*.

## 09/19/2016: MTAC REVIEW

### Radiofrequency ablation for the treatment of Barrett's Esophagus

#### Evidence Conclusion:

#### RFA vs alternative treatment

#### **Systematic review comparing radiofrequency ablation and complete endoscopic resection in treating dysplastic Barrett's esophagus: a critical assessment of histologic outcomes and adverse events (Chadwick et al, 2014) (evidence table 1)**

The first study is a systematic review aiming to compare the efficacy and safety of complete endoscopic mucosal resection (EMR) and radiofrequency ablation (RFA) in the treatment of dysplastic BE. It was reported that dysplasia was eradicated in 95% and 92% of patients treated with EMR and RFA respectively. Intestinal metaplasia (IM) eradication was similar between both groups. After (23 and 21 months for EMR and RFA respectively) months of follow-up for patients, who were treated with EMR, dysplasia eradication was achieved in 85% of patients versus 79% among RFA group. In EMR group, additional treatments were reported in 7 studies. In EMR group, overall short term adverse events were 12.5% and most frequently acute bleeding. In RFA group, overall short term adverse events were 2.5% and most frequently acute bleeding (1%). In EMR group, overall long term adverse events were 38% and most frequently stricture compared to 4% in RFA group. Buried BE was 3.8% in EMR group vs. 0% in RFA group (not reported in table). Progression to cancer appeared to be low in both groups.

This indicates that both treatments are effective in the management of HGD BE but more events that are adverse are observed with EMR. However, the review is mostly based on observational studies. Ten studies were directly or indirectly industry funded; only 3 RCTs were represented in the review. Individual studies were small. Follow-ups periods were short (<1 year) and varied greatly limiting accurate assessment of cancer progression and incidence of recurrence. Fair evidence shows that both treatments are effective in managing HGD BE but RFA has less adverse events.

**Radiofrequency ablation vs endoscopic surveillance for patients with Barrett’s esophagus and low-grade dysplasia a randomized clinical trial (Phoa et al 2014)** (evidence table 2)

This RCT investigated whether endoscopic radiofrequency ablation could decrease the rate of neoplastic progression. Compared to control group, patients who were treated with RFA, were less likely to progress to high grade dysplasia or cancer. At the end of endoscopic treatment, (After RFA), 92.6% and 88.2% of complete eradication of dysplasia and IM were observed respectively. During follow-up, patients who were treated with RFA were more likely to obtain complete eradication of dysplasia; the risk of complete eradication of dysplasia was increased by 70.5%. Complete eradication of intestinal metaplasia was maintained in 54of60patients (90.0%) receiving ablation compared with 0 of 68 patients receiving control (risk difference, 90% [95% CI, 82.4%-97.6%]; P < .001). Adverse events are represented by abdominal pain, bleeding, stricture, laceration, retrosternal pain while no adverse events were reported for endoscopic surveillance. The results indicate that in patients with low-grade dysplasia, RFA reduced the risk of progression to high-grade dysplasia or adenocarcinoma by 25% corresponding to an NNT of 4.0. Study had a valid methodology in general. However, it had some limitations: external validity is compromised (referral centers), study was underpowered for cancer-related death outcome which is the primary end point. Endoscopic rescue therapy was performed to decrease residual Barrett tissue. Based on the Cochrane collaboration’s tool for risk of bias assessment, the overall risk of bias is low with unclear information on blinding. Fair evidence supports efficacy of RFA over endoscopic surveillance for low grade dysplasia.

**Endotherapy versus surgery for early neoplasia in Barrett’s esophagus: a meta-analysis (Wu et al., 2014)** (evidence table 5)

This meta-analysis aimed to compare the efficacy and safety of endotherapy and surgery for early neoplasia in BE. A systematic literature search was performed up to December 2012 and included 870 patients. No significant difference between endotherapy and esophagectomy in the outcomes presented in the table below. However, endotherapy was associated with a higher neoplasia recurrence rate and fewer major adverse events. Limitations include: a small number of studies including retrospective studies; patients were not comparable in some studies leading to bias of the results. Different endotherapies including EMR, PDT, RFA and argon plasma coagulation were used. The type of surgery and the experiences of surgeons were different. Publication bias might also exist. Low evidence support similar efficacy between endotherapy and surgery in the treatment of early Barrett’s neoplasia with fewer adverse events.

Efficacy of RFA (non-comparative studies)

**Efficacy and durability of radiofrequency ablation for Barrett’s esophagus: systematic review and meta-analysis** (Orman et al, 2013) (evidence table 3)

This systematic review aimed to determine the efficacy and durability of RFA for patients with dysplastic and nondysplastic BE. The authors found 91% of patients achieved CE-IM while 78% achieved CE-D and that in 13% of cases, IM recurred after successful treatment. Most common adverse events were stricture (5%) and pain (3%). Although the study has valid methodology, limitations included the poor quality of included studies and external validity. Settings include referral centers with capability in RFA. Heterogeneity was high. Adverse events may have been underestimated due to the retrospective design of a number of studies. Individual studies were small in size. Follow-ups periods were short. RFA was not compared to alternative treatment limiting accurate assessment. The results indicate that CE-IM and CE-D were achieved in most of the patients undergoing RFA with low IM recurrence and low adverse events.

Several prospective studies have assessed the efficacy of RFA. Their findings can be found in the following table. However, none of these studies compare RFA to alternative treatment.

Author, year	N	Intervention	Protocol	BE baseline	Median Follow-up (mos)	Findings	Adverse events
(Phoa et al., 2014)	132	ER combined with RFA	Visible lesions were removed with ER, followed by serial RFA every 3 months. Follow-up endoscopy was scheduled at 6 months after the first negative post-treatment endoscopic control and annually thereafter	BE≤12 cm with HGD and/or EC	27	CE-neo:92% CE-IM: 87% Recurrence: neo and IM 4% & 8% respectively	Mucosal lacerations (8%) and stenosis (6%).

(He et al., 2015)	96	RFA	RFA was used at baseline to treat all unstained lesions (USL), and then biopsy (and focal RFA if USL persisted) was performed every 3 months until all biopsies were negative for MGIN, HGIN, and ESCC	moderate/high grade intraepithelial neoplasia [MGIN/HGIN] and early flat-type esophageal squamous cell carcinoma [ESCC]	12	73% & 84% of complete response at 3 and 12 months respectively. Progression in 2%	Stricture (21%)
(Haidry et al., 2014)	508	RFA/EMR	Visible lesions were removed by EMR. Thereafter, patients had RFA 3-monthly until all BE was ablated or cancer developed	HGD or IMC	6 years	CE-D: 77% to 92% CE-IM:56% to 83% (p<0.0001) Progression to OAC at 12 months (3.6% vs. 2.1%, p=0.51) Risk of IM recurrence at 5 years: 32%	
(Small et al., 2015)	246	EMR and/or ablation therapy		HGD/IMC		83.7% with HGD 75.7% with IMC	

BE, Barrett's esophagus; ER, endoscopic resection; EMR, endoscopic mucosal resection

### Low grade dysplasia

#### **Meta-analysis of endoscopic therapy for low-grade dysplasia in Barrett's oesophagus (Almond et al 2014)** (evidence table 4)

This systematic review aimed to identify systematically all reports of endoscopic treatment of LGD, and to assess outcomes in terms of disease progression, eradication of dysplasia and intestinal metaplasia, and complication rates. The search was performed from January 1988 to January 2013. 37 studies reporting outcomes of endoscopic therapy for 521 patients with LGD. Study quality was assessed using Jadad scale for controlled trials and the Newcastle–Ottawa scale for uncontrolled trials. The results indicated that 67.8% and 88.9% achieved CE-IM and CE-D respectively. The overall incidence of progression to cancer is 3.90. The authors concluded that RFA does not eradicate the risk of progression to cancer but it appears to be safe and effective at eliminating LGD. Fair evidence supports the efficacy and safety of RFA in the treatment of low grade dysplastic BE. However, studies with longer follow-up are needed.

#### **Conclusion:**

- Fair evidence shows that Radio frequency ablation (RFA) and endoscopic mucosal resection are both effective in managing HGD BE but RFA has less adverse events.
- Fair evidence supports efficacy of RFA over endoscopic surveillance for low grade dysplasia.
- Low evidence support similar efficacy between endotherapy and surgery in the treatment of early Barrett's neoplasia
- There is fair evidence that RFA is effective and safe for the treatment of low grade dysplasia; however, studies with long follow-up are needed.
- There is sufficient evidence to determine whether RFA is effective and safe for the treatment of high grade dysplastic Barrett's esophagus.

#### **Articles:**

The literature revealed a number of articles, but the following articles were selected for critical appraisal: Systematic review comparing radiofrequency ablation and complete endoscopic resection in treating dysplastic Barrett's esophagus: a critical assessment of histologic outcomes and adverse events (Chadwick et al, 2014) [See Evidence Table 1](#). Radiofrequency ablation vs endoscopic surveillance for patients with Barrett's esophagus and low-grade dysplasia a randomized clinical trial (Phoa et al 2014) [See Evidence Table 2](#). Efficacy and durability of radiofrequency ablation for Barrett's esophagus: systematic review and meta-analysis (Orman et al, 2013) [See Evidence Table 3](#). Meta-analysis of endoscopic therapy for low-grade dysplasia in Barrett's oesophagus (Almond et al 2014) [See Evidence Table 4](#). Endotherapy versus surgery for early neoplasia in Barrett's esophagus: a meta-analysis (Wu, Pan, Wang, Gao, & Hu, 2014) [See Evidence Table 5](#).

The use of Radiofrequency ablation for the treatment of Barrett's esophagus with dysplasia does meet the *Group Health Medical Technology Assessment Criteria*.

## **Radiofrequency Ablation in the Treatment of Lung Cancer**

### **BACKGROUND**

Lung cancer is the leading cause of cancer related mortality in the United States. It has two main types; the non-small cell lung cancer (NSCLC) which accounts for approximately 80-85% of cases, and the small cell lung cancer (SCLC). After the initial diagnosis of the disease is made, it is essential to have an accurate TNM staging in order to determine the appropriate therapy. The standard treatment of patients with stage I or II NSCLC is surgical resection, and in order to achieve a potential cure from the disease, the cancer must be completely resectable through pneumonectomy or lobectomy, and the patient should be able to tolerate the surgery, and have adequate pulmonary function. Patients with more advanced or metastatic lung disease, or who cannot tolerate surgery, due to age or the presence of other co-morbidities, are poor surgical candidates. They are traditionally offered treatment with conventional external beam radiotherapy which is considered the most reasonable alternative. However, its results have not been satisfactory, and it has lower overall long-term survival than complete surgical resection. This radiation therapy may also be associated with regional complications as radiation pneumonitis, fibrosis, and esophagitis, and is not indicated for pulmonary metastases. Chemotherapy was found to have only a modest therapeutic effect, and is usually used as palliative therapy. This has led the researchers to develop minimally invasive techniques as stereotactic radiotherapy, brachytherapy, photodynamic therapy, bronchial artery infusion of chemotherapy, cryotherapy and radiofrequency ablation (RFA) (D'Amico 2003, Qiao 2003, Pennathur 2007). Radiofrequency ablation is a relatively new minimally invasive therapy that potentially leads to localized tissue destruction. It works by transferring radiofrequency (RF) energy from a generator through an electrode, to the target tissues. The waves are converted into heat, resulting in thermal damage, and coagulative necrosis of the tissues. For solid organ tumor ablation, thin RF electrodes are introduced laparoscopically or percutaneously to the target lesion under ultrasound, CT, or MRI guidance. A power of 5-120W is delivered to the electrodes, and an alternating current of 450-1,200 kHz passes from the tip to the surrounding tissue. When the temperature of the tumor cells is raised above 70°C cell destruction occurs. Several radiofrequency ablation devices were cleared by the FDA as tools for general ablation of soft tissue by thermal necrosis. The devices were also cleared for ablation of liver lesions, and bone metastases. According to the FDA, they have not been cleared for lung tumor ablation as their safety and effectiveness have not been fully established. In December 2007, the FDA issued a public health notification to alert the health practitioners of the deaths associated with lung tumor ablation using the radiofrequency devices (FDA Web site).

### **06/04/2008: MTAC REVIEW**

#### **Radiofrequency Ablation in the Treatment of Lung Cancer**

**Evidence Conclusion:** There is limited evidence on the efficacy and safety of radiofrequency ablation for the treatment of lung cancer in patients who are not candidates for surgical resection. The body of evidence consists of small observational case series with no control or comparison groups that compare the RF ablation with conventional or other noninvasive techniques used for the treatments of patients with non-operable lung cancer, or those who cannot tolerate surgery. The published studies were heterogeneous; there were differences in the eligibility criteria of the studies, patient characteristics, stage of the disease, cancer type, number and sizes of the lesions, as well as other tumor characteristics. There were also variations in the ablation approaches, types of devices used to deliver the therapy, follow-up, endpoints, and outcome measures. Moreover, the follow-up duration in the majority of the studies was too short to determine the long-term safety and effectiveness of the therapy. Overall, the results of the published studies indicate that the median survival of patients receiving the therapy ranged from 8.6 months to 33 months. The one year survival rate ranged from 63-85%, the two year survival was 55-65% and the three year survival rate was 15-46%. Complete tumor necrosis ranged from 38% to 95%, and local disease recurrence varied from 3% to 38.1%. The studies indicate the RF ablation has better outcomes with tumors smaller than 3 cm in diameter vs. those >3cm in diameter, as this would allow oversizing of the ablation areas. The adverse effects associated with FR ablation included pneumothorax that often needed aspiration, pleural effusion, hemoptysis, pain, as well as other complications some of which required hospitalization of the patients. The authors of the published studies presented the results for all patients combined, with no adjustments for confounding factors as age of the patients, presence of other co-morbidities and/or malignancies, or the use of other adjuvant therapy. Moreover, in the absence of comparison groups, it is hard to determine whether radiofrequency ablation leads to better local control or improved survival outcomes than external beam radiation therapy or any other noninvasive treatment. In conclusion there is insufficient published evidence to determine the efficacy and safety of radiofrequency ablation for the treatment of lung cancer.

**Articles:** The search yielded over 300 articles. Many were review articles or publications not related to the current review. No meta-analyses of empirical studies, randomized or non-randomized controlled studies were identified. The majority were observational prospective case series with population sizes ranging from <10 to 60 patients. There was a larger (N=153) retrospective observational study that evaluated the long-term efficacy and safety of the therapy. Prospective series with at least 50 patients, and/or with longer-term follow-up, as well as the larger retrospective series were selected for critical appraisal. *The following studies were critically appraised:*

De Baire T, Palussiere J, Auperin A, et al. Midterm local efficacy and survival after radiofrequency ablation of lung tumors with minimum follow-up of 1 year. Prospective evaluation. *Radiology* 2006.240:587-596. See [Evidence Table](#). Ambrogi MC, Lucchi M, Dini P, et al. Percutaneous radiofrequency ablation of lung tumors: results in mid-term. *Eur J Cardiothorac Surg*. 2006. 30:177-183. See [Evidence Table](#). Gadaleta C, Catino A, Mattioli V. Radiofrequency thermal ablation in the treatment of lung metastases. *In Vivo*. 2006;20:765-768. See [Evidence Table](#). Simon CJ, Dupuy DE, DiPetrillo TA, et al. Pulmonary radiofrequency ablation: Long-term safety and efficacy. *Radiology* 2007.243:268-275. See [Evidence Table](#).

The use of Radiofrequency ablation in the treatment of lung cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Ablation of Renal Tumors**

#### **BACKGROUND**

With the widespread use of body imaging techniques as magnetic resonance imaging (MRI), computed tomography (CT), there is an increasing number of pre-symptomatic, incidentally detected small renal masses or lesions with unclear clinical significance. The standard treatment for renal masses is radical nephrectomy. Other available treatment options for these small, incidentally discovered masses include watchful waiting or partial nephrectomy. Recently, with the current trend of minimally invasive surgery, nephron-sparing approaches have gained more acceptance. Among these are radiofrequency (RF) ablation, cryoablation, microwaves, and high intensity focused ultrasonography (HIFU). These techniques are still under development and only target selected, small renal tumors with a diameter of 4 cm or less. RF ablation works by transferring RF energy from a generator through an electrode, to the target tissues. The waves are converted into heat, resulting in thermal damage, and coagulative necrosis of the tissues. For solid organ tumor ablation, thin RF electrodes are introduced laparoscopically, or percutaneously to the target lesion under ultrasound, CT, or MRI guidance. A power of 5-120W is delivered to the electrodes, and an alternating current of 450-1,200 kHz passes from the tip to the surrounding tissue. When the temperature of the tumor cells is raised above 70°C cell destruction occurs. The size of the lesion depends on the thermal properties of the tissue, the time, and the amount of the energy delivered. Radiofrequency ablation has been used for selected liver and bone tumors. It is approved by the FDA for ablation of aberrant atrioventricular conduction pathways in patients with Wolf-Parkinson-White syndrome, and for treating soft-tissue lesions in the liver. Its use for human renal tumors is still under investigation, and its efficacy and safety as well as its dosimetry have not been fully established.

#### **12/11/2002: MTAC REVIEW**

##### **Radiofrequency Ablation of Renal Tumors**

**Evidence Conclusion:** There is insufficient published evidence to determine the efficacy and safety of radiofrequency ablation for the treatment of renal tumors.

**Articles:** The search yielded one review article, two case reports and three case series with 10-15 patients each. There were no meta-analyses or randomized controlled studies.

The use of radiofrequency ablation in the treatment of renal tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

#### **BACKGROUND**

The liver is a common site for primary and secondary malignancies. Hepatocellular carcinoma (HCC), the most common primary tumor, is the fifth most common cancer in the world, and the third most common cause of cancer-related mortality. It is responsible for more than half a million deaths across the globe each year. Treatment options for patients diagnosed with primary and secondary malignancies are limited. Less than 15% are candidates for surgical resection at presentation because of inadequate liver functional reserve, extrahepatic disease, anatomic constraints of the tumor, or medical comorbidities. The use of external beam radiation is limited due to the intolerance of normal liver parenchyma to tumoricidal radiation doses ( the dose required to destroy solid tumors (>70 Gy) is much higher than the liver tolerance dose of 35 GY). In addition, systematic chemotherapy was found to have little impact on survival, and negative impact on the health-related quality of life due to the toxicity to other organs and systems. These limitations have led to the emergence of other therapies, such as radiofrequency ablation (RFA), cryosurgical ablation (CSA), percutaneous ethanol injections (PEI), hepatic arterial infusion chemotherapy, transarterial chemo-embolization (TACE), and selective intrarterial radioembolization therapy (Steel 2003, Salem 2005, Ibrahim 2008, Bult 2009, Riaz 2009, Bhardwaj 2010). Ablative techniques improve the ability to treat patients with unresectable hepatic tumors. Thermal ablative techniques, such as RFA, destroy tumors via a source that changes temperature to levels that are associated with cell death while causing minimal damage to adjacent, normal tissue. Chemical ablative techniques, such as PEI, involve the injection of cancer killing chemicals such as pure alcohol (ethanol) or acetic acid directly into the tumor. The

choice of technique depends on equipment availability and physician preference. PEI is a chemical ablative technique where absolute or 95% ethanol is injected into tumor tissue resulting in coagulative necrosis through cytoplasmic dehydration, denaturation of cellular proteins, and small vessel thrombosis. When the consistency of the tumor is 'soft' within a 'hard' cirrhotic liver (most HCCs), the distribution of ethanol is relatively uniform; however, when the tumor is 'hard' within a 'soft' normal liver (most metastases), the distribution is not as uniform. For this reason, PEI works better for HCC than for metastases. Complications of PEI include: hyperthermia, pain, elevated serum liver function tests, needle-tract seeding, pleural effusion, biliary stricture, portal vein thrombosis, and bleeding in the biliary tract (Clark 2007, Yamane 2009). The most commonly used ablative technique in the United States is RFA. RFA causes tumor destruction through the use of alternating high-frequency electric current in the radiofrequency range (460-500 kHz). This current is delivered through an electrode placed in the center of a lesion. Ions within the cell follow the alternating current creating frictional heat producing local tissue temperatures that can exceed 100°C. This ionic agitation leads to tissue destruction via tissue boiling and creation of water vapors. Once temperatures greater than 60°C are reached, protein denaturation, tissue coagulation, and vascular thrombosis result in a zone of complete ablation. Partial tissue destruction can occur up to 8 mm in diameter from the zone of complete ablation. RFA can be delivered either percutaneously, laparoscopically, or through open approaches (laparotomy). Complications from RFA include: pleural effusion, hepatic abscess, biliary injury, liver failure, intra-abdominal hemorrhage, pneumothorax, and hypoxemia. The most troubling complications arise when a probe is placed too close to the diaphragm or intra-abdominal organ, resulting in ablation of the surrounding viscera with the accompanying complications of perforation, diaphragmatic injury, or pulmonary damage. Limitations of RFA include: treating lesions in perihilar areas or near large vascular structures, and real time monitoring of the ablative zone is difficult due to air released during heating (Yamane 2009, Arciero 2006). RFA has received FDA approval for generic tissue ablation and the ablation of unresectable colorectal cancer metastases.

#### **08/11/1999: MTAC REVIEW**

##### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

**Evidence Conclusion:** The best published scientific evidence evaluating percutaneous radiofrequency (RF) ablation of liver cancer consists of one case series of 39 patients with primary hepatocellular carcinoma and 11 patients with other primary tumors who had liver metastases. The majority of patients had 3-4 treatments with one or more nodules being ablated at each session. Five patients experienced mild pain during the procedure; no other complications were reported. The 5-year survival rate among those with primary hepatocellular carcinoma was 40%; the period of follow-up for persons with liver metastases was too short for the calculation of a 5-year survival rate. Because the survival rate of patients treated with RF ablation was not directly compared to that of a control group, it is not possible to determine whether this treatment improves survival among patients with liver cancer.

**Articles:** Rossi S, DiStasi M, Buscarini E, Quartetti P, Garbagnati F, Squassante L, Paties CT, Silverman DE, Buscarini L. Percutaneous RF interstitial thermal ablation in the treatment of hepatic cancer. *AJR Am J Roentgenol* 1996; 167: 759-68. See [Evidence Table](#).

The use of radiofrequency ablation in the treatment of primary HCC does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **08/08/2001: MTAC REVIEW**

##### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

**Evidence Conclusion:** Only one study on radiofrequency ablation was a controlled trial. The remainder were case series. The trial reported on a clinically intermediate outcome, liver necrosis, not survival. The case series reports had survival information but this was not presented in a standardized format (e.g. 1-year survival, 3-year survival). Instead, they reported on survival after a certain mean or median follow-up time (patients had different amounts of follow-up time) which is more difficult to interpret. For primary HCC, in the one trial comparing RF ablation to an alternative technique, PEI, both techniques resulted in high rates of complete necrosis and the difference in rates was not statistically significant (Livraghi). PEI required more sessions and RF ablation had more adverse effects (there was 1 major and 4 minor complications with RF ablation, none with PEI). In the case series reviewed (Curley), there was a 72% survival rate after a median of 19 months of follow-up (all patients had at least 12 months follow-up). Livraghi (2001)(not critically appraised for this review) reported on a case series of patients with HCC treated with PEI. The 1-year survival rate for patients with a single HCC 5 cm or smaller was 98, 93 and 64%, respectively for Child's A, B and C cirrhosis. For metastatic hepatic cancer, de Barre found that 81% patients survived after a mean follow-up of 14 months; 62% of these who survived had hepatic disease or distant metastases. 2-year or longer follow-up data were not available. This does not appear to be a dramatic increase in survival compared to untreated metastatic liver cancer (mean survival 6 to 21 months), but there is not strong evidence to support this claim. No studies compared RF ablation treatment to another treatment for metastatic liver cancer such as cryosurgery. In a case series on cryosurgery for hepatic colorectal metastases (Ruers, 2001)

(not critically appraised for this review), the 1-year survival was 76% and the 2-year survival was 61%. The effectiveness of RF ablation may differ depending on the type of metastatic tumor.

**Articles:** The search yielded 85 articles, many of which were review articles, opinion pieces, dealt with technical aspects of the procedures or addressed other, similar treatments. There were no randomized controlled trials or meta-analysis. There was one non-randomized controlled trial and the rest of the empirical articles were case series. Articles on HCC and metastatic liver cancer were analyzed separately. Two studies on primary hepatocellular carcinoma were reviewed (the non-randomized trial and a recent case series with a moderate sample size by a different research group): Livraghi T, Goldberg SN, Lazzaroni S, Meloni F, Solbiati L, Gazelle GS. Small hepatocellular carcinoma: Treatment with radiofrequency ablation versus ethanol injection. *Radiology* 1999; 210: 655-661. See [Evidence Table](#). Curley SA, Izzo F, Ellis LM, Vauthey JN, Vallone P. Radiofrequency ablation of hepatocellular cancer in 110 patients with cirrhosis. *Ann Surg* 2000; 232: 381-91. See [Evidence Table](#). One study on metastatic liver cancer was reviewed (the largest case series with the longest follow-up): de Barre T, Ellas D, Dromain C, El Din MG, Kuocho V, Ducreux M. et al. Radiofrequency ablation of 100 hepatic metastases with a mean follow-up of more than 1 year. *AJR* 2000; 175: 1619-25. See [Evidence Table](#).

The use of radiofrequency ablation in the treatment of primary HCC does not meet the *Group Health Medical Technology Assessment Criteria*.

## 06/21/2010: MTAC REVIEW

### Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer

**Evidence Conclusion:** While there are many studies comparing RFA with resection and other ablative techniques, such as PEI, for the treatment of liver cancer, the data are difficult to compare since the studies are heterogeneous in study design, patient selection, data collection, tumor characteristics, primary cause of liver disease, route of access, electrode types used, and periinterventional systemic treatment.

#### Primary Liver Cancer

**RFA vs. Resection** The study selected for critical appraisal was a randomized controlled trial that compared the results of RFA with resection for the treatment of solitary and small HCC. Overall and disease-free survival rates were not statistically different for patients with solitary HCC < 5 cm in diameter treated with either RFA or resection. Additionally, patients treated with RFA had less major complications than patients treated with resection (0.04% vs. 56%,  $p < 0.05$ ). Treatment groups were comparable at baseline for all characteristic measured with the exception of serum alanine aminotransferase (ALT). Patients in the RFA group had higher serum ALT concentrations compared to patients in the resection group. Factors that limit the validity of the study include: uneven dropout rates, use of additional techniques, and lack of generalizability (Chen 2006). Another nonrandomized study comparing RFA with resection demonstrated similar survival outcomes between RFA and resection for tumors <5 cm (Montorsi 2005). One recent retrospective study suggested that overall and disease-free survival was higher for patients treated with resection compared to patients treated with RFA. However, in a subgroup analysis by tumor size, there was no significant difference in survival between RFA and resection for patients with tumors  $\leq 3$  cm. Results from this study should be interpreted with caution as this study contained significant selection bias; most patients who underwent RFA had more advanced tumors and worse liver function than those who received resection (Guglielmi 2008).

**RFA vs. PEI** There are several published randomized controlled trials and meta-analyses comparing the efficacy of RFA versus PEI. Two of the most recent meta-analyses were selected for appraisal (Germani 2010, Bouza 2009). Results were consistent across the two analyses. Compared to patients treated with PEI, patients treated with RFA had higher three-year overall survival rates (73% RFA vs. 58% PEI,  $p < 0.001$ ) and lower rates of local recurrence (7% RFA vs. 22% PEI,  $p < 0.001$ ). Patients treated with RFA experienced more complications (19% RFA vs. 11% PEI,  $p < 0.001$ ) than those treated with PEI; however, there was no difference in the rate of major complications (4% RFA vs. 3% PEI,  $p = 0.22$ ). The most frequent complication reported in both groups was severe pain. All studies included in the analysis were classified to be trials with high-risk of bias.

**RFA + PEI vs. RFA alone** There have been several published studies comparing PEI + RFA versus RFA alone. A randomized controlled trial was selected for review (Zhang 2007). Results from this trial suggest that overall survival is higher for patients with HCC treated with PEI + RFA versus RFA only ( $p = 0.04$ ). In a subgroup analysis by tumor size, survival was significantly better for those treated with PEI + RFA who had tumors between 3.1 and 5.0 cm compared to those treated with RFA only ( $p = 0.03$ ). There was no significant difference in survival for patients with tumors  $\leq 3$  cm or tumors 5.1-7.0 cm. The local recurrence rate was higher for those treated with RFA alone compared to those treated with PEI + RFA ( $p = 0.01$ ). There was no significant difference in overall, intrahepatic, or extrahepatic recurrence rates. There were no procedure related mortalities or major complications. Pain and fever were the most commonly seen minor complications. Data after 2-years should be interpreted with caution as less than 45% of patients were followed for 3-years. Results are not generalizable to women as less than 15% of the patients enrolled in the study were women. Additionally, the predominant cause of HCC in the study was hepatitis B while the predominant cause of HCC in Japan, Europe, and the United States is hepatitis C and alcohol abuse.

**Secondary Liver Cancer RFA vs. Resection** No randomized controlled trials evaluating RFA compared to resection for unresectable liver metastases from

colorectal cancer were identified. Results from a retrospective cohort study indicate that patients treated with resection had the highest overall and disease-free survival rates and the lowest rates of recurrence compared to patients treated with RFA alone or RFA + resection. Results from this study should be interpreted with caution as this study contained significant selection bias. Patients who were treated with RFA were not eligible for resection (Abdalla 2004). The majority of other studies (Park 2007, Aloia 2006, Hur 2009) comparing RFA and resection reached similar conclusions regarding survival and recurrence rates; however, a few studies have found that survival rates were comparable (Oshowo 2003). It is hard to compare results across studies as the primary cause of the disease differs, techniques differ, and disease characteristics differ. Additionally, none of the treatment groups were comparable at baseline. Patients treated with RFA were not eligible for resection. **Conclusion:** There is fair evidence that overall and disease-free survival rates were not statistically different for patient with solitary HCC <5 cm in diameter treated with either RFA or surgical resection. There is fair evidence that patients with HCC treated with RFA have better survival and lower recurrence rates than patients treated with PEI. There is fair evidence that for patients with HCC and tumors between 3.1 and 5.0 cm in diameter the combined treatment of PEI plus RFA versus RFA alone increases survival; however, long term follow-up is needed. There is insufficient evidence to determine the efficacy of RFA compared to surgical resection for patients with liver metastases.

**Articles:** The literature search yielded around 250 articles pertaining to the use of RFA. The majority of these articles were case series and cohort studies. Only one randomized controlled trial (Chen 2006) was identified that compared RFA with resection for small HCC. There were several RCTs and meta-analyses comparing RFA with PEI. The two most recent meta-analyses (Bouza 2009, Germani 2010) were selected for review. There were several studies comparing the combined use of PEI and RFA. Many of these studies did not have a control group or did not assess survival as an outcome. A RCT that compared PEI + RFA with RFA alone was selected for review (Zhang 2007). No randomized controlled trials or meta-analyses were found pertaining to the use of RFA for metastatic liver cancer. The literature consisted mainly of case series and cohort studies. A retrospective cohort study (Abdalla 2004) that compared resection to RFA was selected for review. The following studies were critically appraised. Chen MS, Li JQ, Zheng Y et al. A prospective randomized trial comparing percutaneous local ablative therapy and partial hepatectomy for small hepatocellular carcinoma. *Ann Surg* 2006; 243:321-328. See [Evidence Table](#). Bhardwaj N, Strickland AD, Ahmad F et al. Liver ablation techniques: a review. *Surg Endosc* 2010; 24:254-265. Bouza C, López-Cuadrado T, Alcázar R et al. Meta-analysis of percutaneous radiofrequency ablation versus ethanol injection in hepatocellular carcinoma. *BMC Gastroenterol* 2009; 9:31-39. See [Evidence Table](#). Germani G, Pleguezuelo M, Gurusamy K et al. Clinical outcomes of radiofrequency ablation, percutaneous alcohol ablation and acetic acid injection for hepatocellular carcinoma: A meta-analysis. *J Hepatol* 2010; 52:380-388. See [Evidence Table](#). Zhang YJ, Liang HH, Chen MS et al. Hepatocellular carcinoma treated with radiofrequency ablation with or without ethanol injection: A prospective randomized controlled trial. *Radiology* 2007; 244:599-607. See [Evidence Table](#). Abdalla EK, Vauthey JN, Ellis LM et al. Recurrence and outcomes following hepatic resection, radiofrequency ablation, and combined resection/ablation for colorectal liver metastases. *Ann Surg* 2004; 239:818-827. See [Evidence Table](#).

The use of radiofrequency ablation in the treatment of primary HCC does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Radiofrequency Ablation for the Treatment of Barrett's Esophagus

- HALO System

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Covered

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

*\*Pending MTAC Review September 2016 – See Medical Policy Coordinator for more details*

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Barrett's esophagus (BE) is an acquired condition in which the normal squamous cell lining of the esophagus is replaced by columnar epithelium containing goblet cells, also known as intestinal metaplasia. This change is induced by recurrent mucosal injury related to gastroesophageal reflux disease (GERD). Barrett's esophagus is associated with a 30-50 fold greater risk of developing esophageal adenocarcinoma (EAC), the incidence of which has increased by more than 500% in the last four decades. BE gradually progresses from a non-dysplastic BE, to BE with low-grade dysplasia (LGD), to BE with high grade dysplasia (HGD), before becoming invasive EAC. It was found that most cases of BE do not progress beyond the non-dysplastic metaplasia or transient LGD, but once HGD develops the risk of progression to adenocarcinoma rises dramatically with an estimated annual risk of 5-10% per patient. Esophageal adenocarcinoma is a highly lethal cancer with a 5-year survival rate less than 15% (Sharma 2008, Sheehan 2009, Watson 2009).

Management of Barrett's esophagus is challenging, simply because there are no biomarkers or predictors to indicate which patient with nondysplastic intestinal metaplasia, LGD, or HGD will progress to a more advanced disease. There is no defined optimal strategy for treating Barrett's esophagus. However, the standard management of nondysplastic BE or BE with LGD is the control of the underlying GERD and observation of the patient with lifelong surveillance and biopsies to monitor the progression of the disease in an attempt to identify those who might benefit from treatment at a pre-invasive stage of EAC. Surgical intervention, most commonly esophagectomy is usually recommended if HGD develops or a multifocal disease is found. This practice however, does not eliminate cancer risk or achieve complete regression of BE. In addition, endoscopic detection of dysplasia is difficult, random biopsies are associated with sampling errors, histological evaluation of the biopsies is subject to potential interobserver errors, and esophagectomy is a highly invasive procedure associated with serious complications and high mortality rates, in addition to the loss of the functional esophagus (Bergman 2009, Eldeif 2009, Watson 2009).

There has been a growing interest in endoscopic therapies for BE as less invasive treatment options than surgical esophagectomy. These include endoscopic resection and endoscopic ablation techniques. Ablative therapy is based on the hypothesis that injury to the metaplastic epithelium combined with vigorous acids suppression would lead to reversion of the columnar epithelium to squamous epithelium and reduce the risk of progression to cancer. The overall goals of ablation therapy for BE are to completely eliminate columnar epithelium, eliminate risk of progression to cancer, and decrease the need for surveillance endoscopy. Ideally ablative techniques should be

safe, easy to apply, provide uniform application to the esophagus, and require a limited number of sessions to achieve the results. Available modalities of ablative therapy include argon plasma coagulation, multipolar electrocoagulation, cryotherapy, laser photodynamic therapy, and others. These procedures are not without risk, and may lead to bleeding, strictures, perforation, and ulceration. The literature indicates that none of these ablation techniques is considered as the most appropriate option in regard to safety, efficacy and ease of treatment for both the patients and providers (Fleischer 2008, Wani 2009, Watson 2009).

Radiofrequency ablation (RFA) is a relatively new minimally invasive therapy that is claimed to be effective, well tolerated, and associated with no buried glands after re-epithelization unlike other mucosal ablation modalities. It works by transferring radiofrequency (RF) energy from a generator through an electrode, to the target tissues. The waves are converted into heat, resulting in thermal damage, and coagulative necrosis of the tissues.

Radiofrequency ablation using the HALO system potentially allows this rapid delivery of high power energy with reliable energy density control and depth of tissue penetration. In vitro studies showed that the deepest ablative effect at the treatment settings was the muscularis mucosa and superficial sub-mucosa. HALO system uses a stepwise regimen of circumferential balloon-based ablation followed by focal endoscopic-based ablation until potential radiation of all BE is achieved (Sharma 2009, dos Santos 2010).

For circumferential Barrett's esophagus, initial ablation is typically attempted with HALO360 (BARRX Medical Inc, Sunnyvale, CA) balloon-based ablation catheter. The device consists of 60 bipolar electrode rings (250µm width each) tightly spaced (250µm intervening distance), and wrapped over a 3 cm distance around a 4 cm balloon that delivers the ablative radiofrequency energy to the tissue. The balloon (which comes in 22, 25, 28, 31 and 34 mm outer diameter to measure the size of the targeted esophagus) dilates the esophagus to a predetermined pressure and flattens its wall to a standardized tension to allow uniform energy delivery to the mucosa over a large surface area (>30 cm<sup>2</sup>). A high power (300W) ultra-short (300ms) burst of energy is then applied to allow ablation to a uniform depth; approximately the depth of the muscularis mucosa. The treatment is continued until the entire Barrett's segment is ablated. For segments that are more than 3cm in length the BE is ablated in 3cm increments after repositioning the catheter (with no more than 6cm ablated at one session). After the first treatment the catheter is withdrawn, the coagulative debris cleaned and the abnormal tissues ablated for a second time (Sharma 2007, Watson 2009, Van Vilsteren 2010).

The HALO 90 (BARRX Medical Inc, Sunnyvale, CA) endoscope-based catheter is typically used for secondary focal ablation of non-circumferential tongues or islands of intestinal metaplasia. The device (20mm long and 13mm wide) is mounted on an articulated platform, attached to the tip of a standard flexible adult endoscope and introduces transorally. The microelectrode array is similar in pattern and spacing to the HALO 360 device, but it does not utilize a catheter based balloon as no esophageal sizing is necessary. It also has a smaller ablation zone (approximately 2.6cm<sup>2</sup> in diameter). The energy is delivered twice to each region, the coagulum cleaned, and the energy is applied twice again for a total of 4 applications (vs. 2 in HALO360). HALO 90 may also be used to treat the esophagus in a circumferential fashion in the region of the gastroesophageal junction where the anatomy may not allow successful positioning of the HALO 360 device (Watson 2009).

Both HALO 360 and HALO 90 devices manufactured by BARRX Medical Inc (Sunnyvale, CA) have received FDA clearance for use in the coagulation of bleeding and non-bleeding sites in the gastrointestinal tract including but not limited to, the esophagus. Indications include: esophageal ulcers, Mallory-Weiss, tears, arteriovenous malformations, angiomata, Barrett's esophagus, dieulafoy, lesions, and angiodysplasia" (FDA Web sites).

## Medical Technology Assessment Committee (MTAC)

### *Radiofrequency ablation for the treatment of Barrett's Esophagus*

#### **02/01/2010: MTAC REVIEW**

**Evidence Conclusion:** The literature search revealed only one published randomized controlled trials (Shaheen et al, 2009) that compared radiofrequency ablation of Barrett's esophagus to a sham endoscopic procedure. The trial had valid design and analysis; it was multicenter, appropriately randomized, controlled, blinded, had sufficient statistical power, and with low dropout rate. However, radiofrequency ablation was compared to a sham procedure and not to another established alternative procedure with a curative intent for BE with dysplasia e.g. endoscopic resection, esophagectomy, or photodynamic therapy. Moreover, the trial had only one year of follow-up which is insufficient to determine the long-term efficacy, and safety of the procedure. Due to the short follow-up duration, the authors used neoplastic progression and eradication of dysplasia and metaplasia as surrogates for death from cancer. The trial randomized 127 patients (in a 2:1 ratio) with low or high grade dysplasia to undergo either radiofrequency ablation or sham endoscopic therapy. Randomization was stratified according to grade of dysplasia (LGD or HGD) and length of BE lesion (<4 or 4-8cm). Those in the ablation group underwent step-wise circumferential and focal ablation using HALO 360 and HALO 90 systems (BARRX Medical Inc, Sunnyvale, CA). Patients in the two groups underwent endoscopic surveillance for the study period; biopsies were obtained

throughout the BE length every 3 months in patients with HGD or 6 months among those with LGD. After 12 months of follow-up, the results of the trial showed that more than three fourths of patients treated with radiofrequency ablation had complete eradication of intestinal metaplasia and dysplasia (77 % of all BE was completely reversed into normal epithelium among those who received RFA, vs. 2% in the control; 90% of patients with LGD, and 81.5% with HGD had complete eradication of the dysplasia vs. 23% and 19% of the controls respectively). The ablation therapy was also associated with a significant decrease in the risk of cancer but, as acknowledged by the authors this should be interpreted with caution due to the small number of cases. RFA therapy was not without risk as 5 (6%) cases developed esophageal stricture that required endoscopic dilatation, and 3 (3.5%) had other serious events as bleeding and chest pain.

Conclusion:

- There is fair evidence from one RCT with short-term follow-up that radiofrequency ablation using the HALO systems is superior to sham therapy (no therapy) in the treatment of BE with dysplasia.
- There is insufficient evidence to determine that RFA has better outcomes and less harms than alternative therapies with curative intent for BE with dysplasia.
- There is insufficient evidence to determine the long-term efficacy, and safety of radiofrequency ablation therapy in the management of patients with Barrett’s esophagus with dysplasia, and whether the risk of ablation is less than the risk of progression of BE.
- There is insufficient evidence to determine that radiofrequency ablation therapy eliminates the necessity for of further endoscopic surveillance of patients with Barrett’s esophagus with dysplasia.
- There is insufficient evidence to determine that radiofrequency ablation therapy reduces or eliminates cancer risk in patients with Barrett’s esophagus with dysplasia.

**Articles:** The search yielded around forty articles. Many were reviews, letters, and editorials. There was one randomized controlled trial and number of case series and reports. The RCT and the majority of the case series were conducted by the same group of investigators. The RCT with the following citation was critically appraised. Shaheen NJ, Sharma P, Overholt B, et al. Radiofrequency ablation in Barrett’s esophagus with dysplasia. N Engl J Med 2009;360:2277-2288. See [Evidence Table](#)

The use of Radiofrequency ablation for the treatment of Barrett’s esophagus with dysplasia does not meet the *Group Health Medical Technology Assessment Criteria*.

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	<a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	None

**Covered without review:** *Esophagus, liver tumors, and renal tumors*

#### For Non-Medicare Members

Service	Criteria Used
Barrett's Esophagus	Radiofrequency ablation is considered medically necessary for the treatment of members with Barrett's esophagus (BE) who have histological confirmation of low-grade dysplasia by two or more endoscopies three or more months apart.
Lung Cancer	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
Renal Tumors Primary HCC and Metastatic Liver Cancer	Medical necessity review is no longer required for this service.
Vertebral Augmentation for Painful Spinal Metastases	See criteria for <a href="#">Vertebroplasty</a>

**Covered without review:** *Esophagus, liver tumors, and renal tumors*

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Medical Technology Assessment Committee (MTAC)

#### Radiofrequency Ablation in the Treatment of Lung Cancer

##### BACKGROUND

Lung cancer is the leading cause of cancer related mortality in the United States. It has two main types; the non-small cell lung cancer (NSCLC) which accounts for approximately 80-85% of cases, and the small cell lung cancer

(SCLC). After the initial diagnosis of the disease is made, it is essential to have an accurate TNM staging in order to determine the appropriate therapy. The standard treatment of patients with stage I or II NSCLC is surgical resection, and in order to achieve a potential cure from the disease, the cancer must be completely resectable through pneumonectomy or lobectomy, and the patient should be able to tolerate the surgery, and have adequate pulmonary function. Patients with more advanced or metastatic lung disease, or who cannot tolerate surgery, due to age or the presence of other co-morbidities, are poor surgical candidates. They are traditionally offered treatment with conventional external beam radiotherapy which is considered the most reasonable alternative. However, its results have not been satisfactory, and it has lower overall long-term survival than complete surgical resection. This radiation therapy may also be associated with regional complications as radiation pneumonitis, fibrosis, and esophagitis, and is not indicated for pulmonary metastases. Chemotherapy was found to have only a modest therapeutic effect, and is usually used as palliative therapy. This has led the researchers to develop minimally invasive techniques as stereotactic radiotherapy, brachytherapy, photodynamic therapy, bronchial artery infusion of chemotherapy, cryotherapy and radiofrequency ablation (RFA) (D'Amico 2003, Qiao 2003, Pennathur 2007). Radiofrequency ablation is a relatively new minimally invasive therapy that potentially leads to localized tissue destruction. It works by transferring radiofrequency (RF) energy from a generator through an electrode, to the target tissues. The waves are converted into heat, resulting in thermal damage, and coagulative necrosis of the tissues. For solid organ tumor ablation, thin RF electrodes are introduced laparoscopically or percutaneously to the target lesion under ultrasound, CT, or MRI guidance. A power of 5-120W is delivered to the electrodes, and an alternating current of 450-1,200 kHz passes from the tip to the surrounding tissue. When the temperature of the tumor cells is raised above 70°C cell destruction occurs. Several radiofrequency ablation devices were cleared by the FDA as tools for general ablation of soft tissue by thermal necrosis. The devices were also cleared for ablation of liver lesions, and bone metastases. According to the FDA, they have not been cleared for lung tumor ablation as their safety and effectiveness have not been fully established. In December 2007, the FDA issued a public health notification to alert the health practitioners of the deaths associated with lung tumor ablation using the radiofrequency devices (FDA Web site).

#### **06/04/2008: MTAC REVIEW**

##### **Radiofrequency Ablation in the Treatment of Lung Cancer**

**Evidence Conclusion:** There is limited evidence on the efficacy and safety of radiofrequency ablation for the treatment of lung cancer in patients who are not candidates for surgical resection. The body of evidence consists of small observational case series with no control or comparison groups that compare the RF ablation with conventional or other noninvasive techniques used for the treatments of patients with non-operable lung cancer, or those who cannot tolerate surgery. The published studies were heterogeneous; there were differences in the eligibility criteria of the studies, patient characteristics, stage of the disease, cancer type, number and sizes of the lesions, as well as other tumor characteristics. There were also variations in the ablation approaches, types of devices used to deliver the therapy, follow-up, endpoints, and outcome measures. Moreover, the follow-up duration in the majority of the studies was too short to determine the long-term safety and effectiveness of the therapy. Overall, the results of the published studies indicate that the median survival of patients receiving the therapy ranged from 8.6 months to 33 months. The one year survival rate ranged from 63-85%, the two year survival was 55-65% and the three year survival rate was 15-46%. Complete tumor necrosis ranged from 38% to 95%, and local disease recurrence varied from 3% to 38.1%. The studies indicate the RF ablation has better outcomes with tumors smaller than 3 cm in diameter vs. those >3cm in diameter, as this would allow oversizing of the ablation areas. The adverse effects associated with FR ablation included pneumothorax that often needed aspiration, pleural effusion, hemoptysis, pain, as well as other complications some of which required hospitalization of the patients. The authors of the published studies presented the results for all patients combined, with no adjustments for confounding factors as age of the patients, presence of other co-morbidities and/or malignancies, or the use of other adjuvant therapy. Moreover, in the absence of comparison groups, it is hard to determine whether radiofrequency ablation leads to better local control or improved survival outcomes than external beam radiation therapy or any other noninvasive treatment. In conclusion there is insufficient published evidence to determine the efficacy and safety of radiofrequency ablation for the treatment of lung cancer.

**Articles:** The search yielded over 300 articles. Many were review articles or publications not related to the current review. No meta-analyses of empirical studies, randomized or non-randomized controlled studies were identified. The majority were observational prospective case series with population sizes ranging from <10 to 60 patients. There was a larger (N=153) retrospective observational study that evaluated the long-term efficacy and safety of the therapy. Prospective series with at least 50 patients, and/or with longer-term follow-up, as well as the larger retrospective series were selected for critical appraisal. *The following studies were critically appraised:*  
De Baire T, Palussiere J, Auperin A, et al. Midterm local efficacy and survival after radiofrequency ablation of lung tumors with minimum follow-up of 1 year. Prospective evaluation. *Radiology* 2006;240:587-596. See [Evidence Table](#). Ambrogi MC, Lucchi M, Dini P, et al. The use of Radiofrequency ablation in the treatment of lung cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Ablation of Renal Tumors**

#### **BACKGROUND**

With the widespread use of body imaging techniques as magnetic resonance imaging (MRI), computed tomography (CT), there is an increasing number of pre-symptomatic, incidentally detected small renal masses or lesions with unclear clinical significance. The standard treatment for renal masses is radical nephrectomy. Other available treatment options for these small, incidentally discovered masses include watchful waiting or partial nephrectomy. Recently, with the current trend of minimally invasive surgery, nephron-sparing approaches have gained more acceptance. Among these are radiofrequency (RF) ablation, cryoablation, microwaves, and high intensity focused ultrasonography (HIFU). These techniques are still under development and only target selected, small renal tumors with a diameter of 4 cm or less. RF ablation works by transferring RF energy from a generator through an electrode, to the target tissues. The waves are converted into heat, resulting in thermal damage, and coagulative necrosis of the tissues. For solid organ tumor ablation, thin RF electrodes are introduced laparoscopically, or percutaneously to the target lesion under ultrasound, CT, or MRI guidance. A power of 5-120W is delivered to the electrodes, and an alternating current of 450-1,200 kHz passes from the tip to the surrounding tissue. When the temperature of the tumor cells is raised above 70°C cell destruction occurs. The size of the lesion depends on the thermal properties of the tissue, the time, and the amount of the energy delivered. Radiofrequency ablation has been used for selected liver and bone tumors. It is approved by the FDA for ablation of aberrant atrioventricular conduction pathways in patients with Wolf-Parkinson-White syndrome, and for treating soft-tissue lesions in the liver. Its use for human renal tumors is still under investigation, and its efficacy and safety as well as its dosimetry have not been fully established.

#### **12/11/2002: MTAC REVIEW**

#### **Radiofrequency Ablation of Renal Tumors**

**Evidence Conclusion:** There is insufficient published evidence to determine the efficacy and safety of radiofrequency ablation for the treatment of renal tumors.

**Articles:** The search yielded one review article, two case reports and three case series with 10-15 patients each. There were no meta-analyses or randomized controlled studies.

The use of radiofrequency ablation in the treatment of renal tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

#### **BACKGROUND**

The liver is a common site for primary and secondary malignancies. Hepatocellular carcinoma (HCC), the most common primary tumor, is the fifth most common cancer in the world, and the third most common cause of cancer-related mortality. It is responsible for more than half a million deaths across the globe each year. Treatment options for patients diagnosed with primary and secondary malignancies are limited. Less than 15% are candidates for surgical resection at presentation because of inadequate liver functional reserve, extrahepatic disease, anatomic constraints of the tumor, or medical comorbidities. The use of external beam radiation is limited due to the intolerance of normal liver parenchyma to tumoricidal radiation doses (the dose required to destroy solid tumors (>70 Gy) is much higher than the liver tolerance dose of 35 GY). In addition, systematic chemotherapy was found to have little impact on survival, and negative impact on the health-related quality of life due to the toxicity to other organs and systems. These limitations have led to the emergence of other therapies, such as radiofrequency ablation (RFA), cryosurgical ablation (CSA), percutaneous ethanol injections (PEI), hepatic arterial infusion chemotherapy, transarterial chemo-embolization (TACE), and selective intrarterial radioembolization therapy (Steel 2003, Salem 2005, Ibrahim 2008, Bult 2009, Riaz 2009, Bhardwaj 2010). Ablative techniques improve the ability to treat patients with unresectable hepatic tumors. Thermal ablative techniques, such as RFA, destroy tumors via a source that changes temperature to levels that are associated with cell death while causing minimal damage to adjacent, normal tissue. Chemical ablative techniques, such as PEI, involve the injection of cancer killing chemicals such as pure alcohol (ethanol) or acetic acid directly into the tumor. The choice of technique depends on equipment availability and physician preference. PEI is a chemical ablative technique where absolute or 95% ethanol is injected into tumor tissue resulting in coagulative necrosis through cytoplasmic dehydration, denaturation of cellular proteins, and small vessel thrombosis. When the consistency of the tumor is 'soft' within a 'hard' cirrhotic liver (most HCCs), the distribution of ethanol is relatively uniform; however, when the tumor is 'hard' within a 'soft' normal liver (most metastases), the distribution is not as uniform.

For this reason, PEI works better for HCC than for metastases. Complications of PEI include: hyperthermia, pain, elevated serum liver function tests, needle-tract seeding, pleural effusion, biliary stricture, portal vein thrombosis, and bleeding in the biliary tract (Clark 2007, Yamane 2009). The most commonly used ablative technique in the United States is RFA. RFA causes tumor destruction through the use of alternating high-frequency electric current in the radiofrequency range (460-500 kHz). This current is delivered through an electrode placed in the center of a lesion. Ions within the cell follow the alternating current creating frictional heat producing local tissue temperatures that can exceed 100°C. This ionic agitation leads to tissue destruction via tissue boiling and creation of water vapors. Once temperatures greater than 60°C are reached, protein denaturation, tissue coagulation, and vascular thrombosis result in a zone of complete ablation. Partial tissue destruction can occur up to 8 mm in diameter from the zone of complete ablation. RFA can be delivered either percutaneously, laparoscopically, or through open approaches (laparotomy). Complications from RFA include: pleural effusion, hepatic abscess, biliary injury, liver failure, intra-abdominal hemorrhage, pneumothorax, and hypoxemia. The most troubling complications arise when a probe is placed too close to the diaphragm or intra-abdominal organ, resulting in ablation of the surrounding viscera with the accompanying complications of perforation, diaphragmatic injury, or pulmonary damage. Limitations of RFA include: treating lesions in perihilar areas or near large vascular structures, and real time monitoring of the ablative zone is difficult due to air released during heating (Yamane 2009, Arciero 2006). RFA has received FDA approval for generic tissue ablation and the ablation of unresectable colorectal cancer metastases.

#### **08/11/1999: MTAC REVIEW**

##### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

**Evidence Conclusion:** The best published scientific evidence evaluating percutaneous radiofrequency (RF) ablation of liver cancer consists of one case series of 39 patients with primary hepatocellular carcinoma and 11 patients with other primary tumors who had liver metastases. The majority of patients had 3-4 treatments with one or more nodules being ablated at each session. Five patients experienced mild pain during the procedure; no other complications were reported. The 5-year survival rate among those with primary hepatocellular carcinoma was 40%; the period of follow-up for persons with liver metastases was too short for the calculation of a 5-year survival rate. Because the survival rate of patients treated with RF ablation was not directly compared to that of a control group, it is not possible to determine whether this treatment improves survival among patients with liver cancer.

**Articles:** Rossi S, DiStasi M, Buscarini E, Quartetti P, Garbagnati F, Squassante L, Paties CT, Silverman DE, Buscarini L. Percutaneous RF interstitial thermal ablation in the treatment of hepatic cancer. *AJR Am J Roentgenol* 1996; 167: 759-68. See [Evidence Table](#).

The use of radiofrequency ablation in the treatment of primary HCC does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **08/08/2001: MTAC REVIEW**

##### **Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer**

**Evidence Conclusion:** Only one study on radiofrequency ablation was a controlled trial. The remainder were case series. The trial reported on a clinically intermediate outcome, liver necrosis, not survival. The case series reports had survival information but this was not presented in a standardized format (e.g. 1-year survival, 3-year survival). Instead, they reported on survival after a certain mean or median follow-up time (patients had different amounts of follow-up time) which is more difficult to interpret. For primary HCC, in the one trial comparing RF ablation to an alternative technique, PEI, both techniques resulted in high rates of complete necrosis and the difference in rates was not statistically significant (Livraghi). PEI required more sessions and RF ablation had more adverse effects (there was 1 major and 4 minor complications with RF ablation, none with PEI). In the case series reviewed (Curley), there was a 72% survival rate after a median of 19 months of follow-up (all patients had at least 12 months follow-up). Livraghi (2001)(not critically appraised for this review) reported on a case series of patients with HCC treated with PEI. The 1-year survival rate for patients with a single HCC 5 cm or smaller was 98, 93 and 64%, respectively for Child's A, B and C cirrhosis. For metastatic hepatic cancer, de Barre found that 81% patients survived after a mean follow-up of 14 months; 62% of these who survived had hepatic disease or distant metastases. 2-year or longer follow-up data were not available. This does not appear to be a dramatic increase in survival compared to untreated metastatic liver cancer (mean survival 6 to 21 months), but there is not strong evidence to support this claim. No studies compared RF ablation treatment to another treatment for metastatic liver cancer such as cryosurgery. In a case series on cryosurgery for hepatic colorectal metastases (Ruers, 2001) (not critically appraised for this review), the 1-year survival was 76% and the 2-year survival was 61%. The effectiveness of RF ablation may differ depending on the type of metastatic tumor.

**Articles:** The search yielded 85 articles, many of which were review articles, opinion pieces, dealt with technical aspects of the procedures or addressed other, similar treatments. There were no randomized controlled trials or meta-analysis. There was one non-randomized controlled trial and the rest of the empirical articles were case

series. Articles on HCC and metastatic liver cancer were analyzed separately. Two studies on primary hepatocellular carcinoma were reviewed (the non-randomized trial and a recent case series with a moderate sample size by a different research group): Livraghi T, Goldberg SN, Lazzaroni S, Meloni F, Solbiati L, Gazelle GS. Small hepatocellular carcinoma: Treatment with radiofrequency ablation versus ethanol injection. *Radiology* 1999; 210: 655-661. See [Evidence Table](#). Curley SA, Izzo F, Ellis LM, Vauthey JN, Vallone P. Radiofrequency ablation of hepatocellular cancer in 110 patients with cirrhosis. *Ann Surg* 2000; 232: 381-91. See [Evidence Table](#). *One study on metastatic liver cancer was reviewed (the largest case series with the longest follow-up):* de Barre T, Ellas D, Dromain C, El Din MG, Kuoch V, Ducreux M. et al. Radiofrequency ablation of 100 hepatic metastases with a mean follow-up of more than 1 year. *AJR* 2000; 175: 1619-25. See [Evidence Table](#).

The use of radiofrequency ablation in the treatment of primary HCC does not meet the *Group Health Medical Technology Assessment Criteria*.

## 06/21/2010: MTAC REVIEW

### Radiofrequency Ablation of Primary HCC and Metastatic Liver Cancer

**Evidence Conclusion:** While there are many studies comparing RFA with resection and other ablative techniques, such as PEI, for the treatment of liver cancer, the data are difficult to compare since the studies are heterogeneous in study design, patient selection, data collection, tumor characteristics, primary cause of liver disease, route of access, electrode types used, and periinterventional systemic treatment.

#### Primary Liver Cancer

**RFA vs. Resection** The study selected for critical appraisal was a randomized controlled trial that compared the results of RFA with resection for the treatment of solitary and small HCC. Overall and disease-free survival rates were not statistically different for patients with solitary HCC < 5 cm in diameter treated with either RFA or resection. Additionally, patients treated with RFA had less major complications than patients treated with resection (0.04% vs. 56%,  $p < 0.05$ ). Treatment groups were comparable at baseline for all characteristic measured with the exception of serum alanine aminotransferase (ALT). Patients in the RFA group had higher serum ALT concentrations compared to patients in the resection group. Factors that limit the validity of the study include: uneven dropout rates, use of additional techniques, and lack of generalizability (Chen 2006). Another nonrandomized study comparing RFA with resection demonstrated similar survival outcomes between RFA and resection for tumors < 5 cm (Montorsi 2005). One recent retrospective study suggested that overall and disease-free survival was higher for patients treated with resection compared to patients treated with RFA. However, in a subgroup analysis by tumor size, there was no significant difference in survival between RFA and resection for patients with tumors  $\leq 3$  cm. Results from this study should be interpreted with caution as this study contained significant selection bias; most patients who underwent RFA had more advanced tumors and worse liver function than those who received resection (Guglielmi 2008).

**RFA vs. PEI** There are several published randomized controlled trials and meta-analyses comparing the efficacy of RFA versus PEI. Two of the most recent meta-analyses were selected for appraisal (Germani 2010, Bouza 2009). Results were consistent across the two analyses. Compared to patients treated with PEI, patients treated with RFA had higher three-year overall survival rates (73% RFA vs. 58% PEI,  $p < 0.001$ ) and lower rates of local recurrence (7% RFA vs. 22% PEI,  $p < 0.001$ ). Patients treated with RFA experienced more complications (19% RFA vs. 11% PEI,  $p < 0.001$ ) than those treated with PEI; however, there was no difference in the rate of major complications (4% RFA vs. 3% PEI,  $p = 0.22$ ). The most frequent complication reported in both groups was severe pain. All studies included in the analysis were classified to be trials with high-risk of bias.

**RFA + PEI vs. RFA alone** There have been several published studies comparing PEI + RFA versus RFA alone. A randomized controlled trial was selected for review (Zhang 2007). Results from this trial suggest that overall survival is higher for patients with HCC treated with PEI + RFA versus RFA only ( $p = 0.04$ ). In a subgroup analysis by tumor size, survival was significantly better for those treated with PEI + RFA who had tumors between 3.1 and 5.0 cm compared to those treated with RFA only ( $p = 0.03$ ). There was no significant difference in survival for patients with tumors  $\leq 3$  cm or tumors 5.1-7.0 cm. The local recurrence rate was higher for those treated with RFA alone compared to those treated with PEI + RFA ( $p = 0.01$ ). There was no significant difference in overall, intrahepatic, or extrahepatic recurrence rates. There were no procedure related mortalities or major complications. Pain and fever were the most commonly seen minor complications. Data after 2-years should be interpreted with caution as less than 45% of patients were followed for 3-years. Results are not generalizable to women as less than 15% of the patients enrolled in the study were women. Additionally, the predominant cause of HCC in the study was hepatitis B while the predominant cause of HCC in Japan, Europe, and the United States is hepatitis C and alcohol abuse.

**Secondary Liver Cancer RFA vs. Resection** No randomized controlled trials evaluating RFA compared to resection for unresectable liver metastases from colorectal cancer were identified. Results from a retrospective cohort study indicate that patients treated with resection had the highest overall and disease-free survival rates and the lowest rates of recurrence compared to patients treated with RFA alone or RFA + resection. Results from this study should be interpreted with caution as this study contained significant selection bias. Patients who were treated with RFA were not eligible for resection (Abdalla 2004). The majority of other studies (Park 2007, Aloia 2006, Hur 2009) comparing RFA and resection

reached similar conclusions regarding survival and recurrence rates; however, a few studies have found that survival rates were comparable (Oshowo 2003). It is hard to compare results across studies as the primary cause of the disease differs, techniques differ, and disease characteristics differ. Additionally, none of the treatment groups were comparable at baseline. Patients treated with RFA were not eligible for resection. **Conclusion:** There is fair evidence that overall and disease-free survival rates were not statistically different for patient with solitary HCC <5 cm in diameter treated with either RFA or surgical resection. There is fair evidence that patients with HCC treated with RFA have better survival and lower recurrence rates than patients treated with PEI. There is fair evidence that for patients with HCC and tumors between 3.1 and 5.0 cm in diameter the combined treatment of PEI plus RFA versus RFA alone increases survival; however, long term follow-up is needed. There is insufficient evidence to determine the efficacy of RFA compared to surgical resection for patients with liver metastases.

**Articles:** The literature search yielded around 250 articles pertaining to the use of RFA. The majority of these articles were case series and cohort studies. Only one randomized controlled trial (Chen 2006) was identified that compared RFA with resection for small HCC. There were several RCTs and meta-analyses comparing RFA with PEI. The two most recent meta-analyses (Bouza 2009, Germani 2010) were selected for review. There were several studies comparing the combined use of PEI and RFA. Many of these studies did not have a control group or did not assess survival as an outcome. A RCT that compared PEI + RFA with RFA alone was selected for review (Zhang 2007). No randomized controlled trials or meta-analyses were found pertaining to the use of RFA for metastatic liver cancer. The literature consisted mainly of case series and cohort studies. A retrospective cohort study (Abdalla 2004) that compared resection to RFA was selected for review. The following studies were critically appraised. Chen MS, Li JQ, Zheng Y et al. A prospective randomized trial comparing percutaneous local ablative therapy and partial hepatectomy for small hepatocellular carcinoma. *Ann Surg* 2006; 243:321-328. See [Evidence Table](#). - Last 6 months of clinical notes from requesting provider &/or specialist

#### Background

The nose is responsible for almost 2/3 of the resistance to airflow during breathing, with most of the resistance occurring in the anterior part of the nose, called the nasal valve, comprised of the external and internal valves. External valve collapse may be idiopathic or associated with a history of trauma or previous surgery; common causes of internal valve collapse are septal deviation and previous surgery. Restoration of the normal aperture of the internal and external components of the nasal valve are important treatment strategies for the correction of nasal obstruction.

### Medical Technology Assessment Committee (MTAC)

#### **BREVAGen**

##### BACKGROUND

According to the American Cancer Society, breast cancer is the second leading cause of death in women in the United States after lung cancer. Current methods of assessing breast cancer risk include the Breast Cancer Risk Assessment Tool (BCRAT) otherwise known as the Gail model. This model incorporates individual risk factors such as basic demographic information, reproductive history and medical history. Recent genome wide association studies have identified several single nucleotide polymorphisms (SNPs) associated with an increased risk of breast cancer leading to an additional dimension and understanding of risk (Easton, Pooley et al. 2007; Stacey, Manolescu et al. 2007; Stacey, Manolescu et al. 2008). The BREVAGen™ (Phenogen Sciences, Inc., Charlotte, NC) is a risk stratification test for sporadic breast cancer. Intended for use as an adjunct to the Gail model, the test consists of two parts, the first, a series of questions to determine clinical risk and the second, a buccal swab to analyze specific genetic markers. The latter part of the test, includes a panel of seven SNPs associated with breast cancer risk and does not include either of the BRCA mutations. Ultimately, a patient's risk is calculated by multiplying the product of the individual SNP risks by the Gail model risk. According to the

BREVA Gen™ website, the test is only suitable for women of European descent aged 35 years or older. No test combining the results of SNP analysis with clinical factors to predict breast cancer risk has been approved or cleared by the U.S. Food and Drug Administration (FDA). BREVA Gen™ is offered as a laboratory developed tests and only requires oversight under the Clinical Laboratory Improvement Amendments of 1988 (CLIA). The development and use of this laboratory developed test is restricted to laboratories certified as high complexity under CLIA. Under the current regulatory program, CLIA requires that laboratories demonstrate quality systems which includes validation and proficiency testing.

## 12/16/2013: MTAC REVIEW

### BREVA Gen

**Evidence Conclusion:** *Analytic Validity* Although the seven breast cancer associated SNPs were identified in genome wide association studies (Easton, Pooley et al. 2007; Stacey, Manolescu et al. 2007; Stacey, Manolescu et al. 2008), there are no publications that specifically report on the analytic validity of the BREVA Gen™ panel. *Clinical Validity* The BREVA Gen™ test was clinically validated in a nested case-control cohort study. The study included 1,664 women from the US Women's Health Initiative (WHI) who developed breast cancer between randomization and study completion and 1,636 age-matched breast cancer-free controls (Mealiffe, Stokowski et al. 2010). Overall, the study suggests that the BREVA Gen may add predictive accuracy to the Gail Model, however, the degree of improved risk prediction is modest and the clinical implications are not well established. The study is not generalizable as the included population was limited to postmenopausal white non-Hispanic women. In addition, four of the authors were employees of the developer of the BREVA Gen™ during the time of publication and the analyses were relevant to the development of the product. Ideally, additional studies should be completed to further assess the clinical validity of the combined Gail and SNP risk model. *Clinical Utility* Theoretically, the BREVA Gen™ test can provide information that can help guide physicians in making individualized patient management decisions, such as appropriate counseling, screening regimens and risk reduction strategies, however, there is no published literature to support the clinical utility. *Conclusion:* There is no evidence to determine the analytic validity of the BREVA Gen™. There is some evidence to suggest that the addition of the BREVA Gen™ panel is superior in determining breast cancer risk compared to Gail score alone. There is no evidence to determine the clinical utility of the BREVA Gen™.

**Articles:** A search of PubMed was completed for the period through November 2013 for studies on the accuracy of BREVA Gen™ for detecting the absence or presence of certain common genetic variations associated with an increased risk for developing breast cancer. The search strategy used the terms BREVA Gen, Breast Cancer Risk Tool, Gail Model, genetic risk, single nucleotide polymorphism, breast cancer, and sporadic with variations. To identify ongoing clinical trials, a search of the National Institute of Health Clinical Trials website was also conducted using the same methodology. Articles were limited to those published in the English language with human subject enrollment. The search was supplemented by an examination of article reference lists in addition to the PubMed related articles function. The literature search for BREVA Gen™ revealed one publication that clinically validates the Breast Cancer Risk Model in combination with the genetic and clinical information. The following study was selected for review: Mealiffe ME, Stokowski RP, Rhees BK, et al. Assessment of clinical validity of a breast cancer risk model combining genetic and clinical information. *Journal of the National Cancer Institute*. 2010;102(21):1618-1627. [See Evidence Table](#).

The use of BREVA Gen does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Fibroblast Growth Factor Receptor 3 (FGFR3) for Urothelial Carcinoma**

#### BACKGROUND

It is estimated that approximately 70,530 new cases of bladder cancer will be diagnosed in the United States in 2010, and 14,680 will die of the disease (Jemal 2010). The most commonly occurring form of bladder cancer in the United States is urothelial carcinoma (also known as transitional cell carcinoma). The clinical spectrum of urothelial carcinoma can be divided into 3 categories: non-muscle-invasive, muscle-invasive, and metastatic disease. This review will focus on non-muscle-invasive urothelial cancer (NMIUC), which makes up approximately 75-80% of urothelial carcinoma. NMIUC includes stage Ta (noninvasive papillary carcinoma), Tis (carcinoma in situ), and T1 (tumor invades subepithelial connective tissue) tumors. The standard treatment for stage Ta, Tis, and T1 tumors is transurethral resection of bladder tumor (TURBT). Depending on prognosis adjuvant intravesical chemotherapy or immunotherapy may also be considered. However, despite treatment a significant number of patients will develop recurrence within 1 to 2 years of the initial treatment. Because of the high risk of recurrence careful surveillance is required for patients with NMIUC (Chou 2010, Cheng 2011, NCCN 2011, Pollard 2010). Assessing the risk of progression and recurrence is important for planning therapy. The risk for tumor progression and recurrence is estimated using factors such as histological grade, stage, depth of invasion, and extent of disease; however, the ability of these factors to predict clinical outcome is limited (Burger 2008, Cheng 2011, NCCN 2011). Recently, it has been suggested that molecular biomarkers such as fibroblast growth factor receptor 3 (FGFR3) may be useful for predicting clinical outcome and planning therapy. FGFR3 regulates cell growth,

differentiation, and angiogenesis. More than 70% of low-grade noninvasive papillary urothelial carcinomas harbor FGFR3 mutations. Studies suggest that urothelial carcinomas that harbor FGFR3 mutations may be associated with improved prognosis (Cheng 2011). The CertNDx molecular grading assay (Predictive Biosciences, Inc.) was designed as a tool to be used in conjunction with clinical and histological parameters to aid in the clinical management of NMIUC. This test uses two biomarkers to determine molecular grade. The first biomarker is FGFR3 and the second is Ki-67, which is a marker of cell proliferation (Cheng 2011). Patients with molecular grade 1 (mG1) have FGFR3 mutations and low Ki-67 levels. Patients with molecular grade 2 (mG2) have FGFR3 mutations with high Ki-67 levels or wild-type FGFR3 and low Ki-67 levels. Patients with molecular grade 3 (mG3) are FGFR3 wild-type and have high Ki-67 levels. Patients with molecular grade 1 have favorable prognosis, patients with molecular grade 2 have intermediate prognosis, and patients with molecular grade 3 have poor prognosis.

#### **10/17/2011: MTAC REVIEW**

#### **Fibroblast Growth Factor Receptor 3 (FGFR3) for Urothelial Carcinoma**

**Evidence Conclusion:** Analytic validity- No studies were identified that addressed the analytic validity of the CertNDx molecular grading assay. Clinical validity - A recent prospective observational study evaluated the prognostic value of both WHO 1973 and 2004 grading systems, markers CK20, FGFR3, and Ki-67, and molecular grade (combination of FGFR3 and Ki-67) in 221 patients with urothelial carcinoma. In univariate analysis, WHO grade 1973, WHO grade 2004, pathological stage, FGFR3, Ki-67 status, and molecular grade were significantly associated with progression in stage; however, in a multivariate model, only WHO grade 1973 and 2004 remained significantly associated with progression in stage. None of the variables measured were significantly associated with recurrence-free survival (Burger 2008). Another study that included 255 patients with primary urothelial carcinoma also found that the combination of FGFR3 and Ki-67 status was not an independent predictor of recurrence-free or disease-specific survival (van Oers 2007). However, an observational study that included 286 patients with urothelial carcinoma found that in a multivariate analysis, the combination of FGFR3 and Ki-67 status predicted progression, recurrence rate, and disease-specific survival (van Rhijn 2003). Clinical utility - No studies were identified that addressed the clinical utility of the CertNDx molecular grading assay. Conclusion: Analytic validity: No studies were identified that addressed the analytic validity of the CertNDx molecular grading assay. Clinical validity: Results from observational studies regarding the prognostic value of molecular grade (FGFR3/Ki-67) are mixed. Clinical utility: No studies were identified that addressed the clinical utility of the CertNDx molecular grading assay.

**Articles:** No studies were identified that addressed the analytic validity or clinical utility of the CertNDx molecular grading assay. Several studies were identified that evaluated the clinical validity of the CertNDx molecular grading assay. The most recent study was selected for review. The following study was critically appraised: Burger M, van der Aa MN, van Oers JM, et al. Prediction of progression of non-muscle-invasive bladder cancer by WHO 1973 and 2004 grading and by FGFR3 mutation status: a prospective study. *Eur Urol.* 2008;54:835-843. See [Evidence Table](#).

The use of FGFR3 for urothelial carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **MammaPrint Test**

##### **BACKGROUND**

Breast cancer affects almost 10% of women in western countries and is a major cause of morbidity and mortality. Most patients with lymph node negative disease may be successfully treated with surgery and local irradiation. Those with more aggressive disease may benefit from adjuvant chemotherapy and hormone therapy which could significantly improve their overall and disease-free survival. It is generally accepted that breast cancer patients with the poorer prognosis would gain the most benefits from systemic adjuvant therapy. The use of this adjuvant therapy is thus one of the most critical treatment decisions during the clinical management of breast cancer patients. Currently those with aggressive breast cancer are identified according to a combination of criteria including age, clinical stage and size of the tumor, histological type and grade of cancer, axillary node status, and hormone-receptor status. The ability of these criteria to predict outcome and disease progression is imperfect. Within a given patient population at a specific predicted risk of recurrence, there are some patients whose actual clinical outcome does not match that predicted by the indicators. As a result some of those who need adjuvant therapy do not receive it, while others may receive unnecessary toxic therapy (Kallioniemi 2002, DeVigier 2002). To overcome these issues, scientists are attempting to identify more accurate prognostic indicators. Microarray technology is revolutionizing researchers' understanding of cancer biology through the simultaneous study of the expression of tens of thousands of genes. Molecular profiling is the classification of tissue or other specimens for diagnostic, prognostic, and predictive purposes based on multiple gene expression. The potential value of gene expression profiling in assessing the risk of post-surgical breast cancer recurrence has been extensively investigated over the last few years. This has led to important insights in the molecular heterogeneity of cancers by

revealing biologically and clinically relevant subtypes of tumors previously indistinguishable by the conventional approaches (Bertucci 2005). Due to the biological heterogeneity of breast cancers, women with the same stage of the disease may vary widely in their response to treatment and prognosis. Several gene expression-based predictors for breast cancer have been developed, but have not been used in routine clinical practice. According to researchers, this is mainly due to the limited validation and the limited clinical description of the molecular subtypes. Validation is a major challenge for microarray studies especially those with clinical implications as it requires a large sample size and because the results are influenced by the patient selection and by choice of the methods used to analyze gene expression data (Calza 2006, Hu 2006, Ioannidis 2007). The Amsterdam 70-gene profile (MammaPrint®) was first developed using supervised gene expression profiling analysis of frozen tumor samples from two distinct patient populations. All were <55 years of age, and had lymph node negative disease. 44% had distant metastases within 5 years of completing treatment and 56% did not. By comparing the gene expression profile of patients with or without metastases, a signature 70-gene set that correlated with the outcome was identified and internally validated with the same group (van't Veer 2002), and externally validated in two retrospective groups (Van De Vijver 2002 and Buyse 2006, see evidence tables). MammaPrint® from Agendia is a qualitative in vitro diagnostic test service performed in a single laboratory using the gene expression profile of breast cancer tissue samples to assess a patient's risk for distant metastases. The MammaPrint assay uses a panel of the Amsterdam 70-gene profile described above. It is a microarray based gene expression analysis of RNA extracted from breast tumor tissue. The MammaPrint® analysis is designed to determine the activity of specific genes in a tissue sample compared to a reference standard. Its index ranges from -1.0 to +1.0. Tumor samples with an index above the threshold of +0.4 are classified as low risk, and those with an index equal to or less than the threshold are classified as high risk. The test requires fresh frozen samples which are shipped to the Agendia reference laboratory in the Netherlands. It is performed for breast cancer patients <61 years old, with Stage I invasive breast cancer or Stage II node negative invasive breast cancer, with tumor size <5 cm. It is indicated for use by physicians as a prognostic marker only, along with other clinicopathological factors. It is not intended for diagnosis, or for predicting or detecting response to therapy, or to help select the optimal therapy for patients (FDA).

#### **08/06/2007: MTAC REVIEW**

##### **MammaPrint Test**

**Evidence Conclusion:** The identification and validation of gene expression panels to improve risk prediction or treatment outcomes is a multistep process that starts by 1. Identifying the candidate genes (analytic validity), followed by 2. Evaluating the genetic panel associations with risk prediction or treatment outcomes in preliminary performance studies in relevant population (clinical validity), and 3. Determining whether the use of the multigenetic assay would direct the management of patients and improve outcomes (clinical utility). The most reliable method for validation is to derive a prognostic/predictive gene set from a training set and then apply it to a completely independent set, the test set, (Simon 2003, Ioannidis 2006, and Hu 2006). The MammaPrint test was developed based on research performed in the Netherlands Cancer Institute, The training set was derived from a study by van't Veer and colleagues that included 98 women < 55 years of age at diagnosis, with primary breast cancer (34 developed distant metastases within 5 years, 44 were disease free after at least 5 years). All patients were lymph node negative. 5 µg total RNA was isolated from frozen tumor material for each patient. The authors used inkjet-synthesized oligonucleotide microarrays that included 25,000 genes. Following several techniques 5000 genes were selected from the microarray, and then optimized to 70 genes with which a prognosis profile was established. The authors conducted a cross validation and concluded that a classification system based on these 70 genes outperformed all clinical variables in predicting the likelihood of distant metastases within five years. They noted however, that a selection of the patients based on the outcome (distant metastases or disease free in 5 years) was a limitation to the study. The same research team followed the initial study with a validation study (Van De Vijver, 2002) that included 295 women with either lymph node negative or lymph node positive breast cancer. The authors calculated the correlation coefficient of the level of expression of the 70- predictor genes identified in their initial study. They then classified the women with a correlation coefficient > 0.4 as having a good prognosis gene expression signature, and all the others as having a poor prognosis gene expression signature. In this validation set however the authors included 61 patients from the original training group used to derive the RNA expression signature, which could overestimate the relative risk and inflate the discriminating power of the test. The validation study included women < 55 years of age, with small tumors and at stage I or II of the disease which may not represent the entire spectrum of patients with breast cancer. Adjuvant hormone therapy or chemotherapy or both were given to most of the patients with lymph node positive disease. The Translational Research Network of the Breast International group (TRANSBIG) also conducted an independent validation study of the prognostic signatures in a retrospective series of 302 untreated patients in five European countries. The study included only women node negative early stage breast cancer who had not received systemic adjuvant therapy, and thus may not represent the all patients with breast cancer. Its overall results showed that the 70-gene signature provided prognostic information on time to distant metastases and overall survival independent of the other clinical predictors. In conclusion, the selection of the 70- predictor genes was based on analyses of tumors from patients

< 55 years of age with lymph node negative cancer who do not represent all women with breast cancer. The test proved to perform well as an independent prediction tool among the selected women studied. This however, does not necessarily indicate that it would predict treatment response. To date there are no published studies that show if modification of adjuvant therapy based on this test would improve disease free or overall survival. A large randomized controlled trial (Microarray for Node negative Disease may Avoid Chemotherapy [MINDACT]) that will evaluate the clinical utility of MammaPrint is underway. The trial will directly compare the use of prognostic information provided by the standard clinicopathological criteria vs. the MammaPrint test to decide whether to offer adjuvant chemotherapy to node-negative breast cancer patients. The MINDACT plans to prospectively include 6000 women, and follow-them up for a long duration in order to determine 5-year disease free-survival rate.

**Articles:** The literature search revealed multiple articles on molecular and gene-expression profiling in general. For the MammaPrint test in particular, there was a published study on the training set (to develop or derive the predictive classifier or model) by Van't Veer and colleagues, and three validation studies to evaluate the predictive accuracy of the model (Van De Vijver 2002, Buyse 2006, and Glas 2006). All studies were reviewed but only the first two validation studies were critically appraised, Glas, et al's study was not selected for critical appraisal due to patient overlap with the van De Vijver study. It is to be noted that Van De Vijver, van't Veer, and several other principal authors are named inventors on a patent application for the 70-gene signature used in the studies. All studies also had financial ties to the manufacturer. *The following studies were critically appraised:*

Van De Vijver MJ, He YD, van't Veer LJ, et al. A gene expression signature as a predictor of survival in breast cancer. *N Engl J Med* 2002;347:1999-2009. See [Evidence Table](#). Buyse M, van't Veer, L, Viale G et al on behalf of the TRANSBIG Consortium. Validation and clinical utility of a 70-gene prognostic signature for women with node negative breast cancer. *J Natl Cancer Inst* 2006;98:1183-1192. See [Evidence Table](#).

The use of the MammaPrint test in the treatment of recurring cancer does not meet the *Group Health Medical Technology Assessment Criteria*.

## **OVA1™ Test for the Assessment of Suspected Ovarian Cancer**

### **BACKGROUND**

In the United States, ovarian cancer is the fifth leading cause of all cancer-related death among women. It is estimated that in 2010, there were 21,880 new cases of ovarian cancer and 13,850 deaths from ovarian cancer (Jemal 2010). The incidence of ovarian cancer increases with age with approximately two thirds of cases being diagnosed in women over the age of 55. Women with a family history of ovarian or breast cancer or who are carriers of the BRCA gene mutations are also at increased risk for ovarian cancer (Clarke-Pearson 2009). For patients with early stage disease, survival rates are greater than 90%; however, they are less than 30% for patients with advanced disease. Because of the lack of specific symptoms during the early stage approximately 70% of cases are diagnosed with advanced disease (Carter 2011). The most commonly used tests for the detection of ovarian cancer are transvaginal ultrasound (TVS) and serum CA-125. Recently, the FDA approved the OVA1™ test (Quest Diagnostics, Inc.) to be used as an adjunct to clinical/radiological evaluations for women planning surgery for an adnexal mass. This test measures the serum levels of 5 potential biochemical markers for ovarian cancer (transthyretin, apolipoprotein A1, transferrin, CA-125, and  $\beta$ 2-microglobulin). The results of the test are then interpreted using a proprietary algorithm to yield a single score ranging from 0 to 10 to indicate the likelihood that the adnexal mass is benign or malignant. A high probability for malignancy is defined as a score of at least 5.0 in premenopausal women or 4.4 in postmenopausal women. The goal of the OVA1™ test is to provide additional information to aid in identifying patients who should be referred to a gynecologic oncologist for surgery (Carter 2011, Muller 2010). Studies suggest that women who receive their initial surgical care from an experienced gynecologic oncologist have improved outcomes and greater overall survival. Because of this the National Comprehensive Cancer Network (NCCN) recommends that all patients should undergo surgery by an experienced gynecologic oncologist (NCCN 2011). It is important to emphasize that this test is not approved for ovarian cancer screening and is not intended for use as a stand alone test. Another limitation of this test is that assay interference may occur in patients with rheumatoid factor levels of at least 250 IU/mL and triglyceride levels greater than 4.5 g/L (Muller 2010). In 2009, the FDA approved the use of this test for women over the age of 18 with an ovarian adnexal mass for which surgery is planned and have not yet been referred to an oncologist.

### **10/17/2011: MTAC REVIEW**

#### **OVA1™ Test for the Assessment of Suspected Ovarian Cancer**

**Evidence Conclusion:** *Analytic validity* - No studies were identified that evaluated the analytic validity of the OVA1™ test. *Clinical validity* - A recent observational study that included 524 women with ovarian tumors who were planning to undergo surgery compared the sensitivity and specificity of physician assessment alone (which included the use of CA 125) or combined with the OVA1™ test for identifying ovarian tumors at high risk for malignancy. Results from this study suggest that the addition of the OVA1™ test to physician assessment increased the sensitivity and the negative predictive value, but decreased the specificity and the positive predictive value (Ueland 2011). The performance of the American College of Obstetricians and Gynecologists (ACOG)

referral guideline for women with a pelvic mass and the effect of replacing CA 125 with the OVA1™ test was also evaluated in this study population. The substitution of CA 125 for the OVA1™ test increased the sensitivity and the negative predictive value of the ACOG guidelines, but decreased the specificity and the positive predictive value (Miller 2011). *Clinical utility* - No studies were identified that evaluated the clinical utility of the OVA1™ test. *Conclusion: Analytic validity:* No studies were identified that evaluated analytic validity of the OVA1™ test. *Clinical validity:* Results from a recent observational study suggest that when added to physician assessment or substituted for CA 125, the OVA1™ test increased the sensitivity and negative predictive value of these assessments, but decrease the specificity and positive predictive value. *Clinical utility:* No studies were identified that evaluated the clinical utility of the OVA1™ test.

**Articles:** No studies were identified that assessed the analytic validity or clinical utility of the OVA1™ test. Two studies were identified that addressed the clinical validity of the OVA1™ test. Both of these studies were selected for review. The following studies were selected for critical appraisal: Ueland FR, Desimone CP, Seamon LG, et al. Effectiveness of a multivariate index assay in the preoperative assessment of ovarian tumors. *Obstet Gynecol* 2011; 117:1289-1297. See [Evidence Table](#). Ware Miller R, Smith A, DeSimone CP, et al. Performance of the American College of Obstetricians and Gynecologists' ovarian tumor referral guidelines with a multivariate index assay. *Obstet Gynecol.* 2011;117:1298-1306. See [Evidence Table](#).

The use of OVA1 for ovarian tumors does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Robotic Assisted Surgeries (RAS)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	The use of robotic surgical systems will not be separately reimbursed. Per Medicare Guidelines, the procedure itself only qualifies for reimbursement. See <a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	None

##### For Non-Medicare Members

Robotic Assisted Surgery is a covered benefit without medical review when the underlying surgery is covered.

[Please refer to Group Health payment policy for reimbursement clarifications.](#)

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Robotic assisted surgery involves use of a computerized system operated by a surgeon at a computer console connected with robotic arms. The system is used to assist in laparoscopic surgical procedures. Robotic assisted surgery may allow for finer more precise control of the instruments by the surgeon, though surgery may take longer. Laparoscopic surgery is associated with improved postsurgical pain and recovery and with lower risk of infection and blood loss for some procedures compared with open surgery.

In 2000, the da Vinci robot was approved by the Food and Drug Administration (FDA) for general laparoscopic surgery. Numerous other indications for the da Vinci system have since been approved by the FDA, including urological procedures, gynecologic laparoscopic procedures, general thoracoscopic procedures, and others. In 2007, the American Medical Association determined that an additional CPT code for robotic-assisted procedures was not necessary.

Robotic assisted surgery has been used in the following procedures:

Prostatectomy; Hysterectomy; Nephrectomy; Cardiac Surgery; Adjustable Gastric Band; Adnexectomy; Adrenalectomy; Cholecystectomy; Colorectal Surgery (Colorectal Resection, Colectomy, Mesorectal Excision); Cystectomy; Esophagectomy; Fallopian Tube Reanastomosis; Fundoplication; Gastrectomy; Heller Myotomy; Ileovesicostomy; Liver Resection; Lung Surgery; Myomectomy; Oropharyngeal Surgery; Pancreatectomy; Pyeloplasty; Rectopexy; Roux-en-Y Gastric Bypass; Sacrocolpopexy; Splenectomy; Thymectomy; Thyroidectomy; Trachelectomy; and Vesico-vaginal Fistula.

In March 2013, the American Congress of Obstetricians and Gynecologists released a statement that said in part, "There is no good data proving that robotic hysterectomy is even as good as—let alone better—than existing, and far less costly, minimally invasive alternatives."

The Health Care Authority in Washington State conducted an evidence review for each procedure listed above and found the evidence to be minimal in most cases. The outcome of their review was to not pay additionally for the use of the robotic device use.

## Clinical Review Criteria

### Seat Lift Chair (Mechanism Only)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

National Coverage Determination (NCD)

[Seat Lift \(280.4\)](#)

Local Coverage Determination (LCD)

[Seat Lift Mechanism \(L33801\)](#)

##### For Non-Medicare Members

- I. A seat lift mechanism is covered if **All of the following** criteria are met:
  - A. Has DME benefit
  - B. The patient must have severe arthritis of the hip or knee or have a severe neuromuscular disease.
  - C. The seat lift mechanism must be a part of the physician's course of treatment and be prescribed to effect improvement, or arrest or retard deterioration in the patient's condition.
  - D. The patient must be completely incapable of standing up from a regular armchair or any chair in their home. (The fact that a patient has difficulty or is even incapable of getting up from a chair, particularly a low chair, is not sufficient justification for a seat lift mechanism. Almost all patients who are capable of ambulating can get out of an ordinary chair if the seat height is appropriate and the chair has arms.)
  - E. Once standing, the patient must have the ability to ambulate.
- II. Coverage of seat lift mechanisms is limited to those types which operate smoothly, can be controlled by the patient, and effectively assist a patient in standing up and sitting down without other assistance. Excluded from coverage is the type of lift which operates by a spring release mechanism with a sudden, catapult-like motion and jolts the patient from a seated to a standing position.
- III. Coverage is limited to the seat lift mechanism, even if it is incorporated into a chair (E0627). Payment for a seat lift mechanism incorporated into a chair (E0627) is based on the allowance for the least costly alternative (E0628, E0629).
- IV. The physician ordering the seat lift mechanism must be the treating physician or a consulting physician for the disease or condition resulting in the need for a seat lift. The physician's record must document that all appropriate therapeutic modalities (e.g., medication, physical therapy) to enable the patient to transfer from a chair to a standing position have been tried and failed.

This criteria set is not applicable to seat lift mechanisms for wheelchairs. Please see the [wheelchair criteria](#).

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The seat-lift mechanism is a device that is installed in a chair to help the patient to stand when they are unable to do so from a low chair that has arm rests to support the patient to a standing position. It should be one of those devices that operates smoothly, can be controlled by the patient, and effectively assists a patient standing up and sitting down without assistance.

## Clinical Review Criteria

### Sensory Integration Therapy (SIT)

- For children with developmental and behavioral disorders

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The sensory integration (SI) framework was first described by an occupational therapist Jean Ayres, PhD, in the early 1970s and refers to the body's way of handling and processing sensory inputs from the environment. This was based on a theory that the sensory system develops over time just like other higher order learning skills (such as cognition, language, and academic performance) and that deficits can occur in the process of developing a well-organized sensory system. A well-organized sensory system can integrate input from multiple sources primarily the three basic senses: vestibular, proprioceptive, and tactile. The vestibular system responds to gravity and movement, and the proprioceptive system receives inputs from joints and muscles. When these systems interact with the tactile sensation, sensory integration takes place. Normally, effective sensory integration occurs automatically, unconsciously, and without effort, but for some children it does not develop as efficiently as it should. Any dysfunction or disorder in the SI process may lead to problems in learning, response to sensory input, behavior, or motor development. According to Ayres' theory these could be manifested as coordination problems; unusually high or low activity level; delays in speech, language, or motor skills; delays in academic achievements; under-reactivity to sensory stimulation; sensitivity to touch, movements, sounds, or sights; poor organization of behavior; lack of self-control; poor self-concept; and other signs and symptoms (Ayres 1972, 1977).

Based on her theory, Ayres developed the sensory integration therapy (SIT) with the goal of improving the way the brain processes and adapts to sensory information, as opposed to teaching specific skills. The therapy involves activities that are believed to organize the sensory system by providing vestibular, proprioceptive, and tactile sensory input. Techniques used include vestibular stimulation such as swinging in a hammock, using swing balls, bounce pads or scooter boards; tactile stimulation achieved by brushing parts of the child's body or the use of weighted vests and other clothing (Ayres 1977).

Since that sensory integration dysfunction was described, sensory-based therapies have been increasingly used by occupational therapists and other health professionals to treat children with a range of symptoms and disabilities including autism, attention deficit hyperactivity disorder, fragile-x syndrome, brain injuries and others (Zimmer 2014). SIT is usually provided by certified therapists with special training and mentorship in the theory, techniques, and assessment tools unique to sensory integration theory. It is delivered in one-on-one sessions

individualized to the child, one to three times a week, for several months or years. In these therapy sessions, the therapists combine primitive forms of sensation with motor activities according to a manualized protocol (Schaaf 2014).

Some authors distinguish sensory integration therapy from sensory-based interventions (SBIs) which are adult-directed sensory strategies that are applied to the child, most often in the school environment, to improve behaviors associated with modulation disorders. SBIs require less engagement of the child and are integrated into his/her daily routine to improve behavioral regulation (Case-Smith 2014).

SIT is controversial and a topic for debate by many professionals in medicine, psychology, and education (May-Benson 2010). According to a Policy Statement from the American Academy of Pediatrics on SIT (Zimmer et al, 2012) proponents of SI theory believe that inappropriate or deficient sensory processing is a developmental disorder responsive to therapy and that treatment can improve developmental outcomes. A definition of sensory processing disorder has been proposed, but is not universally accepted. Standardized measures such as the Sensory Profile have been developed to classify a child's sensory deficit. However, the possible diagnosis of a sensory processing disorder remains a challenging clinical issue, and it is unclear whether children who present with findings described as sensory processing difficulties have an actual disorder of the sensory pathway of the brain or that the deficits observed are associated with other developmental and behavioral disorders. The symptoms described in children with sensory processing disorders, overlap the behavioral differences seen in children with autism spectrum disorders, attention-deficit hyperactivity disorder, and developmental coordination disorders. Evaluating the effectiveness of sensory integration therapy presents another challenge due to the wide spectrum of symptom severity and presentation of the disorder, variations in response due to several factors, and lack of consistent outcome measures (Zimmer 2012).

SIT is a therapy and thus it is not regulated by the FDA. SIT has been reviewed by MTAC earlier in 2005 and did not meet the committee's evaluation criteria. It is being re-reviewed based on requests for its coverage.

## Medical Technology Assessment Committee (MTAC)

### **Sensory Integration Therapy**

#### **11/28/2005: MTAC REVIEW**

**Evidence Conclusion:** The results of Vargus' (1999) meta-analysis show that sensory integration therapy was not more effective than other alternative therapies in improving psychoeducational, behavior, language, motor, and sensory perceptual functions among the groups studied. The studies included in the meta-analysis did not provide sufficient data on the ages of participants, the types of disabilities, or details on therapies provided. There were also variations and differences in the characteristics of the participants, intervention methods, hours of therapy received, ratio of therapists to children, evaluation of the therapy, duration between therapy and re-testing, and outcomes measured. The authors of the meta-analysis were thus unable to determine the effect of sensory integration therapy among different ages or among individuals with different types of disabilities.

Humphries and colleagues (1992) compared sensory integrative therapy among children with learning disabilities and sensory integration dysfunction to another active treatment (perceptual-motor training), and to no treatment. There were some significant baseline differences between the study groups, and both the sensory integrative therapy and the perceptual-motor therapy were performed by the same occupational therapists, which may be a potential source of bias. Their results show significant pretest-posttest differences between the three groups in the motor functions but not in the psychoeducational variables. The difference in the motor performance between the two active therapies was statistically insignificant. In conclusion, the current literature does not provide a clear definition or description of the sensory integration therapy, and does not provide evidence that the therapy is more effective than an alternative therapy or no treatment for children with learning disabilities, or neurodevelopmental delay.

**Articles:** The search yielded 126 publications, the majority of which were review articles. There were four systematic reviews; two meta-analyses: Ottenbacher 1982 and Vargus 1998; an article combining the results of only two studies (Kaplan 1993); and a number of controlled trials. Many of the studies revealed by the search were conducted in the 1970s and 1980s, their sample sizes varied from 10 to 92 participants, and the majority were poorly controlled. The search on the use of sensory integration therapy for autistic children revealed one small case series with 10 children. The most recent meta-analysis and a randomized controlled trial (RCT) were critically appraised. The RCT selected was included in the meta-analysis but was reviewed, as it was the largest trial identified and had a relatively better quality design. *Evidence tables were made for the following studies:* Vargas S, Camilli G. A meta-analysis of research on sensory integration treatment. *Am J Occup Ther.* 1999;53:198-198. See [Evidence Table 1](#). Humphries T, Wright M, Snider L, McDougal B. A comparison of the effectiveness of sensory integrative therapy and perceptual-motor training in treating children with learning disabilities. *J Dev Behav Pediatr.* 1992;13:31-40. See [Evidence Table 1](#).

The use of Sensory integration therapy in the treatment of neuro-developmentally delayed children does not meet the *Group Health Medical Technology Assessment Criteria*.

## 12/06/2015: MTAC REVIEW

### Sensory Integration Therapy

**Evidence Conclusion:** The results of the meta-analysis (Vargus, et al, 1999) reviewed earlier for MTAC suggested that the benefits of sensory integration therapy on psychoeducational and motor functions was significantly better than no treatment among the individuals studied, but it was not superior to other alternative treatments. The authors cautioned about interpreting the results and concluded that there was insufficient evidence to determine the effectiveness of the SI approach. The search for more recent evidence after that last review identified a pilot trial that investigated the effectiveness of SI interventions in children with autism spectrum disorders, a RCT that compared SIT to usual care in children with autism, and a larger RCT that compared SIT to two other active treatments and a control among children with mild mental retardation. Schaaf and colleagues, 2014 (Evidence table 1), randomly assigned 32 children aged 4-8 years, with autism and sensory difficulties to either an occupational therapy/sensory intervention (OT/SI) group or a control group. The study was randomised, and controlled, with proper randomization procedure, and power analysis. However, it was very small and parents who rated their child's goals and other outcomes were not blinded to the treatment allocation, which is a source of bias. In addition the OT/SI was not compared to an alternative occupational therapy with the same intensity and duration of intervention. The overall results showed significant positive improvement in Goal Attainment Scores (GAS) in the two study groups, but children in the OT/SI group scored significantly higher than the controls. The only other statistically significant differences between the two groups were for the less care-giver assistance during self-care, and social activities observed in the treatment group. There were no statistically significant differences between the study groups in adaptive behaviors. The authors concluded that the results of the study provide preliminary support for the efficacy of manualized SI intervention. They however, noted that the results should be interpreted with caution until they are replicated in future larger studies. Pfeiffer and colleagues, 2011 (Evidence table 2), conducted a pilot trial to identify appropriate outcome measures, and address the effectiveness of sensory integration (SI) interventions in children with autism spectrum disorders (ASD). They randomized 37 children with ASD, 6-12 year of age to undergo either a fine motor (FM) or sensory integration therapy. Pretests and posttests measured social responsiveness, sensory processing, functional motor skills, and social-emotional factors. The study was randomized, controlled, and blinded. However, it was a small pilot trial with no power analysis or follow-up after the therapy ended. Its overall results showed significant positive improvement in GAS in the two study groups. Children in the SIT group had more significant changes in GAS and improvement in mannerism vs. those in the FM group. The differences in the other outcomes were statistically insignificant. The authors discussed limitations to the study and suggestions for future studies. They explained that standardized measures for determining progress are often inappropriate for children on the autistic spectrum because of the wide variety in behavior and developmental levels among the children, and their ability to complete the test while maintaining its validity. The authors also indicated that another challenge for using a standardized measure is the fact that the SIT forms, activities, and goals are individualized to the specific needs of each child, resulting in a wide range of goals and outcomes among the participants within a study. Wuang and colleagues, 2009 (Evidence table 3) compared the effect of SIT, neurodevelopmental treatment (NDT), and perceptual-motor (PM) approach, and no treatment in 160 children 7-8 years of age with mild mental retardation. 120 were randomly assigned to one of the three active treatments and 40 children who fulfilled the inclusion criteria but could not attend the sessions because of its timing, were not randomized, did not receive any intervention during the study period, but were used as controls.

Each of the active interventions was delivered in a 1-hr. session 3 days per week for 40 weeks, and the children were assessed with measures of sensorimotor function at baseline and after completion of the study. The results show that postintervention, the active treatment groups significantly outperformed the control group on almost all measures. The SIT group demonstrated a greater pretest-posttest change on fine motor, upper-limb coordination, and SI functioning. The PM group showed significant gains in gross motor skills, whereas the NDT group had the smallest change in most measures. The study had its advantages and limitations discussed in evidence table 3. Among the limitations is the inclusion of a selected group of patients, non-adjusting for confounding factors, and a lack of long-term follow-up. The authors recommended that the results be replicated in more studies with long-term follow-up. A 2012 Policy Statement by the American Academy of Pediatrics on sensory integration therapies for children with developmental and behavioral disorders states that is unclear whether children who present with sensory-based problems have an actual "disorder" of the sensory pathways of the brain or whether these deficits are characteristics associated with other developmental and behavioral disorders. Because there is no universally accepted framework for diagnosis, sensory processing disorder generally should not be diagnosed. Other developmental and behavioral disorders must always be considered, and a thorough evaluation should be completed. Difficulty tolerating or processing sensory information is a characteristic that may be seen in many developmental behavioral disorders, including autism spectrum disorders, attention-deficit/hyperactivity disorder,

developmental coordination disorders, and childhood anxiety disorders. Occupational therapy with the use of sensory-based therapies may be acceptable as one of the components of a comprehensive treatment plan. However, parents should be informed that the amount of research regarding the effectiveness of sensory integration therapy is limited and inconclusive. Important roles for pediatricians and other clinicians may include discussing these limitations with parents, talking with families about a trial period of sensory integration therapy, and teaching families how to evaluate the effectiveness of a therapy (Zimmer 2012). **Conclusion:** The evidence remains insufficient to support the effectiveness of sensory integration therapy in improving the behaviors and functional skills in children with developmental and/or behavioral disorders. Due to the individual nature of SIT and the large variation in individual therapists and patients, large multicenter randomized controlled trials among a more diverse population, with blinded assessment, and long-term follow-up are needed to determine the effectiveness the efficacy of this therapy and durability of outcomes.

**Articles:** The search for studies published after the 2005 MTAC review, revealed over 150 publications, the majority of which were unrelated to the current review. There were three systematic reviews without meta-analyses, two small RCTs among children with autism spectrum disorders (ASD), one quasi-randomized trial among children with mild mental retardation, a number of small non-randomized comparative studies, observational studies with no controls, case series, and case reports on sensory integration therapy for children. The three randomized controlled trials were selected for critical appraisal. Pfeiffer BA, Koenig K, Kinnealey M, et al. Effectiveness of sensory integration interventions in children with autism spectrum disorders: a pilot study. *Am J Occup Ther.* 2011 Jan-Feb; 65(1):76-85. See [Evidence Table 1](#). Schaaf RC, Benevides T, Mailloux Z, et al. An intervention for sensory difficulties in children with autism: a randomized trial. *J Autism Dev Disord.* 2014 Jul; 44(7):1493-506. See [Evidence Table 2](#). Wuang YP, Wang CC, Huang MH, et al. Prospective study of the effect of sensory integration, neurodevelopmental treatment, and perceptual-motor therapy on the sensorimotor performance in children with mild mental retardation. *Am J Occup Ther.* 2009 Jul-Aug; 63(4):441-452. See [Evidence Table 3](#).

The use of Sensory Integration Therapy does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Serum Biomarker Tests for Multiple Sclerosis

- gMS®Dx Testing
- gMS®Pro EDSS Testing

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Cytogenetic Studies (190.3)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Multiple sclerosis (MS) is a chronic illness of the central nervous system. Diagnosis of MS can be very difficult as there are no clinical findings that are unique to MS. The revised McDonald's Criteria, which incorporated clinical, radiologic, and laboratory findings are often used to diagnose MS. However, because the use of these criteria frequently results in delayed diagnosis, researchers have been trying to find reliable biomarkers that would help to establish a diagnosis (Harris 2009).

The **gMS®Dx test**, a new blood based test for MS biomarkers, was developed by Glycominds to help physicians identify patients with a high probability of developing MS. The biomarker used in the gMS®Dx test is based on IgM antibodies against the a-glucose antigen (GAGA4). The test is designed to be used in patients as a part of the MS diagnostic work-up and is recommended for use in suspected MS patients for which the diagnosis of MS has not yet been confirmed. The results of the test are reported as negative (patient may still have MS or other neurological disease, continue with routine testing), positive (patient has a high likelihood of having MS), high positive (patient has a very high likelihood of having MS) (Glycominds 2012). One advantage of the gMS®Dx test is that blood samples are relatively easy to obtain and are minimally invasive. A limitation of using biomarkers for diagnosing MS is that they may be affected by other systematic events such as viral infections (Harris 2009). An additional limitation of the gMS®Dx test is that the biologic basis for the MS biomarker is unclear (Freeman 2009).

Multiple sclerosis (MS) is a complex disease with heterogeneous clinical presentation and disease course. Because prognosis is so hard to predict there has been interest in identifying biomarkers that are associated with disease progression (Harris 2009).

Glycominds has developed the **gMS®Pro EDSS test**, a blood based test that uses biomarkers to identify patients at high risk for severe disease progression. The biomarkers used in the gMS®Pro EDSS test are based on IgM antibodies against the a-glucose antigen (GAGA2, GAGA3, GAGA4, GAGA6). The aim of this test is to help clinicians choose the most appropriate disease treatment. The test is designed for use in patients at their first episode and for patients with relapse-remitting multiple sclerosis during their first decade of the disease. The results of the test are reported as negative (patient has a low risk to fast disability progression as measured by

EDSS) or positive (patient has a high risk to fast disability progression as measured by EDSS) (Glycominds 2012). One advantage of the gMS®Pro EDSS test is that blood samples are relatively easy to obtain and are minimally invasive. A limitation of using biomarkers for diagnosing MS is that biomarkers may be affected by other systematic events such as viral infections (Harris 2009). An additional limitation of the gMS®Pro EDSS test is that the biologic basis for the MS biomarkers is unclear (Freeman 2009).

## Medical Technology Assessment Committee (MTAC)

### **gMS®Dx and gMS®Pro EDSS**

#### **06/18/2012: MTAC REVIEW**

**Evidence Conclusion:** Diagnostic accuracy: Results from a recent observational study with several limitations suggest that the gMS®Dx test has a sensitivity of 33.7% (95% CI, 30.2 to 37.3) and a specificity of 98.5% (95% CI, 91.7 to 100) for differentiating relapsing remitting multiple sclerosis (RRMS)/secondary progressive multiple sclerosis (SPMS) from other neurological disorders (Brettschneider 2009). Impact on diagnosis: There is insufficient evidence to determine whether the gMS®Dx test will impact diagnosis. Impact on patient management: There is insufficient evidence to determine whether the gMS®Dx test will change patients management. Conclusion: Diagnostic accuracy: Weak evidence suggest that the gMS®Dx test has a sensitivity of 33.7% and a specificity of 98.5% for differentiating RRMS/SPMS from other neurological disorders. Impact on diagnosis: There is insufficient evidence to determine whether the gMS®Dx test will impact diagnosis. Impact on patient management: There is insufficient evidence to determine whether the gMS®Dx test will change patients management.

### **gMS®Pro EDSS testing**

#### **06/18/2012: MTAC REVIEW**

**Evidence Conclusion:** Accuracy: A prospective cohort study that included 286 patients with clinically isolated syndrome (CIS) evaluated the prognostic value of the gMS®Pro EDSS test. Results from this study suggest that the gMS®Pro EDSS test does not significantly predict prognosis, conversion to McDonald MS, or EDSS progression in patients with CIS. Results from this study should be interpreted with caution as this is an exploratory analysis (Freedman 2011). Results from a retrospective study of 100 RRMS patients taken at their first presentation of RRMS suggest that using a panel of 4 different antibodies had a sensitivity of 37.9% and a specificity of 83.3% for predicting early relapse in patients with RRMS following their first presentation. Results from this study should be interpreted with caution as this is a retrospective exploratory analysis (Freedman 2009). Impact on patient management: No studies were identified that address the impact of gMS®Pro EDSS on patients management. Conclusion: Accuracy: There is insufficient evidence to determine the accuracy of the gMS®Pro EDSS test. Impact on patient management: There is insufficient evidence to determine whether the gMS®Pro EDSS test will change patients management.

**Articles: gMS®Dx test:** Several observational study were identified that addressed the diagnostic accuracy of the gMS®Dx test. The largest study was selected for review. No studies were identified that addressed the impact of the test on diagnosis or patients management. The following study was selected for review: Brettschneider J, Jaskowski TD, Tumani H, et al. Serum anti-GAGA4 IgM antibodies differentiate relapsing remitting and secondary progressive multiple sclerosis from primary progressive multiple sclerosis and other neurological diseases. J Neuroimmunol. 2009;217:95-101. **gMS®Pro EDSS test:** Two studies were identified that addressed the accuracy of the gMS®Pro EDSS test. No studies were identified that addressed the clinical utility of the gMS®Pro EDSS test. The following study was selected for review: Freedman M, Metz C, Kappos L, et al. Predictive nature of IgM anti-alpha-glucose serum biomarker for relapse activity and EDSS progression in CIS patients: a BENEFIT study analysis. Mult Scler. 2011. [Epub ahead of print] See [Evidence Table](#). Freedman MS, Laks J, Dotan N, Altstock RT, Dukler A, Sindic CJ. Anti-alpha-glucose-based glycan IgM antibodies predict relapse activity in multiple sclerosis after the first neurological event. Mult Scler. 2009;15:422-430. See [Evidence Table](#).

The use of gMS®Dx and gMS®Pro EDSS testing does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Sex-Hormone Binding Globulin (SHBG)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Medicare covers the code as the test is often done for other reasons and this is a new indication not addressed in Medicare coverage documents.

##### For Non-Medicare Members

##### SHBG for Predicting Diabetes Risk

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

SHBG is not covered for symptoms of erectile dysfunction, fatigue, impotence or low libido as the medical literature does not support its use in these circumstances.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Causes of abnormal SHBG include the following:

- Increased SHBG concentrations: aging, hyperthyroidism, high estrogen concentrations, liver disease, HIV, anti-seizure drugs
- Decreased SHBG concentrations: moderate obesity, insulin resistance, type 2 diabetes, hypothyroidism, growth hormone excess, exogenous androgens/anabolic steroids, glucocorticoids, progestins, nephrotic syndrome
- Free testosterone — If serum free testosterone concentration is measured, the following points should be kept in mind:
  - Serum free testosterone should be performed by equilibrium dialysis and only in those few laboratories that specialize in endocrine testing.
  - The free testosterone concentration, as calculated from the total testosterone, SHBG, and albumin concentrations, may also be reliable, but there are many different equations for this calculation and they give vastly different results, some of which reflect the results obtained by equilibrium dialysis better than others. Consequently, it is essential that the result be compared with the normal range for the laboratory that performed the assay.
  - Free testosterone measured by an analog method, which is the assay most commonly offered by hospital and commercial laboratories, does not correlate with the results of equilibrium dialysis. This test gives misleading information and should never be ordered.
  - The problem with the analog method was illustrated in a study in which sera from patients who had a variety of SHBG concentrations were assayed by each of the above methods. The results using each of the assays correlated well with the results using each of the other methods, except for free testosterone by the analog method, in which the results were both systematically lower than in the other methods and varied as a function of SHBG.
  - Bioavailable testosterone, ie, the total of free testosterone and that bound weakly to albumin, which is not precipitated by ammonium sulfate, also appears to accurately reflect androgen status.

When during the day should the serum testosterone concentration be measured? — Interpretation of serum testosterone measurements in young men should take into consideration its diurnal fluctuation, which reaches a

maximum at about 8 AM and a minimum, approximately 70 percent of the maximum, at about 8 PM. It is easier to distinguish subnormal from normal when normal is higher, so the measurements should always be made in the morning, ideally between 8 to 10 AM. Food, especially glucose ingestion, also decreases the serum testosterone concentration, so the blood should also be drawn fasting.

How often should testosterone be measured? — The serum testosterone concentration fluctuates somewhat even early in the morning, although to a limited degree. If a single 8 to 10 AM value is well within the normal range, testosterone production can be assumed to be normal. If a single 8 to 10 AM value is low or borderline low or does not fit with the clinical findings, the measurement should be repeated once or twice before making the diagnosis of hypogonadism. If the results are equivocal, measurement of free testosterone can be considered.

Sex hormone-binding globulin (SHBG) is a serum protein that binds to circulating androgens and estrogens, specifically testosterone and estradiol, with high affinity and serves as a transporter/reservoir. It is believed that SHBG regulates the access and action of these hormones. Initially it was thought that when bound to SHBG these sex hormones were biologically inactive. However, emerging evidence suggests that even sex hormones bound to SHBG may be biologically active. SHBG is produced mainly in the liver; however, other tissues including the placenta, testis, brain, and endometrium also produce SHBG. Age and obesity along with a variety of hormonal, nutritional, metabolic, and genetic factors have been found to influence the production of SHBG. Several conditions such as diabetes, polycystic ovarian syndrome, obesity, hypothyroidism, and hyper-insulinemia are associated with low levels of SHBG; however, causality has yet to be proven. Because of SHBG association with type 2 diabetes, there has been growing interest in the use of SHBG levels as a tool for the early identification of this disease (Brand 2010, Dahan 2006, Hoppé 2010, Xita 2010).

## Medical Technology Assessment Committee (MTAC)

### Sex-Hormone Binding Globulin

#### 02/14/2011: MTAC REVIEW

**Evidence Conclusion:** *Men:* Two prospective cohort studies evaluated the association between SHBG levels and the risk of type 2 diabetes in men. The first study followed 1,454 men from the Troms study, a population-based prospective cohort study, who did not have diabetes at baseline for a mean of 9.1 years. Seventy-six men were diagnosed with diabetes (incidence rate of 5.8 per 1,000 person years). After controlling for age, HDL-cholesterol, systolic blood pressure, and waist circumference there was no association between SHBG and the risk of diabetes (Vikan 2010). The second study followed 1,128 men aged 40-70 years who participated in the Massachusetts Male Aging Study, a population-based prospective cohort study, for an average of 13 years. Ninety men were diagnosed with diabetes (incidence rate of 6.2 per 1,000 person years). Results from this analysis suggest that in men, even after controlling for age, BMI, high blood pressure, smoking, alcohol intake, and physical activity, SHBG levels were associated with the development of type 2 diabetes (Laksham 2010). It should be noted that the mean levels of SHBG were higher in the Vikan study compared to the Laksham study (52.7 nmol/l vs. 32.0 nmol/l). This may be due to the fact that blood sample were drawn at different times of the day. Diabetes status was determined through self-report in both studies. Additionally, neither study adjusted for insulin levels, which have been found to inhibit SHBG production. An earlier systematic review and meta-analysis of 3 prospective cohort studies found that men with higher SHBG levels (>28.3 vs. ≤28.3 nmol/l) had a 52% lower risk of type 2 diabetes (RR 0.48, 95%CI 0.33-0.69) (Ding 2006). *Women:* One prospective cohort study was identified that evaluated the association between SHBG levels and the risk of type 2 diabetes in postmenopausal women. In this study, 1,612 women were followed for a median of 4.7 years and 116 women were diagnosed with diabetes. Results from this study suggest that in postmenopausal women SHBG levels are associated with the development of type 2 diabetes even after adjusting for age, race/ethnicity, education, income, family history of diabetes, examination site, insulin resistance, and adiposity.

#### Relative hazards of developing incident type 2 diabetes by quartile of baseline SHBG level

	Model 1*	Model 2†	Model 3‡
	HR (95% CI)		
<b>SHBG (nmol/l)</b>			
Q1 (8.9-37.8)	1.0 (Ref)	1.0 (Ref)	1.0 (Ref)
Q2 (38.0-51.4)	0.39 (0.25-0.61)	0.49 (0.31-0.76)	0.41 (0.24-0.69)
Q3 (51.5-71.5)	0.29 (0.18-0.47)	0.44 (0.26-0.74)	0.53 (0.30-0.92)
Q4 (71.8-255.5)	0.24 (0.14-0.42)	0.43 (0.24-0.76)	0.52 (0.27-0.98)
<b>P-trend</b>	<0.0001	0.0004	0.017

\*Adjusted for age, race/ethnicity, education, income, family history of diabetes, and examination site.

†Adjusted for model 1 plus BMI and homeostasis model assessment of insulin resistance (HOMA-IR).

‡Adjusted for model 2 plus LDL, HDL, triglycerides, use of lipid-lowering medication, systolic blood pressure, total daily caloric intake, physical activity, smoking, inflammatory factors (IL-6 and CRP), age at menopause,

years since menopause, type of menopause, age at first live birth, five or more live births, past use of hormone replacement therapy or oral contraceptive.

An earlier systematic review and meta-analysis of 2 prospective cohort studies found that women with higher SHBG levels (>60.0 vs. ≤60.0nmol/l) had an 80% lower risk of type 2 diabetes (RR 0.20, 95%CI 0.12-0.30) (Ding 2006). Conclusion: Several observational studies suggest that lower SHBG levels are associated with an increased risk of developing of type 2 diabetes; however, SHBG cutpoints for determining increased risk have not been established. Additionally, there is insufficient evidence to determine the clinical utility of using SHBG to predict type 2 diabetes.

**Articles:** The literature search revealed several case-control, cross-sectional, and prospective cohort studies that examined the association between SHBG and the risk of type 2 diabetes. Three recent prospective cohort studies were selected for review. No studies were identified that addressed the clinical utility of using SHBG to predict type 2 diabetes. The following studies were critically appraised: Kalyani RR, Franco M, Dobs AS, et al. The association of endogenous sex hormones, adiposity, and insulin resistance with incident diabetes in postmenopausal women. *J Clin Endocrinol Metab* 2009; 94:4127-4135. See [Evidence Table](#). Lakshman KM, Bhasin S, and Araujo AB. Sex hormone-binding globulin as an independent predictor of incident type 2 diabetes in men. *J Gerontol A Biol Sci Med Sci* 2010; 65A: 503-509. See [Evidence Table](#). Vikan T, Schirmer H, Njølstad I, and Svartberg J. Low testosterone and sex hormone-binding globulin levels and high estradiol levels are independent predictors of type 2 diabetes in men. *Eur J Endocrinol* 2010; 162:747-754. See [Evidence Table](#)

The use of SHBG does not meet the *Group Health Medical Technology Assessment Criteria*.

Indication	Policy
Chronic Plantar Fasciitis Lateral Epicondylitis (Tennis Elbow) Non-Union or Delayed Union Fractures	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Evidence and Source Documents

[Extracorporeal Shock Wave Therapy \(ESWT\) for Delayed or Nonunion Fractures](#)

[Extracorporeal Shock Wave Therapy \(ESWT\) for Chronic Plantar Fasciitis](#)

## [Extracorporeal Shock Wave Therapy \(ESWT\) for Lateral Epicondylitis](#)

### Background

Extracorporeal shock waves are characterized by high positive pressure with a rapid rise time and short (microsecond) duration. The shock waves are concentrated into small focal areas of 2 to 8 mm to optimize therapeutic effects and minimize the impact on adjacent tissues. There are several types of shock wave generating systems; they can involve electrohydraulic, electromagnetic or piezoelectric mechanisms. The shape of the pulses differs depending on the mechanism. In all of the systems, shock waves are concentrated by focusing reflectors on the target site. The shock waves can be further localized using imaging modalities such as ultrasound. Beneficial effects are expected to be observed between 6-12 weeks after treatment (Speed 2004; Wilner & Strash, 2004).

Extracorporeal shock wave therapy (ESWT) is used as a non-invasive alternative to surgery for patients with chronic plantar fasciitis who have not responded to conservative therapy such as use of orthotics, physical therapy, night splints, heel cups and treatment with non-steroidal anti-inflammatory drugs (NSAIDs). Plantar fasciitis is believed to result from a biochemical imbalance that places abnormal tension on the plantar fascia which leads to inflammation and tension on the calcaneal periosteum. The mechanism by which ESWT relieves symptoms of plantar fasciitis is not known; however, there may be an effect through tissue disruption of the tendinous fibers followed by neovascularization and replenishment of the extracellular matrix (Atkin, 1999; Wilner & Strash, 2004).

The HealthTronics OssaTron (October, 2000), Dornier Epos Ultra (January, 2002), Medispec Orthospec (April, 2005) and Orthometrix Orbasone (August, 2005) devices have all been approved by the FDA for the treatment of chronic proximal plantar fasciitis in individuals aged 18 or older who have a history of unsuccessful conservative treatments. The OssaTron and Orbasone are electrohydraulic devices, the Epos Ultra uses electromagnetic technology and the Orthospec uses sound waves.

Low-intensity ultrasound treatment was approved by the FDA in 2000 for treating non-union fractures. Healing is delayed in approximately 10% of the fractures that occur in the United States. The definitions of non-unions differ, but a fracture is generally considered to be a non-union if it has not healed by 6-9 months. Factors contributing to the occurrence of delayed unions and non-unions include the location and severity of the fracture, the extent of soft tissue damage, adequacy of stabilization or fixation, and lifestyle factors such as smoking and high alcohol intake (Hadjiargyrou et al., 1998; Biederman et al., 2003).

Some investigators believe that extracorporeal shock wave treatment (ESWT) has greater potential for treating delayed union and non-union fractures than ultrasound. Shockwaves are characterized by high positive pressure with a rapid rise time and short duration. Following the high positive pressure is an exponential decrease in pressure. The low-frequency components of shock waves allow them to pass through fluid and body tissues with less energy loss than ultrasound. Thus, shock wave treatment may be better than ultrasound for penetrating tissues and delivering adequate pressure for stimulation of bone growth (Rompe et al., 2001; Speed 2004; Wilner & Strash, 2004).

ESWT has not been approved by the FDA for treating non-union or delayed union fractures. The use of shock waves for bone repair has been studied in animal models and initial clinical studies.

Extracorporeal shock wave therapy (ESWT) is used as a non-invasive alternative to surgery for patients with soft tissue conditions including lateral epicondylitis (tennis elbow). ESWT is generally reserved for patients who have not responded to conservative therapy such as physical/occupational therapy, bracing or splinting, local steroid injections and non-steroidal anti-inflammatory drugs (NSAIDs).

Lateral epicondylitis is characterized by pain at the epicondyle on the lateral side of the elbow. The etiology is not well known, but it is generally believed to be due to musculotendinous lesions. The onset of pain can occur abruptly after an unaccustomed activity or can develop gradually in individuals who perform activities requiring repetitive and vigorous use of the forearm. Pain is often mild at first but can worsen over time (Buchbinder 2004; Melikyan, 2003).

#### ***Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis***

#### BACKGROUND

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Plantar fasciitis is the most common cause of inferior heel pain characterized by deep pain in the plantar aspect of the heel particularly on arising from the bed in the morning. While the pain may subside with activity, in some patients it persists, interrupting the activities of daily living. Approximately 10% of people develop this condition throughout their lifetime (Riddle and Schappert 2004). While the etiology has not fully been established, it is believed to result from a biomechanical abnormality that places tension on the plantar fascia and leads to inflammation and tension on the calcaneal periosteum. Several risk factors such as bone spurs, pronated foot type, obesity, limb-length discrepancy and weight-bearing appear to increase the risk of plantar fasciitis (Theodore, Buch et al. 2004). In the past, conservative therapies for plantar fasciitis, such as rest and stretching, have been successful (Digiovanni, Nawoczenski et al. 2006). Orthotics, physical therapy, night splints, heel cups and treatment with non-steroidal anti-inflammatory drugs (NSAIDs) have also been used in acute cases. While conservative therapies are successful in 85%-90% of patients (Gill 1997), there remain some persistent cases of plantar fasciitis. Extracorporeal shock wave therapy (ESWT) is a noninvasive intervention for patients with chronic plantar fasciitis who have not responded to conservative therapy. Thought to be an alternative to surgical intervention, the mechanism by which ESWT relieves symptoms of plantar fasciitis is not fully understood. The shock waves are believed to stimulate an extracellular response causing neovascularization, promoting tissue repair and regeneration (Atkin, 1999; Wilner & Strash, 2004). Shock waves are characterized by high positive pressure with a rapid rise time and short (microsecond) duration and are concentrated into small focal areas to optimize therapeutic effects and minimize the impact on adjacent tissues. With a variety of devices on the market, shock waves might involve electrohydraulic, electromagnetic or piezoelectric mechanisms and, in each case, the shape of the pulse differs. Beneficial effects are expected to be observed between 6-12 weeks after treatment (Speed 2004; Wilner & Strash, 2004). At the current time, there are five devices approved by the US Food and Drug Administration (FDA) for the treatment of chronic proximal plantar fasciitis (pain persisting for six months and not responding to conservative management). The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations. © Group Health Cooperative. All Rights Reserved. These include the HealthTronics OssaTron (October, 2000), Dornier Epos Ultra (January, 2002), Medispec Orthospec (April, 2005) and Orthometrix Orbasone (August, 2005).

#### **12/2001: MTAC REVIEW**

##### **Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis**

**Evidence Conclusion:** There were two RCTs evaluating shock wave generating devices for chronic plantar fasciitis. The Ogden study was the only RCT evaluating the OssaTron system. The Rompe study evaluated a similar device, the Siemens Osteostar. The Ogden study had substantial threats to validity including inadequate description of randomization and statistical analysis techniques and incomplete presentation of data. In the Ogden article, a significantly higher proportion of patients in the active treatment group than the placebo group met success criteria at 12 weeks. The Rompe study was single blind and had a small sample size; selection bias is a possibility. Rompe found a significantly greater reduction in pain in the active treatment group compared to the placebo group at 6 weeks. Neither study discussed possible adverse effects of treatment or presented long-term effectiveness data. **Articles:** The search yielded 10 articles. There were three empirical articles on extracorporeal shock wave treatment for chronic plantar fasciitis using the OssoTron system. One of these articles was a randomized controlled trial and 2 were case series. There were 4 articles on shock wave stimulation using devices other than the OssoTron system, 3 case series and one RCT. The two RCTs were critically appraised: Ogden JA, Alvarez R, Levitt R, Cross GL, Marlow M. Shock wave therapy for chronic proximal plantar fasciitis. *Clin Orthop* 2001; (387): 47-59. See [Evidence Table](#). Rompe JD, Hopf C, Nafe B, Burger R. Low-energy extracorporeal shock wave therapy for painful heel: A prospective single-blind study. *Arch Orthop Trauma Surg* 1996; 115; 75-79. See [Evidence Table](#).

The use of OssaTron in the treatment of chronic plantar fasciitis does not meet the *Group Health Medical Technology Assessment Criteria for effectiveness*.

#### **12/11/2001: MTAC REVIEW**

##### **Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis**

**Evidence Conclusion:** A new, valid randomized controlled trial (Buchbinder et al.) did not find that treatment with extracorporeal shock wave therapy using a device made by Dornier MedTech America was more effective than placebo treatment for plantar fasciitis. The Buchbinder et al. study was stronger methodologically than previous RCTs (Ogden et al., Rompe et al.) that had suggested that extracorporeal shock wave therapy might be effective. Unlike the earlier studies, Buchbinder et al. was double blind, adequately described the statistical procedures used and did an intention to treat analysis. Buchbinder et al. provides reasonably strong evidence that extracorporeal shock wave therapy does not improve pain and function 12 weeks after treatment in patients with plantar fasciitis.

**Articles:** The search yielded five articles, two of which were included in the previous MTAC review. Of the three

new articles, two were case series and one was a randomized controlled trial using the Dornier MedTech OPOS Ultra extracorporeal shock wave device. Buchbinder R, Ptasznik R, Gordon J. et al. Ultrasound-guided extracorporeal shock wave therapy for plantar fasciitis. JAMA 2002; 288: 1364-1372. See [Evidence Table](#).

The use of ESWT in the treatment of chronic plantar fasciitis does not meet the *Group Health Medical Technology Assessment Criteria for effectiveness*.

#### **12/08/2004: MTAC REVIEW**

##### **Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis**

**Evidence Conclusion:** There is conflicting evidence from four double-blind, sham-controlled randomized controlled trials. According to primary outcome assessment at 12 weeks, two of the RCTs reviewed (Buchbinder; Haake) did not find that ESWT was significantly more effective than a sham intervention at 12 weeks while the other two (Theodore; Ogden) did find a significant benefit of ESWT. It is not clear why findings varied. Clinical experts have stated the belief that efficacy is dependent on machine types and study protocols. Three studies used Dornier shock wave devices and the fourth (Ogden) used the OssaTron device. Three studies (all except Buchbinder) only included patients who had failed conservative therapy. The total number of shocks delivered was 2000-4000 in the negative studies and 1500-3800 in the positive studies. The energy of individual impulses may have been lower in the negative studies. Haake used shock waves of 0.08 mJ/mm<sup>2</sup> and in Buchbinder, shockwaves varied between 0.02-0.33 mJ/mm<sup>2</sup>. In the positive studies, shock waves were 0.22 mJ/mm<sup>2</sup> and 0.36 mJ/mm<sup>2</sup>. There were financial links with the device manufacturer in the positive studies, and there did not appear to be links in the negative studies. The studies either had a total of 12 weeks follow-up, or patients were unblinded at 12 months and eligible for other treatments. Therefore, high-quality comparative data on the effectiveness of ESWT beyond 12 weeks are not available. None of the studies reported serious adverse effects associated with ESWT.

Since the highest grade of evidence in previous reviews of this item was randomized controlled trials (RCTs), only RCTs and meta-analyses of RCTs were considered for the update. Ideally, RCTs of shock wave therapy for plantar fasciitis would have the following characteristics: Use a commercially available device Sham-controlled, or use of alternative treatment Double-blind Sufficient statistical power No financial conflicts of interest Long-term follow-up for efficacy and safety

**Articles:** The search yielded 18 articles, several of which were reviews. There were six publications reporting on five randomized controlled trials (two articles on the same study) and a meta-analysis of both controlled and uncontrolled studies. The meta-analysis was excluded because it was not limited to controlled studies, and only considered articles published through 2000, prior to the initial MTAC review. Three sham-controlled RCTs with sufficient statistical power were critically appraised. One RCT was excluded because it was not sham-controlled and another because it had a small sample size and no evaluation of statistical power. The studies reviewed include: Haake M, Buch M, Schoellner C et al. Extracorporeal shock wave therapy for plantar fasciitis: randomized controlled multicentre trial. BMJ 2003 327:75. See [Evidence Table](#). Theodore GH, Buch M, Amendola A. et al. Extracorporeal shock wave therapy for the treatment of plantar fasciitis. Foot Ank Int 2004; 25: 290-297. See [Evidence Table](#). Ogden JA, Alvarez RG, Levitt RL et al. Electrohydraulic high-energy shock wave treatment for chronic plantar fasciitis. J Bone Joint Surg 2004; 86-A: 2216-2228. See [Evidence Table](#). Buchbinder R, Ptasznik R, Gordon J. et al. Ultrasound-guided extracorporeal shock wave therapy for plantar fasciitis. JAMA 2002; 288: 1364-1372. See [Evidence Table](#).

The use of ESWT in the treatment of chronic plantar fasciitis does not meet the *Group Health Medical Technology Assessment Criteria for effectiveness*.

#### **04/02/2007: MTAC REVIEW**

##### **Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis**

**Evidence Conclusion:** There is some new evidence that ESWT treatment is effective in the short-term (3 months) for treating chronic plantar fasciitis that is unresponsive to conservative therapies. Both randomized controlled trials reviewed for the 2007 MTAC update found significantly greater reduction in pain after 3 months with active ESWT treatment compared to a placebo intervention. Overall, the findings from double-blind placebo-controlled RCTs are mixed. Some, including the two recent studies, have found a significant benefit with ESWT treatment whereas other studies did not. Studies have varied in the type of design used and the protocol e.g. number of sessions, energy level, number of shocks delivered, etc. The positive studies such as the two new studies, but not the negative studies, appear to have financial links with the device manufacturer, although specific biases introduced by industry funding were not identified. The absolute benefit of ESWT in statistically significant studies tended to be small, e.g. 1 point or less difference between groups on a 10-point visual analogue scale. Evidence of long-term effectiveness is lacking. None of the RCTs had blinded assessment of pain outcomes beyond 3 months. None of the studies reported serious adverse effects associated with ESWT. No Cochrane

collaboration meta-analysis was identified. The Kaiser Interregional New Technology Committee (INTC) reviewed this topic in November, 2006 and concluded that there was insufficient evidence of efficacy based on methodological limitations of studies and lack of long-term follow-up. New RCTs identified in the literature search were screened using the same criteria as in the previous MTAC review. These criteria are: Use of a commercially available device Included patients who meet FDA approved indication for treatment Sham-controlled, or use of alternative treatment Double-blind Sufficient statistical power No financial conflicts of interest Long-term follow-up for efficacy and safety

**Articles:** Four double-blind sham-controlled RCTs have been reviewed by MTAC (Haake et al., 2003; Theodore et al., 2004; Ogden et al., 2004; Buchbinder et al. 2002). Two additional double-blind sham-controlled RCTs conducted with patients who had failed conservative therapy for at least 6 months were identified. Both used commercially available devices. Neither study had long-term follow-up of effectiveness or had financial links with the device manufacturers. These two studies were critically appraised. Other new RCTs were excluded from further review. Two studies (Porter and Shadbolt, 2005; Wang et al., 2006) used ESWT as the initial treatment, not an FDA-approved indication. Another RCT (Rompe et al., 2005) compared two techniques for delivering ESWT; there was no comparison group that did not receive shockwave treatment. References for the critically appraised studies are as follows: Malay DS, Pressman MM, Assili A et al. Extracorporeal shockwave therapy versus placebo for the treatment of chronic proximal plantar fasciitis: Results of a randomized, double-blinded, multicenter intervention trial. *J Foot & Ankle Surg* 2006; 45(4): 196-210. See [Evidence Table](#). Kudo P, Dainty K, Clarfield M et al. Randomized, placebo-controlled, double-blind clinical trial evaluating the treatment of plantar fasciitis with an extracorporeal shockwave therapy (ESWT) device: A North American Confirmatory Study. *J Orthop Res* 2006; 24: 115-123. See [Evidence Table](#).

The use of ESWT in the treatment of chronic plantar fasciitis does not meet the *Group Health Medical Technology Assessment Criteria* for effectiveness.

#### 04/21/2014: MTAC REVIEW

##### **Extracorporeal Shock Wave Therapy (ESWT) for Chronic Plantar Fasciitis**

**Evidence Conclusion:** While the 2007 MTAC review identified two RCTs to support short-term effectiveness of ESWT when compared with placebo, the cumulative body of evidence (including four RCTs from previous reviews) was conflicting and lacked support of long-term effectiveness. The current literature search identified one meta-analysis pooling data from seven RCTs specifically aimed at examining the effectiveness of ESWT compared to placebo. Three additional trials were identified that compare ESWT to endoscopic plantar fasciotomy (EPF). The meta-analysis by Aqil and colleagues included seven RCTs with strict inclusion criteria. Due to differences in outcome measures and follow-up timeframes, pooled analysis of only four of the included studies was possible. Ultimately, ESWT had favorable results compared with placebo with five of the six included studies reaching significance after short term follow up (12 weeks). (Aqil, Siddiqui et al. 2013). Saxena et al. treated 25 athletes experiencing chronic plantar fasciitis with EPF, ESWT or placebo ESWT (P-ESWT). At one year follow up, the overall Visual analogue Scale (VAS) and Roles and Maudsley (RM) scores showed statistical improvement within both the EPF and ESWT groups. Treatment outcomes in the EPF group were significantly better than both ESWT and P-ESWT. The investigators report, however, that patients enrolled in ESWT were able to continue with their exercise regimen, while the EPF group were delayed in their return to athletic activity by 2.8 months on average (Saxena, Fournier et al. 2013). Radwan and colleagues randomized 65 patients to either ESWT or EPF for the treatment of resistant plantar fasciitis. At follow-up (3 weeks, 3 months and 12 months), both groups achieved progressive improvements, however, the majority of improvements in the ESWT group were seen between week three and week 12 while the EPF group saw more improvement lasting from week three to 12 months post-intervention. With that said, there were no significant differences detected between groups through the different time periods for any measured parameter except for the AOFAS maximum walking distance and gait sub-scores at three weeks (ESWT group p=005 and EPF group, p=002) (Radwan, Mansour et al. 2012). Finally, in 2010 Othman and colleagues prospectively evaluated 37 patients with chronic plantar fasciitis who self-selected either EPF or ESWT treatment after discussion of possible outcomes. Their results maintain similar trends with slightly better results seen in the EPF group but identification of the ESWT intervention as the preferred treatment option due to the benefits of no complications, no immobilization and earlier return to work (Othman and Ragab 2010). In general, study quality was good with randomization and appropriate comparison groups. For the most part, outcome measures were consistent throughout the selected literature, however, the intensity and the frequency of ESWT application varied and sample sizes were relatively small. The results from the recent meta-analysis provide evidence to suggest that ESWT is a safe and effective treatment of chronic plantar fasciitis compared to placebo in the short term. When compared to surgical intervention, however, ESWT does not perform as well. EPF produces better outcomes but is associated with morbidities such as prolonged healing, loss of time from work, nerve injury and tarsal instability. **Conclusion:** There is insufficient evidence from large, well design randomized trials that ESWT is an effective treatment for chronic plantar fasciitis. There is insufficient

evidence to support the safety of ESWT as a treatment option for chronic plantar fasciitis. **Articles:** The literature search revealed over 200 publications which included systematic reviews and practice recommendations. After articles were screened for randomization and outcome comparison one meta-analysis pooling data from RCTs and three RCTs/clinically controlled trials that compared ESWT with the surgical intervention, endoscopic plantar fasciotomy (EPF), were identified. The following articles were selected for critical appraisal: Aqil A, Siddiqui MRS, Solan M, Redfern DJ, Gulati V, Cobb JP. Extracorporeal shock wave therapy is effective in treating chronic plantar fasciitis: a meta-analysis of RCTs. *Clinical Orthopedic Related Research* 2013;471:3645-3652. See [Evidence Table](#). Saxena A, Fournier M, Gerdesmeyer L, Gollwitzer H. Comparison between extracorporeal shockwave therapy, placebo ESWT and endoscopic plantar fasciotomy for the treatment of chronic plantar heel pain in the athlete. *Muscles, Ligaments and Tendons Journal* 2012;2(4):312-316. See [Evidence Table](#). Radwan YA, Mansour AMR, Badawy WS. Resistant plantar fasciopathy: shock wave versus endoscopic plantar fascial release. *International Orthopaedics* 2012;36:2147-2156. Endoscopic plantar fasciotomy versus extracorporeal shock wave therapy for treatment of chronic plantar fasciitis. *Arch Orthop Trauma Surg* 2010;130:1343-1347. See [Evidence Table](#).

The use of ESWT in the treatment of chronic plantar fasciitis does not meet the *Group Health Medical Technology Assessment Criteria* for effectiveness.

### **Extracorporeal Shock Wave Therapy (ESWT) for Lateral Epicondylitis**

#### **BACKGROUND**

Extracorporeal shock waves are characterized by high positive pressure with a rapid rise time and short (microsecond) duration. The shock waves are concentrated into small focal areas of 2 to 8 mm to optimize therapeutic effects and minimize the impact on adjacent tissues. There are several types of shock wave generating systems; they can involve electrohydraulic, electromagnetic or piezoelectric mechanisms. The shape of the pulses differ depending on the mechanism. In all of the systems, shock waves are concentrated by focusing reflectors on the target site. The shock waves can be further localized using imaging modalities such as ultrasound. Beneficial effects are expected to be observed between 6-12 weeks after treatment (Speed 2004; Wilner & Strash, 2004). Extracorporeal shock wave therapy (ESWT) is used as a non-invasive alternative to surgery for patients with soft tissue conditions including lateral epicondylitis (tennis elbow). ESWT is generally reserved for patients who have not responded to conservative therapy such as physical/occupational therapy, bracing or splinting, local steroid injections and non-steroidal anti-inflammatory drugs (NSAIDs). Lateral epicondylitis is characterized by pain at the epicondyle on the lateral side of the elbow. The etiology is not well known, but it is generally believed to be due to musculotendinous lesions. The onset of pain can occur abruptly after an unaccustomed activity or can develop gradually in individuals who perform activities requiring repetitive and vigorous use of the forearm. Pain is often mild at first but can worsen over time (Buchbinder 2004; Melikyan, 2003). Two ESWT devices, the Siemens Sonocur (July, 2002) and the HealthTronics OssaTron (March, 2003) have been approved by the FDA for the treatment of chronic lateral epicondylitis in individuals age 18 or older who have a history of unsuccessful conservative treatments. The OssaTron is an electrohydraulic device and the Sonocur uses electromagnetic technology. Extracorporeal shockwave therapy for epicondylitis was previously reviewed by MTAC in February, 2005 and did not meet MTAC evaluation criteria.

#### **02/07/2005: MTAC REVIEW**

#### **Extracorporeal Shock Wave Therapy (ESWT) for Lateral Epicondylitis**

**Evidence Conclusion:** This review evaluated ESWT for patients with epicondylitis who had failed conservative therapy. Three double blind sham-controlled RCTs were identified, with mixed findings. The Melikyan and Haake studies did not find significant differences between the active treatment and control group on any outcome measure. Rompe found that the group receiving active ESWT had a significantly better outcome at 3 months. Pain reduction but not function was better in the treatment group at 12 months. The Melikyan study may have been underpowered (did not discuss power), but the Haake and Rompe studies were planned to have sufficient sample sizes to detect clinically significant differences. Differences in study methodology include whether the use of concurrent conservative treatments was allowed, whether local anesthesia was used during ESWT and the specific shockwave devices used. In the Haake study, patients were not restricted from using conservative treatments after ESWT. Rompe permitted use of other treatments after 3 months. Melikyan did not mention use of additional treatments. The Haake study used local anesthesia during the intervention, but Rompe and Melikyan, one positive and one negative study, did not. (Anesthesia may make it more difficult to locate the area of greatest pain). The Rompe study used the Siemens SONOCUR plus, Melikyan used the Dornier Epos Ultra and Haake used both of these. There were eight articles reporting on seven randomized controlled trials (two publications on the same study). In addition, there was a Cochrane Library review of randomized controlled trials conducted in 2001. The Cochrane review included only two trials, too few for a meaningful meta-analysis. Most of the RCTs identified were published after the Cochrane Review was completed. Individual RCTs were considered for critical

appraisal. Ideally, RCTs of shock wave therapy for epicondylitis would have the following characteristics: Use a commercially available device, Include patients who meet FDA approved indication for treatment, Sham-controlled, or use of alternative treatment, Double-blind, Sufficient statistical power, No financial conflicts of interest, Long-term follow-up for efficacy and safety

**Articles:** Three of the six RCTs included patients who met the FDA approval criterion of a history of unsuccessful conservative treatment. All of these were double-blind, sham-controlled, used commercially available devices and did not report significant financial conflicts of interest. These three RCTs (four articles) were critically appraised, the citations are as follows: Melikyan EY, Shahin E, Miles J et al. Extracorporeal shock-wave treatment for tennis elbow. *J Bone Joint Surg (Br)* 2003; 85-B: 852-855. See [Evidence Table](#). Haake M, Konig IR, Decker T. et al. Extracorporeal shock wave therapy in the treatment of lateral epicondylitis. *J Bone Joint Surg* 2002; 84-A: 1982-1991. Additional data reported in Haake et al. *Arch Orthop Trauma Surg* 2002; 122: 222-228. See [Evidence Table](#). Rompe JD, Decking J, Schoellner C et al. Repetitive low-energy shock wave treatment for chronic epicondylitis in tennis players. *Am J Sports Med* 2004; 32: 734-743. See [Evidence Table](#).

The use of extracorporeal shock wave treatment in the treatment of lateral epicondylitis does not meet the *Group Health Medical Technology Assessment Criteria* for effectiveness.

#### **04/02/2007: MTAC REVIEW**

##### **Extracorporeal Shock Wave Therapy (ESWT) for Lateral Epicondylitis**

**Evidence Conclusion:** A Cochrane collaboration review concluded that shock wave therapy provides little or no benefit in terms of pain and function in epicondylitis. In meta-analyses of 2 to 3 studies each, shockwave therapy was not significantly better than placebo for the vast majority of outcomes. A limitation of the Cochrane review was that, due to differences in study methods, summary estimates could be obtained only for a few studies at a time, not for all of the trials they identified. Several of the RCTs included in the Cochrane review were examined in greater depth. Three double-blind sham-controlled RCTs, conducted among patients who had failed conservative therapy, were evaluated for the 2005 MTAC review. Findings were mixed. Two studies did not find significant differences between the active treatment and control group on any outcome measure; one of these may have been underpowered. The third found that the group receiving active ESWT had a significantly better outcome at 3 months, and pain reduction but not function was better in the treatment group at 12 months. One additional well-conducted RCT with patients who had failed conservative treatment was identified for this update (Pettrone et al., 2005). The Pettrone study, in which no local anesthesia was used, found that ESWT was significantly more effective than placebo at reducing pain 50% or more after 12 weeks (61% in shockwave group, 29% in placebo group). The new study appeared to be the only RCT evaluated for MTAC in which the authors received a substantial financial contribution from the manufacturer. The body of literature on shockwave therapy for epicondylitis does not permit a clear conclusion about efficacy. Findings from RCTs are contradictory, and a Cochrane review concluded that treatment provides little or no benefit. Differences in outcome may be due in part to variability in study design e.g. type of device, whether or not local anesthesia was used and whether use of any conservative treatments were permitted after ESWT. A Canadian brief technology assessment that searched the literature through March, 2005 was identified (CADTH, 2007). There was no quantitative meta-analysis. The authors concluded that results from RCTs have been conflicting. A Cochrane collaboration systematic review was identified that included literature published through February, 2005. The meta-analysis in the Cochrane review was of limited scope due to the inability to combine trials with varying methodology e.g. different outcome measures, time frames for analysis, etc. Due to the limited meta-analysis in the Cochrane review, individual RCTs were also examined for this MTAC update. For the previous MTAC review, the following criteria were used to identify the strongest and most relevant RCTs: Use of a commercially available device, Included patients who meet FDA approved indication for treatment, Sham-controlled, or use of alternative treatment, Double-blind, Sufficient statistical power, No financial conflicts of interest, Long-term follow-up for efficacy and safety

**Articles:** In 2005, the 3 RCTs that most closely met the above criteria were critically appraised. Other RCTs screened at that time did not include patients meeting the FDA-approved criterion of a history of unsuccessful conservative treatment. One new RCT was identified that was placebo-controlled, double-blind, used a commercially available device (Sonocur) and included patients who had failed conservative treatment. The Cochrane review and new RCT were critically appraised: Buchbinder R, Green SE, Youd JM. Shockwave therapy for lateral elbow pain. *Cochrane Library* 2007: Volume 1. Date of most recent update: March, 2006. See [Evidence Table](#).

The use of extracorporeal shock wave treatment in the treatment of lateral epicondylitis does not meet the *Group Health Medical Technology Assessment Criteria* for effectiveness.

##### **Extracorporeal Shock Wave Therapy (ESWT) for Delayed or Nonunion Fractures**

###### **BACKGROUND**

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Healing is delayed in approximately 10% of the fractures that occur in the United States. The definitions of non unions differ, but a fracture is generally considered to be a non-union if it has not healed by 6-9 months. Factors contributing to the occurrence of delayed unions and non-unions include the location and severity of the fracture, the extent of soft tissue damage, adequacy of stabilization or fixation, and lifestyle factors such as smoking and high alcohol intake (Hadjiargyrou et al., 1998; Biederman et al., 2003). Low-intensity ultrasound treatment was approved by the FDA in 2000 for treating non-union fractures. Some investigators believe that extracorporeal shock wave treatment (ESWT) has greater potential for treating delayed union and non-union fractures than ultrasound. Shockwaves are characterized by high positive pressure with a rapid rise time and short duration. Following the high positive pressure is an exponential decrease in pressure. The low-frequency components of shock waves allow them to pass through fluid and body tissues with less energy loss than ultrasound. Thus, shock wave treatment may be better than ultrasound for penetrating tissues and delivering adequate pressure for stimulation of bone growth (Rompe et al., 2001; Speed 2004; Wilner & Strash, 2004). ESWT has not been approved by the FDA for treating non-union or delayed union fractures. The use of shock waves for bone repair has been studied in animal models and initial clinical studies. MTAC has not previously reviewed ESWT for treating delayed or non-union fractures.

**02/07/2005: MTAC REVIEW**

**Extracorporeal Shock Wave Therapy (ESWT) for Delayed or Nonunion Fractures**

**Evidence Conclusion:** There is insufficient evidence to determine whether extracorporeal shock wave treatment is effective for treating delayed unions and non-unions. Only case series data were available; these described the proportion of cases that healed at the end of the study period. Since the studies did not include concurrent comparison or control groups, it is not possible to know what the healing rate in these groups of patients would have been without the shock wave intervention. The authors of both studies that were reviewed called for controlled studies to be conducted. Treatment of delayed unions or non-unions are not FDA-approved indications for ESWT. The search yielded 19 articles, some of which were on related treatments or related conditions. Ideally, studies on the effectiveness of shock wave therapy would have the following characteristics: Randomized controlled trial, Use a commercially available device, Include patients who meet FDA approved indication for treatment, Sham-controlled, or use of alternative treatment, Double-blind, Sufficient statistical power, No financial conflicts of interest, Long-term follow-up for efficacy and safety

**Articles:** There were no randomized or non-randomized controlled studies. The empirical literature consisted of two prospective and one retrospective case series. The two prospective case series were critically appraised. The citations for the reviewed articles are as follows: Biedermann R, Martin A, Handle G et al. Extracorporeal shock waves in the treatment of nonunions. J Trauma 2003; 54: 936-942. See [Evidence Table](#). Rompe JD, Rosendhl T, Schollner C et al. High-energy extracorporeal shock wave treatment of nonunions. Clin Orthoped Rel Res 2001; 387: 102-111. See [Evidence Table](#).

The use of extracorporeal shock wave treatment in the treatment of delayed union or nonunion fractures does not meet the *Group Health Medical Technology Assessment Criteria* for effectiveness.

## Clinical Review Criteria

### Minimally Invasive Sacroiliac Fusion (SI Fusion)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None
GHC Medical Policy	In the absence of a NCD or a LCD use GHC Medical Policy Minimally Invasive Sacroiliac Fusion (SI Fusion)

##### For Non-Medicare Members

- A. Sacroiliac joint fusion is medically necessary when **ALL of the following** are met:
1. Appropriate imaging studies demonstrate localized sacroiliac joint pathology
  2. The individual is a nonsmoker, or in the absence of progressive neurological compromise will refrain from use of tobacco products for at least 6 weeks prior to the planned surgery
  3. And **ONE of the following**:
    - a. Post-traumatic injury of the SI joint (e.g., following pelvic ring fracture)
    - b. As an adjunctive treatment for sacroiliac joint infection or sepsis
    - c. Management of sacral tumor (e.g., partial sacrectomy)
    - d. When performed as part of multisegmental long fusions for the correction of spinal deformity (e.g., idiopathic scoliosis, neuromuscular scoliosis)
- B. Sacroiliac joint fusion is not covered for ANY other indication, including the following, because it is considered experimental, investigational or unproven:
1. Mechanical low back pain
  2. Sacroiliac joint syndrome
  3. Degenerative sacroiliac joint
  4. Radicular pain syndromes
- C. Percutaneous or minimally invasive sacroiliac joint stabilization (e.g., iFuse Implant System™, SImmetry® SI Joint Fusion System) for sacroiliac joint fusion (CPT codes 0334T, 27279) are not covered for ANY indication because there is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Lower back pain is extremely common and the sacroiliac (SI) joint has been implicated as one of the potential sources dating all the way back to the early 1900s. Formed by the connection of the sacrum and the right and left iliac bones, the SI joint lies at the junction of the spine and the pelvis. Held together by a collection of strong ligaments the SI joint only allows for limited rotation and translation. The SI joint plays a primary role in supporting the weight of the upper body. Pregnancy, gout, rheumatoid arthritis, psoriasis, ankylosing spondylitis, and other conditions that cause abnormal wear may aggravate the joints by placing an increased amount of stress on the SI joints.

There are many different terms for SI joint problems, including SI joint dysfunction, SI joint syndrome, SI joint strain, and SI joint inflammation. With the most common symptoms being pain, stiffness and burning the diagnosis of SI joint conditions can prove difficult for a multitude of reasons. For starters, there are no widely accepted

guidelines for diagnosis and treatment nor has any imaging modality established definitive symptoms that correlate with a visible pathology. These issues are further complicated by the large spectrum of different etiologic factors and variability that contribute to the pain. As a result, diagnosis of SI joint dysfunction relies on thorough history and physical examination.

Conventional treatments for SI joint dysfunction typically consist of non-operative interventions such as injections and anti-inflammatory oral medications. However, oral steroids and physical therapy can also be helpful. In the event that conservative interventions fail, SI joint fusion has been proposed as an additional treatment option. A variety of techniques have been described over the years without the wide acceptance of a single technique. Generally speaking, the surgery entails removal of the cartilage in the SI joints followed by an implant of plates or screws to hold the bones together. The technique may even employ the use of bone grafts to promote fusion. Ultimately, the surgery is designed to eliminate SI joint motion with the overall goal to relieve pain.

## Medical Technology Assessment Committee (MTAC)

### Sacroiliac Fusion (SI Fusion) for Sacroiliac Joint Dysfunction

#### 12/08/2014: MTAC REVIEW

**Evidence Conclusion:** Lower back pain is extremely common and the sacroiliac (SI) joint has been implicated as one of the potential sources dating all the way back to the early 1900s (Goldthwait and Osgood 1905). Formed by the connection of the sacrum and the right and left iliac bones, the SI joint lies at the junction of the spine and the pelvis. Held together by a collection of strong ligaments the SI joint only allows for limited rotation and translation. The SI joint plays a primary role in supporting the weight of the upper body. Pregnancy, gout, rheumatoid arthritis, psoriasis, ankylosing spondylitis, and other conditions that cause abnormal wear may aggravate the joints by placing an increased amount of stress on the SI joints. There are many different terms for SI joint problems, including SI joint dysfunction, SI joint syndrome, SI joint strain, and SI joint inflammation. With the most common symptoms being pain, stiffness and burning the diagnosis of SI joint conditions can prove difficult for a multitude of reasons. For starters, there are no widely accepted guidelines for diagnosis and treatment nor has any imaging modality established definitive symptoms that correlate with a visible pathology. These issues are further complicated by the large spectrum of different etiologic factors and variability that contribute to the pain. As a result, diagnosis of SI joint dysfunction relies on thorough history and physical examination. Conventional treatments for SI joint dysfunction typically consist of non-operative interventions such as injections and anti-inflammatory oral medications. However, oral steroids and physical therapy can also be helpful ([Ashman, Norvell et al. 2010](#)). In the event that conservative interventions fail, SI joint fusion has been proposed as an additional treatment option. A variety of techniques have been described over the years without the wide acceptance of a single technique. Generally speaking, the surgery entails removal of the cartilage in the SI joints followed by an implant of plates or screws to hold the bones together. The technique may even employ the use of bone grafts to promote fusion. Ultimately, the surgery is designed to eliminate SI joint motion with the overall goal to relieve pain. Several implants have received 501(k) approval from the Food and Drug Administration (FDA) and are detailed in table 1. Minimally invasive (MIS) SI joint fusions have not previously been reviewed by the Medical Technology and Assessment Committee (MTAC) and are currently being reviewed due to increased requests for coverage.

**Articles:** The literature search revealed just under 200 articles. No randomized control trials (RCTs) comparing MIS SI joint fusion with non-surgical treatment for the treatment of chronic low back pain due to sacroiliac joint dysfunction were identified. The only comparison studies were cohorts investigating MIS SI joint fusion versus open surgical techniques or SI joint denervation and were not selected because they did not include a nonsurgical group. Currently, there are numerous trials registered with the NIHCT set to compare MIS SI joint fusion with conservative management. The majority of the literature base was small and retrospective. The best available publications were two prospective cohorts with no comparison groups and a retrospective medical chart review of 18 patients who underwent MIS SI joint fusion surgery. The following publications were selected for critical appraisal: Wise, CL and Dall, B. Minimally invasive sacroiliac arthrodesis outcomes of a new technique. *J Spinal Disord Tech* 2008;**21**(8):579-584. [[Evidence Table 1](#)]. Cumming, J and Capobianco, RA. Minimally invasive sacroiliac joint fusion: one-year outcomes in 18 patients. *Annals of Surgical Innovation and Research* 2013;**7**(1):12-18. [[Evidence Table 2](#)]. Duhon BS, Cher DJ, Wine KD, et al. Safety and 6-month effectiveness of minimally invasive sacroiliac joint fusion: a prospective study. *Medical Devices: Evidence and Research* 2013;**6**:219-229. [[Evidence Table 3](#)]

Minimally invasive sacroiliac joint fusion, with or without bone grafts and other metal implant devices and does not meet the *Group Health Medical Technology Assessment Criteria*.

#### Criteria

##### For Medicare Members

##### National Coverage Determination

[Implantable Automatic Defibrillators \(20.4\)](#)

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Cardiovascular disease is the most common cause of death in the Western world, and sudden cardiac death (SCD) accounts for approximately 60% of all cardiovascular mortality. SCD is responsible for ~300,000 annual deaths in the United States; with ventricular fibrillation (VF) accounting for up to one-third of cases (Zipes 1998, Estes 2011, Majithia 2014, Rhyner 2014).

The implantable cardioverter defibrillator (ICD) was developed and introduced to clinical practice around the 1980s to address this issue of fatal SCD from ventricular tachyarrhythmia. The ICD continuously monitors the heart, identifies malignant ventricular tachyarrhythmia, and delivers an electric counter shock to restore normal rhythm. The first defibrillator received FDA approval in 1985 to be used in patients who had survived cardiac arrests. In 2002, the FDA expanded its use to patients with a history of a heart attack and depressed heart function. ICDs are widely used and studies have shown significant mortality benefit in selected patients at increased risk of SCD. However, the use of ICDs may at times be complicated with the implantation procedure, programming, device malfunction, and lead performance deterioration by time. Traditionally, the ICD is implanted transvenously by creating a pocket in the subclavicular areas and gaining vascular access to reach the heart. This approach has its drawbacks and is associated with short- and long-term adverse events. Reported complications associated with ICD systems include lead dislodgement, lead fracture, conductor coil breaks, pneumothorax, cardiac perforation, pericardial effusion, cardiac tamponade, and systemic infection. Lead malfunction occurs in up to 40% of the transvenous leads at 8 years after implantation. Lead failure either generates inappropriate shocks or impedes appropriate therapy. Extraction of the lead is recommended in cases of lead fracture, malfunction, or other mechanical problems that prevent safe and effective ICD shock therapies. This extraction is complex and can be associated with significant risks including death (Olde Nordkamp 2012, Weiss 2013, Aziz 2014, Chang 2014, Majithia 2014).

The complications associated with the intracardiac leads of the implantable cardioverter defibrillators have led to the development of a totally subcutaneous ICD (S-ICD) with the intention to provide the same protection, but with less procedural and device-related risks. The S-ICD system senses, detects, and treats malignant ventricular tachycardia (VT)/ventricular fibrillation (VF) without requiring vascular access or fluoroscopy. The S-ICD system (model SQ-RX 1010, Cameron Health, Inc., San Clemente, CA) includes a dedicated external programmer, a subcutaneous pulse generator enclosed in a titanium case, and a single subcutaneous electrode containing both sensing and defibrillating components. The lead-electrode is composed of proximal and distal sensing electrodes separated by a shocking coil. The pulse generator is implanted in a subcutaneous pocket created over the fifth intercostal space between the mid and anterior axillary lines. The single lead is tunneled from the xiphoid process to the pocket and to the sternal manubrium joint. Fixation is achieved with the addition of a suture sleeve at the level of the xiphoid and a single suture at the superior parasternal portion of the lead. Implantation of the device

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

relies entirely on anatomic landmarks and does not require fluoroscopy (although some investigators advocate brief screening to verify the final position). The currently used pulse generator weighs 145 g, has a volume of 69 ml, and an estimated 5-year battery life. The greatest advantage of S-ICD is that the lead does not pass through the central veins in the chest, nor is it attached to the tissue within the heart chambers. However, the pulse generator of the S-ICD is approximately twice the volume and weight of the currently used transvenous ICD, which may prevent its use in children, and increase the risk of erosion, discomfort, and infection. In addition the weight of the device may cause its dislodgement and changes in the shock configuration (Olde Nordkamp 2012, Weiss 2013, Aziz 2014, Chang 2014, Grace 2014, Majithia 2014).

The S-ICD system detects changes in the ventricular rate by using subsurface electrocardiography through a primary, secondary, or alternate vector. The device is programmed to select the vector that best avoids double QRS counting or T-wave oversensing events that could lead to misinterpretation of the rhythm and delivery of inappropriate shock. The heart rate is measured as the average of 4 consecutive sensed intervals. VF is diagnosed when 18 of 24 consecutive sensed events exceed the shock zone limit. Once the system detects a malignant arrhythmia, it delivers up to 80 J shock to terminate the arrhythmia and will automatically reverse polarity if the initial shock fails to terminate the arrhythmia. The mean defibrillation threshold is significantly higher than with transvenous devices, and some investigators suggest that high-energy shocks may be harmful to the myocardium (Aziz 2014, Majithia 2014, Nair 2014).

Unlike the conventional ICD devices, S-ICD is unable to provide long-term bradycardia pacing or antitachycardia pacing due to the absence of an endocardial lead. It is thus not suitable for patients with an indication for antibradycardia pacing or cardiac resynchronization therapy, or for those with a history of repetitive monomorphic ventricular tachycardia that would benefit from antitachycardia pacing. S-ICD may not be used concurrently with unipolar pacemaker as that would interfere with the S-ICD arrhythmia detection. This absence of bradycardia pacing in the S-ICD might lead to more bradycardia related events as syncope or even death. The device may be potentially useful for patients who are not eligible for transvenous ICDs, or are at high risk of complications e.g. subjects with congenital heart disease, complicated vascular anatomy, at high risk of infection, or in patients in whom vascular access is limited or needs to be conserved e.g. for renal dialysis or long-term intravenous drug therapy (Akerstrom 2013, Olde Nordkamp 2012, Chang 2014, Majithia 2014).

S-ICD received US FDA approval in September 2012, "To provide defibrillation therapy for the treatment of life-threatening ventricular tachyarrhythmia in patients who do not have sympathetic bradycardia, incessant (continual) ventricular tachycardia, or spontaneous frequently recurring ventricular tachycardia that is reliably terminated with anti-tachycardia Pacing". The FDA required that a post-approval registry be created to track outcomes of patients and devices for at least 60 months after implantation.

S-ICD has not been previously reviewed by MTAC; it is being reviewed based on a request for the Clinical Review Unit for coverage decision.

## Medical Technology Assessment Committee (MTAC)

### ***Subcutaneous Implantable Cardioverter Defibrillator***

#### **10/20/2014: MTAC REVIEW**

**Evidence Conclusion:** The results of the published observational studies suggest that S-ICD may be accurate in detecting and reversing induced ventricular arrhythmias, however, the incidence of inappropriate therapy was as high as 13.1% (in a mean duration of 11 months in Weiss et al 2013). Inappropriate shock therapy may decrease the quality of life and increase the mortality risk.

The published studies evaluated the accuracy, efficacy and safety of S-ICD in reversing induced rather than spontaneous arrhythmias. The arrhythmia is not always predictable and as seen in one study (Kobe 2013) the S-ICD system had to be changed to transvenous ICD in a patient who needed antitachycardia pacing (ATP) therapy. A group of investigators (Gold and colleague 2012) noted that though there is no reason to suspect that electrograms may differ between induced and spontaneous rhythms of similar rates and regularity, this possibility of this difference cannot be excluded. *Conclusion:* The results of the published literature indicate that: There is some evidence that S-ICD may be accurate in detecting and reversing induced ventricular arrhythmias. There is insufficient evidence to date, to determine the efficacy or effectiveness to S-ICD in terminating spontaneous VT/VF episodes. S-ICD may lead to inappropriate shock therapy in up to 13.1% of cases. There is insufficient evidence to determine the long-term safety of the S-ICD system. There is insufficient evidence to determine that S-ICD is safer or more effective than conventional transvenous ICD. No randomized controlled trial that compared the two devices head to head was published to date. There is insufficient evidence to determine that the use of S-ICD prevents or reduces sudden death from ventricular arrhythmias.

**Articles:** The literature search revealed over 300 citations on subcutaneous implantable cardioverter defibrillator. The majority were reviews or opinion pieces. No published RCTs that compared the safety and efficacy of the S-ICD head to head with the conventional transvenous ICD or other therapeutic interventions were identified; only the published rationale and design of the ongoing PRAETORIAN trial that is comparing the subcutaneous to the transvenous implantable defibrillators. There were a number of published observational studies including those that led to the European approval as well as the pivotal study (Weiss et al, 2013) leading to the US Food and Drug Administration approval. The search also identified a paper documenting the early results from the EFFORTLESS S-ICD Registry that was created to document the clinical, system, and patient-related outcome data from patients implanted with S-ICD in multiple centers in Europe and New Zealand. The pivotal prospective study (Weiss et al, 2013) and a study with a comparison group (Kobe 2013) were selected for critical appraisal: Weiss R, Knight BP, Gold MR, et al. Safety and efficacy of a totally subcutaneous implantable-cardioverter defibrillator. *Circulation*. 2013; 128(9):944-953. See [Evidence Table](#). Köbe J, Reinke F, Meyer C, et al. Implantation and follow-up of totally subcutaneous versus conventional implantable cardioverter-defibrillators: a multicenter case-control study. *Heart Rhythm*. 2013;10 (1):29-36. See [Evidence Table](#).

The use of Subcutaneous Implantable Cardioverter Defibrillator does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Signal-Averaged Electrocardiography (SAECG)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

No review for Medicare members

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Sudden cardiac death (SCD) is a major health problem worldwide. It has been estimated that between 184,000 and 462,000 Americans die suddenly each year from sustained ventricular tachycardia or ventricular fibrillation. The majority have coronary artery disease and left ventricular dysfunction. Multiple large clinical trials have shown that prophylactic implantable cardioverter defibrillator (ICD) can prevent or abort these arrhythmic events and reduce mortality. It is thus critically important to identify those patients at risk to prevent potentially lethal arrhythmias (Cain 1996, Iravanian 2005, Goldberger 2008, Pandey 2010, Stein 2008).

Several invasive and noninvasive approaches or tests have been studied to stratify the patient with risk of ventricular arrhythmia and sudden death. Noninvasive methods include measurement of QRS duration on the 12-lead ECG, measurement of heart rate variability (HRV) and baroreflex sensitivity, detection of non-sustained ventricular tachycardia; signal averaged electrocardiography (SAECG), and several others (Stein 2008).

SAECG was introduced in the 1970s primarily for the detection of patients at high risk of sudden cardiac death after myocardial infarction. It is based on the idea that most life-threatening ventricular arrhythmias are reentrant in nature among patients with structural heart disease. The arrhythmias require an area of slow conduction to allow their perpetuation. These areas of delayed conduction within the ventricular myocardium (ventricular late potentials) can often be demonstrated by invasive electrophysiological studies performed in sinus rhythm. SAECG seeks to detect the occurrence of late activation within the myocardium noninvasively via surface ECG electrodes. It involves computerized analysis of segments of a standard surface ECG to compare and average consecutive QRS complexes (usually around 300) and produce a filtered QRS complex that provides information on the presence of ventricular late potentials (Chandrasekaran 1999, Stein 2008, Liew 2010).

#### Medical Technology Assessment Committee (MTAC)

##### Signal-Averaged Electrocardiography (SAECG)

###### 12/19/2011: MTAC REVIEW

**Evidence Conclusion:** The literature search did not identify any randomized controlled trials that examined the effect of stratifying patients at risk of sudden death based on SAECG, or its effect on improving health outcomes. The results of the published studies showed that the sensitivity of SAECG to predict arrhythmic events ranged from 15% to 75%. It had very low positive predictive value which indicates that it is not a useful when used alone to identify high risk patients. However, SAECG had a high negative predictive value, which may indicate that it could potentially be useful in identifying low-risk patients. Bailey and colleagues (2001) conducted a meta-analysis to examine the utility of various tests for risk stratification. The analysis included 44 studies that evaluated the accuracy of signal-averaged

electrocardiography, heart rate variability, severe ventricular arrhythmia on ambulatory electrocardiography, left ventricular ejection fraction, and electrophysiological studies in predicting risk major arrhythmic events (MAE) after a myocardial infarction (MI). There were variations between the studies in patient characteristics, cutoff points for the tests, and reporting of cause of cardiac death. In addition, the authors of the meta-analysis did not evaluate the quality of the studies, test for homogeneity or publication bias. Overall the analysis shows that the sensitivity of all tests ranged from 42.8% to 62.4% and the specificity ranged from 77.4% to 85.8%. The pooled sensitivity of SAECG was 62.4% (95% CI; 56.4-67.9%) (ranging from 35%-94% in 22 studies involving 9,883 patients), and the pooled specificity was 77.4% (95% CI; 73.6-80.8%, range 62-95.5%). The technology had a low positive predictive value ranging from 8-29%, but a high negative predictive value (81-99%) suggesting that it may have the potential of avoiding unnecessary implantation of a cardioverter-defibrillator (ICD). 3-stage stratification yielded a low-risk group (80.0% with a two-year MAE risk of 2.9%), a high-risk group (11.8% with a 41.4% risk) and an unstratified group (8.2% with an 8.9% risk equivalent to a 2-year incidence of 7.9%). The authors concluded that sensitivities and specificities for the 5 tests were relatively similar and no one test was satisfactory alone for predicting risk. Combinations of tests in stages allowed the authors to stratify 92% of patients as either high-risk or low-risk. They noted that these data suggest that a large prospective study to develop a robust prediction model is feasible and desirable. The CARISMA study (Huikuri 2009) also evaluated the ability of several invasive and noninvasive risk markers to predict arrhythmias after an acute myocardial infarction, with the potential to be treated with an ICD. 5,869 consecutive patients from 10 European centers were screened 2-7 days after experiencing an acute myocardial infarction (AMI), but only 312 met the inclusion criteria and were included in the study. Risk stratification was performed 6 weeks after the AMI using echocardiography, Holter monitoring, microvolt T-wave alternans, SAECG, standard 12-lead ECG, and electrophysiological studies. The primary endpoint was ECG-documented fatal or near-fatal cardiac arrhythmia (ventricular fibrillation or symptomatic sustained ventricular tachycardia). The arrhythmic events were documented with implantable ECG loop recorder. Patients were followed up for 2 years during which 25 (8%) experienced a fatal or non-fatal tachyarrhythmias. The strongest predictor for these events was heart rate variability ( $p < 0.001$ ) as measured by Holter monitor. This was followed by induction of sustained monomorphic ventricular tachycardia during programmed electrical stimulation ( $P = 0.003$ ). QRS duration measured from SAECG had a lower predictive value especially after adjustments were made for clinical variables. An assessment made for AHRQ in 1998 also found that SAECG had variable sensitivity and specificity, poor positive predictive value, but relatively high negative predictive value (NPV) for post MI fatal arrhythmic events. The high NPV was attributed to the low incidence of fatal arrhythmic events post MI, due to the increase use of antithrombotic therapy. The 2006 American College of Cardiology, American Heart Association and European Society of Cardiology guidelines (Zippes 2006) for management of patients with ventricular arrhythmias and prevention of sudden death, list SAECG with a Class IIb recommendation (Class IIb noted as usefulness/efficacy is less well established by evidence/opinion). The report notes that the presence of an abnormal SAECG was shown to increase the risk of arrhythmic events by 6- to 8-fold in a post-MI setting. However, the restoration of patency to the infarct-related coronary artery with fibrinolysis or angioplasty and the widespread use of surgical revascularization have modified the arrhythmogenic substrate, leading to a noticeable reduction in the predictive power of this tool. The report indicated that SAECG in isolation is no longer useful for the identification of post-MI patients at risk of ventricular arrhythmias. A number of health plans consider signal-averaged electrocardiography investigational and not medically necessary for all indications including risk stratification for arrhythmias after a myocardial infarction. Conclusion: In evaluating any method for risk stratification it is important to demonstrate that the test or marker can be used to select patients for a therapy or intervention that will improve outcome. Signal-averaged electrocardiography (SAECG) has been proposed as a noninvasive method for arrhythmia risk stratification. However, there is insufficient published evidence to its efficacy in establishing the risk of ventricular arrhythmias and sudden death. There is also insufficient evidence to determine clinical utility of SAECG testing in selecting patients for receiving pharmacological therapy, ICD implantation or other treatments.

**Articles:** The literature search did not identify any large prospective or randomized trials that examined the benefit of using SAECG for selecting patients for electro physiologic studies, or its clinical utility for selecting patients for prophylactic therapies and/or interventions, and improving health outcomes. There was a large number of earlier studies conducted in the 1990s that examined the accuracy of SAECG and various other variables in predicting the risk of major arrhythmic events after a myocardial infarction, and a meta-analysis (Bailey 2001) that pooled the results of these studies published before 2001. The search also identified a more recent study (CARISMA study) that evaluated the ability of several invasive and noninvasive risk markers to predict arrhythmias that can potentially be treated with an ICD, and another study that compared the ability of SAECG and ejection fraction for predicting future cardiovascular events including life threatening arrhythmias in different cardiac diseases. The meta-analysis and CARISMA study were selected for critical appraisal: Bailey JJ, Berson AS, Handelsman H. Utility of current risk stratification

test for predicting major arrhythmic events after myocardial infarction. *J Am Coll Cardiol* 2001; 38:1902-1911. See [Evidence Table](#) Huikuri HV, Raatikainen MJ, Moerch-Joergensen R, et al. Prediction of fatal or near-fatal cardiac arrhythmia events in patients with depressed left ventricular function after an acute myocardial infarction. *Eur Heart J*. 2009;30:689-698. See [Evidence Table](#)

The use of SAECG does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Inpatient Skilled Nursing Facility

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

On initial review, Group Health will use the Recovery MCG\* for inpatient skilled nursing facility, but if criteria are not met, then the [Medicare Benefit Policy Manual \(chapter 8, section 30\) for inpatient skilled nursing facility coverage](#) must be used.

##### For Non-Medicare Members

To meet Skilled Nursing facility coverage eligibility requirements, **ALL of the following 3** factors must be met:

##### Admission:

- A. Must meet **One** or more of the following to qualify for admission to Skilled Nursing Service, Skilled Rehab Service or both:
  1. **Requires Skilled Nursing** of RN, LPN, PT, OT, or SLP: Inherent complexity of service is such that it can be performed safely and/or effectively only by, or under, general supervision of licensed professionals and cannot be provided by non-skilled personnel. Requires skilled services on a daily basis. Patients functional or medical complexity are such that outcome would be compromised with less than daily skilled services. Multiple skilled nursing services are required daily 7d/wk. **Skilled Nursing Services** must meet **ONE or more** of the following:
    - a. Injections: IV, IM, SQ (new &/or complex needs, not typically for insulin)
    - b. Intravenous: fluids, meds, or line flushes
    - c. Nebulizers: oxygen eval saturations when unstable, complex
    - d. Enteral feedings new or enteral pt with recent change in medical condition requiring monitoring
    - e. Care of new colostomy or teaching ostomy care associated with complication
    - f. Frequent suctioning, trach, &/or vent needs
    - g. Frequent irrigation, replacement of urinary catheters; care of new/complex suprapubic catheter
    - h. Treatment Stage III/IV pressure ulcers; widespread skin disorder or complex wounds requiring RN/LPN wound tx
    - i. Nursing evaluation of unstable & complex medical condition, e.g. recovery from septicemia, coma, severe resp disease, uncontrolled pain
    - j. Nursing rehab teaching, e.g. bowel & bladder training, adaptive aspects of care.
  2. **Skilled Rehab Services:** Requires rehab teaching, training, or monitoring. Complexity and sophistication of treatment is such that the specialized skills of a therapist are needed. Pt is significantly below baseline level of function and is able to learn and retain new information and skills. **Note:** Rehab services are not required for deconditioning/ temporary reduction in function which could reasonably be expected to spontaneously improve as pt gradually resumes activities. Repetitious exercises to improve gait or maintain strength and endurance and assistive walking are appropriately provided by supportive personnel and do not meet skilled rehab criteria.

Must meet **ALL of the following** below for **Skilled Rehab Services:**

- a. Requires establishment and ongoing assessment of a complex rehab treatment plan such as gait training in patients with neurological, muscular or skeletal abnormality, use of new assistive device, compensatory strategies, cg training, monitoring of activity tolerance with vital signs or O2 checks.
- b. Patient requires more than minimal or light physical assist for basic ADLs and mobility (based on evidence that patients needing only minimal assist do comparably well with Home Health therapy and do not need daily rehab)
- c. Does not require one or two more hospital days to arrange home care plan. If pt requires only one or two more hospital days to arrange home care plan, then would not require inpt SNF daily rehab or nursing.

3. Patients receiving **elective total joint replacements** often need additional caregiving assistance that can be provided by non-professional staff and intermittent therapy services (not daily). In the event a total joint replacement patient is referred to SNF for daily therapy, **you must** check functional mobility levels; patients requiring minimal assistance or less (<25% assist) generally do not require daily therapy by a licensed therapist. Some patients have post-operative pain or nausea which may impede progress initially. For those patients, an additional day or two in the hospital may avoid a SNF stay. Elective Total Joint patients must meet **one** of the following:
  - a. Patient requires moderate or greater level of assistance with overall mobility. (This does not mean that there is just one area where patient needs moderate assistance. i.e.: min A with t/f and gait, but Mod A with supine<>sit would not indicate a daily need.)
  - b. Patient is functioning at minimal assist with mobility- review with NHS/ CRUS MD to determine if patient has need for daily therapy at this high functional level.
- B. **Requires inpatient SNF level of care** - Complexity and frequency of needs for skilled services require inpt setting; requires multiple skilled treatments daily (can be combination of nursing & rehab), or need for daily skilled services exceeds care available at lesser levels such as home with Home Health.
- C. **SNF inpatient services are reasonable and medically necessary** (i.e. consistent with the nature and severity of the individual's illness or injury, the individual's particular medical needs, and accepted standards of medical practice. The services must also be reasonable in terms of duration and quantity.)

### For continued stay and discharge

Group Health has elected to use MCG\* for inpatient skilled nursing facility coverage medical necessity determinations.

**\*MCG are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed by our Nursing Home Services department, you may request a copy of the criteria that is being used to make the coverage determination. Call Nursing Home Services for more information regarding the case under review.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Skilled nursing facility services are frequently required to transition patients from the hospital setting to home. At times these services must be delivered in a skilled nursing facility because of patient care needs and clinical condition. When the member has coverage for this care the skilled nursing facility admission criteria must be met for eligibility. Members who require this level of care but do not have coverage must pay for the service themselves. Because the majority of members requiring this service have Medicare coverage, Medicare criteria were used as a guide in the development of the Group Health criteria.

###### Evaluation of Origin of Behavior Problems

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

**No review required for other indications.**

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Single Photon Emission Computed Tomography (SPECT) is a nuclear medicine technique that can be used to image almost any organ system. SPECT imaging is performed by acquiring multiple images (aka projections) with a gamma camera. A topographic reconstruction algorithm is then applied to the multiple two-dimensional projections, resulting in a three-dimensional dataset. To acquire the images, the gamma camera is rotated around the patient. The camera typically moves 3-6° each time until a 360° rotation is achieved. Each image takes approximately 15-20 seconds, for a total scanning time of approximately 15-20 minutes.

Brain imaging with SPECT is generally performed with the radiopharmaceutical hexamethylpropylene amine oxime (99mTc-HMPAO). 99mTc emits gamma rays that are detectable by a gamma camera. When attached to HMPAO, it can be taken up by brain tissue at a rate proportional to brain metabolism. Brain blood flow is highly correlated to local brain metabolism and energy use. Areas of the brain that are undergoing increased neuronal activity consume greater amounts of oxygen and energy and are perfused more, and areas of the brain that are less functionally active are perfused less. The SPECT image thus indirectly reflects cerebral metabolism. Patients undergoing brain SPECT are exposed to approximately 2-8 mSv of radioactivity, a level comparable to a CT scan. 99mTc-HMPAO SPECT brain scanning provides similar information about local brain function to FDG PET scans and functional MRI. Although PET has a higher resolution, the SPECT equipment is less expensive and may be more widely available. While MRI and PET are limited to hospitals due to their cost, SPECT equipment can be installed in physicians' offices (Overmeyer & Taylor, 2001).

A report contracted by the American Psychiatric Association (APA) in 2005 concluded that SPECT is useful for research on psychiatric disorders, and for diagnosing cerebral trauma, seizure disorders and brain tumors for which there are detectable patterns of perfusion abnormalities. However, the authors found insufficient evidence to support the use of SPECT for the diagnosis and treatment of psychiatric disorders in the pediatric population. The

APA report stated that there is a lack of evidence linking a particular structural or functional brain abnormality to a single psychiatric disorder. In addition, the authors cautioned that the long-term effects of using the radioactive nucleotides associated with SPECT imaging in children and adolescents are not known.

A group of SPECT practitioners have criticized the APA report as being flawed and misleading (Wu et al, unpublished manuscript). They counter the APA claim that SPECT cannot yet diagnose psychiatric illness with the statement that clinicians do not rely on SPECT to make psychiatric diagnoses. Instead, SPECT practitioners use brain imaging as another source of data, along with clinical presentation, to help them make informed decisions about diagnosis. They also state that it is unfair to single out the possible danger associated with radioactive nucleotides used with SPECT imaging since children are treated with other nuclear medicine procedures such as studies for cardiovascular, cerebrovascular and orthopedic disease. They report that the average radiation exposure for one SPECT scan is similar to the exposure from a bone scan, brain CT scan or abdominal x-ray.

## Medical Technology Assessment Committee (MTAC)

### Single Photon Emission Computed Tomography

#### 10/02/2006: MTAC REVIEW

**Evidence Conclusion:** In order to demonstrate that SPECT brain imaging is able to accurately diagnose behavior problems, there needs to be sufficient evidence that particular SPECT findings correlate with specific behavioral conditions, and that SPECT is sensitive and specific at diagnosing these conditions compared to a gold standard diagnostic tool. Most of the published studies on the first topic, SPECT findings associated with a clinical behavior problem are too small to produce reliable estimates. The largest study was by Amen and colleagues (1997). They compared SPECT scans of children with and without ADHD both at rest and while performing an intellectual stress task. The study found significantly decreased prefrontal activity during the intellectual stress activity in the ADHD group, but not the non-ADHD group. The Amen study is inconclusive due to the small sample size and lack of adjustment for confounding variables. Moreover, since only 65% of the participants with ADHD had decreased prefrontal activity during intellectual stress, it is not clear how the SPECT information would be used to help diagnose ADHD. In addition, Dr. Amen has a private clinic that performs SPECT which may bias the study's methods and conclusions. Gustafsson and colleagues performed a variety of tests on 28 children with ADHD, including brain SPECT and EEG. The investigators did not find a significant association between EEG and SPECT findings. They found several statistically significant correlations between regional cerebral blood flow detected by SPECT and several instruments, particularly the number of Minor Physical Abnormalities (MPA). The vast majority of statistical comparisons were not statistically significant, and since such a large number of comparisons were performed at  $p < 0.05$ , some significant findings would be expected by chance alone. No empirical evidence was identified on the effectiveness of brain SPECT at assisting practitioners in making a clinical diagnosis, e.g. of ADHD. Such a study would compare the diagnosis made by practitioners with and without information from SPECT, with the diagnosis confirmed by a qualified objective third party. In addition, there was no empirical evidence on the long-term safety of SPECT brain imaging in children. In conclusion, there is insufficient evidence in the published literature on the ability of SPECT brain imaging to diagnose behavior problems or assist clinicians in making a diagnosis, and insufficient evidence on the safety of brain SPECT in the pediatric population.

**Articles:** Objective 1a: The ideal study design is a comparison of brain function or structure as assessed by SPECT among individuals with and without behavioral problems. Methodological features include sufficient sample size, appropriate selection of controls, matching or controlling for confounding variables, objective confirmation of diagnosis and appropriate statistical analysis. Several studies were identified that compared brain activity using SPECT among children with ADHD and healthy controls. The studies were generally limited by small sample sizes. Most included 20 or fewer children with ADHD and 7 or fewer controls. The largest study ( $n=54$  ADHD,  $n=18$  non-ADHD) was conducted by a prominent SPECT practitioner (Dr. Amen)—this study was critically appraised. Objective 1b: The ideal study of diagnostic accuracy would report the sensitivity and specificity of SPECT imaging, and include an independent blinded comparison to a "gold standard" diagnosis. No studies that met the above criteria were identified. Only one study compared SPECT findings to another imaging technique, EEG (Gustafsson et al., 2000) and this study was critically appraised.

Objective 2: A strong study would compare the accuracy of the diagnosis made with and without information from SPECT imaging, with the diagnosis confirmed by an objective expert such as experienced psychiatrist blinded to diagnosis. No relevant studies were identified. Objective 3: No studies were identified on the long-term safety of SPECT brain imaging in children. *The studies that were critically appraised were:*

Amen DG, Carmichael BD. High-resolution brain SPECT imaging in ADHD. *Ann Clin Psychiatry* 1997; 9: 81-86. See [Evidence Table](#). Gustafsson P, Thernlund G, Ryding E et al. Associations between cerebral blood flow measured by single photon emission computed tomography (SPECT), electro-encephalogram (EEG), behavior symptoms, cognition and neurological soft signs in children with attention-deficit hyperactivity disorder (ADHD). *Acta Paediatr* 2000; 89: 830-835. See [Evidence Table](#).

The use of Single Photon Emission Computed Tomography in the evaluation of origin of behavior problems does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

Group Health has elected to use the Speech Generating Devices (GHC-0516 v17) MCG\* for medical necessity determinations.

**MCG\* are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider and/or specialist (neurology)
- Speech therapy notes

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Augmentative and alternative communication (AAC) is an area of clinical practice that attempts to temporarily or to permanently compensate for the impairment and disability patterns of children with severe oral and written expressive communication disorders. Interventions that use AAC should incorporate the individual's full communication abilities e.g. any existing speech or vocalization, gestures, manual signs, communication boards, and speech output communication devices. Abilities may change over time and the AAC may need to be modified as a child grows and develops.

AAC has four components: symbols, aids, techniques, and strategies. Aids are the physical objects or devices used to transmit or receive messages. These include books, communication boards, charts, mechanical or electronic devices, and computers. The AAC devices have variable capabilities, durability, and cost. The delivery of AAC services to children with severe spoken language disorders requires the collaboration and competence of families, professionals, and paraprofessionals. Effective, co-coordinated multidisciplinary and an integrated service is crucial in achieving optimal outcome for the children.

The role an AAC system plays in a particular child's life varies with the type and severity of the language disorder. Children with congenital language disorders who may benefit from AAC include those with cerebral palsy, dual sensory impairments, developmental apraxia, oro-motor dyspraxia, language learning disabilities, mental retardation, autism, and pervasive developmental disorders. Acquired language disorders include: traumatic brain

injury, aphasia, spinal cord injuries, and other physical disabilities. Not all these indications are covered by health insurance companies.

## Medical Technology Assessment Committee (MTAC)

### Augmentative Communication Devices

#### 02/13/2002: MTAC REVIEW

**Evidence Conclusion:** The study reviewed had several limitations; it had a small sample size, lacked a control group, used only subjective measures, and was subject to selection and observation biases. In conclusion the literature available does not provide enough evidence to determine the effect of the augmentative communication devices on the communication skills of children with speech impairments.

**Articles:** The search yielded 43 articles. Most were reviews, tutorials, notes, and discussions. The search did not reveal any randomized controlled trials, or meta-analyses, only four case reports and two studies that only measured young patients' or parents' satisfactions and /or utilization of the communication systems. The study with the larger sample size was selected for critical appraisal. *An evidence table was created for the following study:* Ko MLB, et al. Outcome of recommendations for augmentative communication in children. *Child Care, Health and Development* 1998; 24(3): 195-205. See [Evidence Table](#).

The use of augmentative communication devices on the communication skills of children with speech impairments not voted using the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

Dorsal column (spinal cord) neurostimulation is the surgical implantation of neurostimulator electrodes within the dura mater (endodural) or the percutaneous insertion of electrodes in the epidural space.

- A. Group Health covers a **short-term** trial of a dorsal column spinal cord stimulator (SCS) as medically necessary for the treatment of chronic, intractable pain secondary to **ONE of the following** indications:
  1. Failed back syndrome (FBS) with intractable neuropathic leg pain **OR**
  2. complex regional pain syndrome (CRPS)/reflex sympathetic dystrophy (RSD) when **ALL of the following** criteria are met:
    - a. Failure of at least six consecutive months of physician-supervised conservative medical management (e.g., pharmacotherapy, physical therapy, cognitive therapy, and activity lifestyle modification)
    - b. Surgical intervention is not indicated
    - c. An evaluation by a mental health provider (e.g., a face-to-face assessment with or without psychological questionnaires and/or psychological testing) reveals no evidence of an inadequately controlled mental health problem (e.g., alcohol or drug dependence, depression, psychosis) that would negatively impact the success of a SCS or contraindicate its placement
- B. Group Health covers **permanent** implantation of a dorsal column spinal cord stimulator (SCS) as medically necessary for the treatment of chronic, intractable pain secondary to **ONE of the following** indications:
  1. Beneficial clinical response from a temporarily implanted electrode has been demonstrated prior to consideration of permanent implantation (Member experienced significant pain reduction (50 % or more) with a 3- to 7-day trial)
  2. Covered for the **ONE of the following** indications:
    - a. Failed back syndrome (FBS) with intractable neuropathic leg pain **OR**
    - b. Complex regional pain syndrome (CRPS)/reflex sympathetic dystrophy (RSD) when **ALL of the following** criteria are met:
      - o failure of at least six consecutive months of physician-supervised conservative medical management (e.g., pharmacotherapy, physical therapy, cognitive therapy, activity lifestyle modification)
      - o surgical intervention is not indicated
      - o an evaluation by a mental health provider (e.g., a face-to-face assessment with or without psychological questionnaires and/or psychological testing) reveals no evidence of an inadequately controlled mental health problem (e.g., alcohol or drug dependence, depression, psychosis) that would negatively impact the success of a SCS or contraindicate its placement

##### High Cervical Epidural Neurostimulation (Spinal Cord Stimulator) for Migraine/Cluster Headaches

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Spinal cord stimulation (SCS) involves insertion of a stimulator electrode into the spinal cord that is connected to a power source. Patients are routinely screened for their likelihood of being a good SCS candidate by temporary placement of a percutaneous epidural electrode. Patients who respond well during the trial period (generally defined as 50% pain relief) can undergo permanent electrode placement. Both temporary and permanent devices are manufactured by Medtronic, Inc.

The most common application of SCS in the United States is chronic low back pain; SCS has also been used for plexus lesions, peripheral nerve injury, reflex sympathetic dystrophy, post amputation pain syndromes, spinal cord injury, post cordotomy dysesthesia, peripheral vascular disease and angina pectoris (North, 1995).

MTAC has previously reviewed SCS. The initial review of SCS in April 2000 evaluated the use of SCS to treat intractable pain and was not limited to a particular disease or condition. At that time, the evidence consisted of case series and a small RCT with threats to validity on SCS for failed back pain syndrome (North, 1995). The item failed MTAC evaluation criteria. Conclusions about the North RCT in this review were: "Preliminary results of this RCT show that more patients assigned to reoperation choose to crossover to SCS than patients assigned to SCS opt for re-operation. It is not known from this study whether actual pain relief is greater for SCS than re-operation."

In October 2000, a second review was conducted due to the publication of a RCT on the effect of SCS on functional status and pain in patients with chronic reflex sympathetic dystrophy (Kemler, 2000). Again, SCS failed MTAC evaluation criteria. Conclusions about the Kemler study in the MTAC report were: "In the intention to treat analysis, this new RCT did not find a difference in functional status improvement between the two groups. There was significantly greater improvement in the SCS group in two outcome measures (pain score as measured by a visual-analogue scale, global perceived effect of intervention), but not in health-related quality of life. A substantial proportion of patients experienced complications. The study had several limitations, which include:

- The choice of physical therapy as the comparison intervention. All patients in the study had already failed 6 months of physical therapy. This may have biased the study towards finding improved outcomes with the SCS intervention, which had not yet been attempted with these patients.
- Potential bias towards more positive responses on self-report measures among patients who received the SCS intervention (a new and more intensive intervention, patients were not blinded).
- The difference in scores between groups on the pain measure, although statistically significant, has unclear clinical significance.
- The analysis that compared patients who actually received SCS to those assigned to physical therapy is subject to selection and observation biases. The analysis is biased towards finding a positive outcome in the SCS group since only patients shown to benefit from SCS during the test period were included and the comparison group included patients previously found to receive no sustained benefit from physical therapy.

Due to the above factors, the new evidence is not sufficient to permit conclusions about the effects of spinal cord stimulation on health outcomes for patients with reflex sympathetic dystrophy."

The current review attempted to identify any recent literature on the use of SCS for intractable pain; the review was not limited to any specific condition.

## Medical Technology Assessment Committee (MTAC)

### *High Cervical Epidural Neurostimulation (Spinal Cord Stimulator) for Migraine/Cluster Headaches*

#### BACKGROUND

Implanted electrical stimulation devices have been used for the management of chronic intractable pain since the late 1960s. One of the most commonly used devices is the spinal cord stimulation (SCS) system. This consists of a lead tipped with 4-16 electrodes and a small implantable device. The latter may be battery operated, or powered by an externally worn power source. Electrical current from the lead generates paresthesia that can be adjusted in intensity and location to achieve the optimum pain relief (North 2003, 2005, Buchser 2006). Candidates for this therapy include patients with intractable chronic pain of the body and limbs, continued pain after back surgery, reflex sympathetic dystrophy, and complex regional pain syndrome. SCS has been used for decades to treat

neurogenic pain. It is now being evaluated for the use in patients with migraines and cluster headaches. Patients with pacemakers, implantable cardioverter defibrillators, untreated drug addicts, and pregnant women are not candidates for the therapy (Arcidicono 2006). It is also contraindicated for patients with chronic anticoagulation, severe distortion or disease of the spinal column, or infection at the insertion site. Patient cooperation is essential for the successful use of SCS therapy. It should not be used by patients who cannot operate the device e.g. those with cognitive, psychiatric, or psychomotor disorders (North 2003, North 2005, and Arcidicono 2006). Spinal cord stimulation was approved by the FDA for the treatment of chronic intractable pain in the trunk and limbs, but it has not been approved for the use in migraines and cluster headaches. This technology has been reviewed previously for the use in back pain, leg pain, refractory angina, and critical leg ischemia

#### **04/19/2010: MTAC REVIEW**

##### **High Cervical Epidural Neurostimulation (Spinal Cord Stimulator) for Migraine/Cluster Headaches**

**Evidence Conclusion:** Currently, there is insufficient evidence to evaluate this technology as the literature only consists of case reports and case series with less than twenty-five participants. Two randomized controlled trials, the Precision Implantable Stimulator for Migraine (PRISM) and the Occipital Nerve Stimulator for the Treatment of Intractable chronic Migraine (ONSTIM), have recently been completed and results are pending.

**Articles:** Currently, there is insufficient evidence to evaluate this technology as the literature only consists of case reports and case series with less than twenty-five participants. Two randomized controlled trials, the Precision Implantable Stimulator for Migraine (PRISM) and the Occipital Nerve Stimulator for the Treatment of Intractable chronic Migraine (ONSTIM), have recently been completed and results are pending.

The use of High cervical epidural neurostimulation (Spinal Cord Stimulator) for the treatment of migraine/cluster headaches does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **Spinal Cord Stimulators in the Treatment of Intractable Pain**

##### **04/12/2000: MTAC REVIEW**

**Evidence Conclusion:** There is weak evidence from the case series studies that about half of patients with back or extremity pain who tolerate SCS for a year have a successful outcome one year post-implantation. The Broggi et al. study provides weak evidence that long term success rates (i.e. 5 years) are low. Conclusions about efficacy cannot be drawn from the RCT because of the small sample size, high refusal rate and poor outcome measurement. Complications from SCS are mainly minor, but these often require reoperation. There is insufficient evidence to draw conclusions about the efficacy of SCS for peripheral vascular diseases, peripheral neuropathy, multiple sclerosis and reflex sympathetic dystrophy.

**Articles:** Articles were selected based on study type; there was one randomized controlled trial (RCT), there were no cohort studies or meta-analyses. The remaining empirical studies were case series. Most addressed one clinical area (predominantly failed back surgery syndrome) and several addressed intractable pain in multiple clinical areas. There was one small case series each on peripheral vascular disease (n=10), reflex sympathetic dystrophy (n=12) and peripheral neuropathy (n=10). Articles on critical limb ischemia, angina pectoris and spinal cord injury were not considered for this review (these conditions were not specified in the MTAC request).

*Evidence tables were created for the three largest case series studies and one RTC. These examined:* Burchiel, KJ, Anderson, VC, Brown, FD, Fessler, RG, Friedman, WA, Pelofsky, S, Weiner, RL, Oakley, J, Shatin, D. Prospective, multicenter study of spinal cord stimulation for relief of chronic back and extremity pain. *Spine* 1996; 21: 2786-2794. See [Evidence Table](#). Failed back surgery syndrome (De la Porte, C, Van de Kelft, E. Spinal cord stimulation in failed back surgery syndrome. *Pain* 1993; 52: 55-61); See [Evidence Table](#). Multiple conditions (Broggi, G, Serville, D, Dones, I, Carbone, G. Italian multicentric study on pain treatment with epidural spinal cord stimulation. *Stereotact Funct Neurosurg* 1994; 62: 273-278). See [Evidence Table](#). (North, RB, Kidd, DH, Piantadosi, S. Spinal cord stimulation versus reoperation for failed back surgery syndrome: A prospective, randomized study design. *Acta Neurochir* 1995; 64: 106-108). See [Evidence Table](#). Kemler MA, Barendse GAM, Kleef VM, deVet HCW, Rijks CPM, Furnee CA, Van Den Wildenberg, NEJM. Spinal cord stimulation in patients with chronic reflex sympathetic dystrophy. *N Engl J Med* 2000; 343: 618-24. See [Evidence Table](#).

The use of Spinal Cord Stimulators in the treatment of intractable pain does not meet the *Group Health Medical Technology Assessment Criteria*.

##### **10/11/2000: MTAC REVIEW**

##### **Spinal Cord Stimulators in the Treatment of Intractable Pain**

**Evidence Conclusion:** In the intention to treat analysis, this new RCT did not find a difference in functional status improvement between the two groups. There was significantly greater improvement in the SCS group in two outcome measures (pain score as measured by a visual-analogue scale, global perceived effect of intervention), but not in health-related quality of life. A substantial proportion of patients experienced complications.

*The study had several limitations, which include:* The choice of physical therapy as the comparison intervention. All patients in the study had already failed 6 months of physical therapy. This may have biased the study towards finding improved outcomes with the SCS intervention, which had not yet been attempted with these patients. Potential bias towards more positive responses on self-report measures among patients who received the SCS intervention (a new and more intensive intervention, patients were not blinded). The difference in scores between groups on the pain measure, although statistically significant, has unclear clinical significance. The analysis that compared patients who actually received SCS to those assigned to physical therapy is subject to selection and observation biases. The analysis is biased towards finding a positive outcome in the SCS group since only patients shown to benefit from SCS during the test period were included and the comparison group included patients previously found to receive no sustained benefit from physical therapy. Due to the above factors the new evidence is not sufficient to permit conclusions about the effects of spinal cord stimulation on health outcomes for patients with reflex sympathetic dystrophy

**Articles:** The search yielded 184 articles. Many of these were reviews or opinion pieces, were on related procedures or evaluated SCS for indications other than pain relief. There were 4 new RCT publications, but none of these was a new study comparing SCS to an alternative intervention. The new articles consisted of an additional publication on the Kemler 2000 data previously reviewed by MTAC, two studies that compared different SCS techniques (two types of electrodes in North, 2002 and two ways to adjust stimulation in North, 2003), and one study that compared two types of drugs given to patients who had SCS implanted (Harke, 2001). No new large case series or cohort studies were identified. There was no new evidence to critically appraise.

The use of Spinal Cord Stimulators in the treatment of intractable pain does not meet the *Group Health Medical Technology Assessment Criteria*.

## **12/04/2006: MTAC REVIEW**

### **Spinal Cord Stimulators in the Treatment of Intractable Pain**

**Evidence Conclusion:** *Spinal cords stimulation (SCS) in complex regional pain syndrome (CRPS) and refractory neuropathic back and leg pain/failed back surgery syndrome (FBSS)* Kemler et al, studied the effect of SCS plus physical therapy versus physical therapy alone, in the treatment of 54 patients with resistant chronic reflex sympathetic dystrophy. The trial was randomized and controlled, and the patients were followed up for 24 months. However, the patients and providers were not blinded, and the primary outcomes were mainly self-reported and subject to bias. There was no comparison arm with a sham treatment to exclude the placebo effect and reduce bias. The SCS therapy was compared to physical therapy, which is not the ideal control as the study participants were those who did not have a sustained response to standard treatment including physical therapy. The results of the trial show that patients randomized to receive SCS plus PT (ITT analysis) or those who actually received a permanent SCS implant plus PT had statistically greater improvement in the two self-reported outcome measures (pain score as measured by a visual-analogue scale, global perceived effect of intervention). No statistical difference between two groups in the functional status was observed. There was a significant improvement in the QoL among patients who actually received the SCS implant plus PT vs. PT alone. The SCS therapy was associated with side effects among all patients who received it, and 38% needed a reoperation related to the implant. North and colleagues' (2005) RCT evaluated the use of spinal cord stimulation versus reoperation for the treatment of patients with failed back surgery syndrome (FBSS). The investigators included 50 patients with pain refractory to conservative treatment, with concordant neurological, tension, and/or mechanical signs and imaging findings of neural compression. The follow-up duration was 2 years, and the study outcomes were the frequency of crossover to alternative procedure, pain control and patient satisfaction. The results show that significantly more patients in the SCS group achieved  $\geq 50\%$  pain relief compared with those who underwent reoperation (37.5 % vs. 12 %,  $p= 0.02$ ). They also required significantly less opioid analgesics. The rate of cross over to the other treatment was significantly less among those randomized to spinal cord stimulation. The trial had several exclusion criteria, which may limit generalization of the results. *Spinal cord stimulation for the management of refractory angina pectoris:* The published studies on the use of SCS for the treatment of refractory angina were all conducted in Europe. In the ESBY trial, 104 patients at high risk for coronary artery bypass surgery were randomized to SCS or CABG. The follow-up duration was 4.8 years, and the primary outcome was the effect of treatment on angina. The trial was randomized, controlled, and had clinically important outcomes. However, due to the nature of the intervention it was unblinded, it was relatively small, and may have had insufficient power to detect statistically significant differences between the two intervention groups. No comparison was made to a sham treatment, thus the placebo effect of the SCS cannot be ruled out. The results of the study show that there was a significant improvement in the quality of life in the two treatment groups when compared to baseline. The differences in the observed improvement in quality of life and survival were not significant between the two interventions. The study was not designed as equivalence study, and the absence of significant difference does not necessarily indicate that the two treatments were comparable or equivalent. The SPiRiT trial compared the effects of SCS versus percutaneous myocardial laser revascularization, on treadmill exercise time, among patients with refractory angina pectoris. The trial was randomized and controlled. However, it was unblinded, with an

intermediate primary outcome, and short follow-up duration. Its results show that there were no significant differences between the two treatment groups in the exercise tolerance at 3 and 12 months (primary outcome). Also, no significant differences were observed in the 2 or more points improvement on the Canadian Cardiovascular Society angina class, or quality of life. Patients in the SCS group had a significantly higher event rate mainly angina or system related. A placebo effect may contribute to the improvement in anginal symptoms after SCS. The only sham controlled RCT conducted was a very small trial (n=25) that implanted the SCS in all patients but was left it inactivated for 6 weeks in the control group. The study was too small, had only 6 weeks of follow-up, and other limitations. *Spinal cord stimulation for the management of critical leg ischemia (CLI)* The published studies on the use of SCS for the treatment of critical leg ischemia were also conducted in European countries. The three meta-analyses published by Ubbink and colleagues (2004, 2005, and 2006) pooled data from 5 RCTs and one nonrandomized controlled trial. The sample sizes in these trials varied from 37 to 120 with a total of 444 participants. All suffered from inoperable CLI with ischemic rest pain or ulcers < 3cm in diameter. In these trials, the patients received standard control treatment with or without SCS, and the primary outcome was limb salvage (no amputation of foot or higher within 12 months). The meta-analysis had valid methodology. The trials included were small, but were judged by the authors to have good quality. The results of the analysis indicate that highly selected patients with inoperable critical limb ischemia had better outcomes with the SCS therapy compared to those who were treated conservatively. They experienced significantly less amputation rates in 12 months (NNT to salvage a limb was 9), and showed significant clinical improvement (NNT to improve the condition from critical leg ischemia to claudications =3). The procedure was not associated with a difference in mortality or QoL vs. conservative treatment. **Conclusion:** There is insufficient evidence to determine the long-term benefits and safety of SCS therapy among patients with refractory neuropathic back and leg pain, failed back surgery, and chronic reflex sympathetic dystrophy. There is insufficient published evidence to determine the long-term efficacy and safety of SCS in treating patients with chronic refractory angina. There is fair evidence from a meta-analysis of small trials that the addition of SCS to the standard conservative therapy for patients with chronic critical leg ischemia may improve the clinical condition of the leg and lead to less amputation rates.

**Articles:** The search yielded 199 articles. Many were reviews or opinion pieces, or small case series with no control or comparison groups. *Spinal cord stimulation (SCS) in complex regional pain syndrome (CRPS) and refractory neuropathic back and leg pain/failed back surgery syndrome (FBSS)* The search revealed 2 systematic reviews (Taylor 2004, and Taylor 2006) of studies that used spinal cord stimulation in complex regional pain syndrome (CRPS) and refractory neuropathic back, and leg pain/failed back surgery syndrome (FBSS). It also revealed a RCT on SCS for chronic pain (North 2005), and a more recent publication with a longer-term follow-up for a RCT (Kemler 2000) that was previously reviewed for MTAC in 2000. Several small case series with no comparison or control groups were also identified. The 2 systematic reviews were conducted by the same principal author, and had several limitations. The results of the included RCTs were presented individually without pooling of data, and the results of case series were pooled. The quality of the included case series was poor as judged by the authors; they were heterogeneous, and subject to bias. Due to these as well as other limitations, the meta-analyses were not presented in evidence tables. Evidence tables were constructed for the North et al RCT, and the more recent publication of Kemler and colleagues' RCT with the 2-year follow-up data. *Spinal cord stimulation for the management of refractory angina pectoris:* The literature search revealed three RCTs and several case series. One RCT compared SCS with coronary artery bypass grafting (ESBY trial), another compared it with percutaneous myocardial laser revascularization (SPiRiT), and in the third trial (Hautvast 1998) all patients received the SCS implant but the stimulator was inactivated in the control group for the 6 weeks of study. This last trial was not critically appraised due to its small sample size (n=25), short follow-up duration as well as other limitations in the trial. The ESBY and SPiRiT trials were critically appraised. *Spinal cord stimulation for the management of critical leg ischemia:* The literature search revealed 5 randomized controlled trials, and one non-randomized comparative study on the use of SCS for the treatment of critical leg ischemia. It also revealed three systematic reviews; all conducted by the same principal authors. These analyses pooled the results of the published RCTs. All three were critically appraised and presented in one evidence table. *The following articles were critically appraised:* Kemler MA, deVet HCW, Barendse GAM, et al. The effect of spinal cord stimulation in patients with chronic reflex sympathetic dystrophy: two years' follow-up of the randomized controlled trial. *Ann Neurol* 2004;55:13-18. See [Evidence Table](#). North RB, Kidd DH, Farrokhi F, et al. ## Clinical Review Criteria

### Spinal Fusion

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Use the non-Medicare criteria, below.

See also the following Medicare Technology Center article - [Spinal Fusion for the Treatment of Low Back Pain Secondary to Lumbar Degenerative Disc Disease](#)

##### For Non-Medicare Members

###### LUMBAR SPINE

Spinal Fusion may be indicated for **ONE or more of the following**

- 1) Spinal fracture (acute) repair indicated by **ONE or more of the following**:
  - Spinal instability due to trauma
  - Neural compression due to trauma
- 2) Lumbar spinal stenosis treatment indicated by **ALL of the following**:
  - Imaging findings of lumbar spondylolisthesis
  - Spondylolisthesis for spine fusion (> or equal to 4 mm).
  - Clinically important findings of spinal stenosis indicated by **ONE or more of the following**:
    - i. Progressive or severe symptoms of neurogenic claudication or radicular pain requiring treatment as indicated by **ALL of the following**:
      - Significant functional impairment
      - Central, lateral recess or foraminal stenosis demonstrated on imaging (e.g., MRI, CT myelography)
      - Failure of at least 3 months of non-operative therapy
    - ii. Severe or rapidly progressive symptoms of motor loss, neurogenic claudication or cauda equina syndrome
- 3) Spondylolysis treatment indicated by **ONE or more of the following**:
  - Rapidly progressive spondylolisthesis with severe neurologic compromise (eg, urinary incontinence)
  - Spondylolisthesis with significant associated findings, including **ALL of the following**:
    - i. Grade 2 or more with ( anterior slippage, **not retro slippage as an indicator**) spondylolisthesis demonstrated on plain x-rays, CT or MRI
    - ii. Back pain, neurogenic claudication symptoms, or radicular pain from lateral recess or foraminal stenosis
    - iii. Significant functional impairment
    - iv. Failure of at least 3 months of non-operative therapy
- 4) Severe degenerative scoliosis treatment with progression of deformity to greater than 30 degrees or 6mm of slippage (olisthesis) having failed 3 months medical therapy and with **ONE of the following**:
  - i. Persistent significant radicular pain or weakness unresponsive to non-operative therapy
  - ii. Persistent neurogenic claudication unresponsive to non-operative therapy
- 5) Anticipated spinal instability due to **ONE or more of the following**:
  - Planned extensive surgery for dislocation, infection, abscess or tumor
  - Current plan for additional primary or revision spinal surgeries (e.g., laminectomy).
- 6) Spinal instability due to prior surgery for neural decompression including laminectomy, dislocation, infection, abscess or tumor.
- 7) Revision fusion surgery due to **ONE of the following**:
  - For adjacent segment disease as indicated by **ALL of the following**:
    - i. Radiographic evidence of adjacent segment disease (e.g., neural compression) that correlates with symptoms

- ii. Persistent disabling symptoms (low back pain, radiculopathy)
- iii. Failure of 3 months of non-operative therapy
- Documented pseudoarthrosis (nonunion of prior fusion) by radiological studies **when ALL of the following are met**
  - i. Previous fusion at least 6 months ago with significant interval improvement
  - ii. Persistent daily axial back pain with or without neurogenic claudication or radicular pain
  - iii. Significant functional impairment inability to perform activities of daily living, school, and work
  - iv. Failure of 3 months of non-operative therapy
- Recurrent same level disc herniation **when ALL of the following are met**
  - i. Previous disc surgery greater than 6 months ago with interval improvement
  - ii. Recurrent neurogenic claudication or radicular pain unresponsive to non-operative treatment for greater than 3 months
  - iii. Neural structure compression documented by recent imaging consistent with signs and symptoms.

The following are not considered medically necessary:

- a) A lumbar fusion for a spinal deformity not meeting one of above criteria performed primarily for low back pain.
- b) A lumbar fusion performed for any condition not listed above, including non-radicular pain with common degenerative changes (degenerative disc disease, facet joint arthrosis, etc.) or post-laminectomy low back pain.

[Allograph](#) and autograph use in spinal fusion is covered if the requested procedure meets the criteria above for a spinal fusion procedure.

[Minimally Invasive Lumbar Decompression](#) - There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

#### [Minimally Invasive Sacroiliac Joint Fusion \(iFuse Implant System™\)](#)

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

#### [Axial Lumbar Interbody Fusion System](#)

There is insufficient evidence in the published medical literature to show that this procedure is as safe as standard procedures and/or provides better long-term outcomes than current standard procedure.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Chronic lower back pain is a major health problem and cause of disability in Western countries. The cause of the persistent pain is not well understood for the majority of patients. It generally occurs without specific damage or signs that can be revealed by imaging or other neurophysiological techniques. It is believed that the pain starts as acute pain of muscle and connective tissue and persists among approximately one third of the patients (Rittweger 2002). Mechanical low back pain may have various causes including degenerative disc disease, degenerative spondylosis, disc herniation, facet arthropathy, and others. Patients with low back pain may also experience reduced lumbar flexibility, reduced flexion-relaxation and static balance. The pain is aggravated by sitting, standing and lifting, which increase axial loading on the spine. Walking may relieve some of the pain but patients experience more relief by lying down as it unloads the spine and reduces intradiscal pressure (Gose 1998).

Conservative medical care for chronic back pain includes bed rest, steroid injection, anti-inflammatory drugs, muscle relaxants, conventional physiotherapy, exercises, stretching, manipulative techniques, ultrasound treatments, electric stimulation techniques and others. These measures ease the pain for some patients but are ineffective, intolerable, or unsuitable for others. Patients not responding to conservative therapy may be offered conventional or percutaneous surgical procedures such as disc space decompression, epidural blocks, and spinal instrumentation. These interventions play an important role in treating patients with low back pain due to herniated disc and degenerative disc problems. However, surgery may not relieve all the pain, and could permanently disrupt the biomechanical and physiological function of the disc. Moreover, not all patients are candidates for surgery.

In patients with non-radicular low back pain, common degenerative spinal changes, and persistent and disabling symptoms, it is recommended that clinicians discuss risks and benefits of surgery as an option (weak recommendation, moderate-quality evidence). The net benefit of lumbar fusion was moderate compared to standard nonsurgical therapy; however, there was no difference between lumbar fusion and intensive rehabilitation.

## Medical Technology Assessment Committee (MTAC)

### Allogenic Bone for Spinal Fusions- Allograft Bone

#### BACKGROUND

Arthrodesis of the spine has been performed for decades for various spinal conditions such as fractures, congenital or developmental deformities, arthritis, degenerative disease, disc lesions, tuberculosis and other infections. With the overall intent to prevent movement in painful bones by permanently joining two or more vertebrae, bone grafting is an integral part of the fusion process. The choice of bone graft is dependent on various factors including patient specific disease, type and location of fusion, the number of levels involved, patient and surgeon preference, as well as, surgeon experience. Non-fusion risks should also be taken into consideration such as patient age, gender, tobacco use and the patient's health status (Deyo 2004).

Historically, autograft bone harvested from the iliac crest of the patient who is undergoing the procedure has been the gold standard. This type of graft requires an additional incision during operation, lengthening surgery and causing morbidity associated with harvesting the tissue. It is further limited by, inconsistent size, quantity, and quality of tissue. One alternative to autograft is allogeneic bone graft, or allograft bone, which is harvested from cadaver bone. Allograft bone is typically acquired through a bone bank and can be procured in greater quantities than autograft (Ehrler and Vaccaro 2000).

Currently, there are three types of allograft, fresh frozen bone allograft, freeze dried bone allograft and demineralized freeze-dried bone allograft. Allograft bone is available in different shapes and sizes to fit into the area of the spine where it is needed. Allograft materials are difficult to standardize because of the heterogeneity of the donor tissue. In addition, allografts can be prepared in a number of different ways with the characteristics of a particular allograft affected by its method of preparation. Regulations for allograft bone procurement, as well as screening and testing procedures are extensive and enforced by both the American Association of Tissue Banks and the U.S. Food and Drug Administration (FDA).

While allogeneic bone avoids the common complication of donor site morbidity that occurs with autogenic bone grafting the obvious disadvantage is potential disease transfer. Contaminants and pathologies that may be transferred include viral and bacterial infections, malignancy, systemic disorders or toxins. The allograft bone used in spinal fusion procedures is provided by tissue banks (bone banks) which are regulated by the FDA. With that said, a retrospective review done by Mroz and colleagues in 2009, examined the safety of allograft bone through data from the FDA, recalls of musculoskeletal allografts data from the Center for Disease Control (CDC), and literature reviews. The review identified 59,476 recalls between 1994 and 2007 citing improper donor evaluation, contamination and infection as the main reasons for recall (Mroz, Joyce et al. 2009). In addition, there have been several reported cases of HIV transmission (Asselmeier, Caspari et al. 1993).

#### 03/04/2014: MTAC REVIEW

##### Allograft Bone

**Evidence Conclusion:** *Efficacy* - A meta-analysis of autograft versus allograft in anterior cervical discectomy and fusion (ACDF) was conducted in 2000 by Floyd and Ohnmeiss and concluded that it was not possible to ascertain whether autograft is clinically superior to allograft. When the data from all four studies were pooled, a significantly higher rate of union and a lower incidence of collapse was found with autograft for both one- and two-level fusions. Patient satisfaction and clinical outcomes were not adequately addressed in all of the studies and although autograft has a higher fusion rate than allograft, the clinical results did not rely solely on radiographic results (Floyd and Ohnmeiss 2000). [Evidence Table Allograph bone1] In a comparison of allograft versus autograft in multilevel ACDF with instrumentation, Samartzis et al reported fusion rates of 94.3% and 100% for allograft and autograft, respectively. In this study, nonunion occurred in patients with allograft but this difference was not statistically significant. Excellent and good clinical outcomes were noted in 88.8% of patients. These results should be interpreted with caution as the study was retrospective in nature and only included 80 non-blinded patients. With that said, the authors mention that meticulous surgical technique and patient selection were more important than graft type for successful outcome (Samartzis, Shen et al. 2003). [Evidence Table Allograph bone2] Samartzis and colleagues completed an additional and similar study in 2005 which demonstrated a fusion rate of 100% and 90.3% for allograft and autograft, respectively, in one-level ACDF. Clinical outcomes in relation to graft-type were also analyzed with no statistical differences detected ( $P > 0.05$ ). The study took place at a single institution and was

retrospective in nature including only 66 non-blinded participants. (Samartzis, Shen et al. 2005). [Evidence Table Allograft bone3] In a prospective randomized study, Gibson and colleagues reported similar clinical results in 69 patients who received either fresh-frozen allograft or autograft during instrumented posterolateral lumbar fusion. The groups were very similar before operation in terms of back pain and leg pain scores, but the allograft group showed a slightly higher overall pain score, which was statistically significant. After one year, however, the scores from the questionnaire were significantly different in that the group that had received allograft bone seemed to have done better in terms of back pain than those who had received the autograft bone (Gibson, McLeod et al. 2002). [Evidence Table Allograft bone4]

**Safety** - Both the Gibson et al., and the 2005 Samartzis et al. studies reported no complications associated with allograft bone use, however, it is unclear how systematic they were in collecting this information (Gibson, McLeod et al. 2002; Samartzis, Shen et al. 2005). None of the other studies reported on the safety or adverse events of allogeneic bone grafts when used in spinal fusions. While it appears that allografts have comparable fusion rates with autografts, proper evaluation of the efficacy and safety is difficult to make as the risk of bias throughout the studies was high, especially concerning small population sizes and retrospective, non-randomized or non-blinded studies. Patient risk factors, including body mass index, smoking, age and sex also contribute to the diversity of the study groups. As mentioned previously, surgical technique may have as much influence on fusion as the choice of graft and the contributions of factors such as nutrition, sex, age, bone metabolic factors, and smoking on the success of autograft versus allograft. These variations of standard procedures make it difficult to define the true effectiveness of grafts. Moreover, the absence of standardized fusion criteria and inconsistent outcome reporting creates heterogeneity of studies making it difficult to compare and contrast autograft and allograft across studies. Beyond the question of efficacy, the potential risk of disease transmission is the large concern which, on the whole, did not seem to be adequately addressed by the literature. The use of allograft bone in spinal fusion surgery warrants further clinical studies.

Conclusions:

- There is low quality evidence to support the effectiveness of allogeneic bone grafts for ACDL.
- There is insufficient evidence to determine the effectiveness of allogeneic bone grafts in lumbar surgery.
- There is insufficient evidence to determine the safety of allogeneic bone grafts in both cervical and lumbar spinal fusions.

**Articles:** The literature search revealed just over 100 studies many of which were case reports examining the performance of allograft for spinal fusion, but very few have been prospectively designed and well conducted. Selection of articles relied on the comparison of allograft to autograft. Studies that combined allograft bone with other materials and studies that compared allograft bone to other spinal fusion techniques were excluded. The following publications were selected for critical appraisal: Floyd, T and Ohnmeiss, D. A meta-analysis of autograft versus allograft in anterior cervical fusion. *European Spine Journal* 2000;9:398-403. [Evidence Table Allograft bone1] Samartzis D, Shen FH, Matthews DK, Yoon T, et al. Comparison of allograft to autograft in multilevel anterior cervical discectomy and fusion with rigid plate fixation. *The Spine Journal* 2003;3:451-459. [Evidence Table Allograft bone2] Samartzis D, Shen FH, Goldberg EJ, An HS. Is autograft the gold standard in achieving radiographic fusion in one-level anterior cervical discectomy and fusion in one-level anterior cervical discectomy and fusion with rigid anterior plate fixation? *2005;30(15):1756-1761*. [Evidence Table Allograft bone3] Gibson S, McLeod I, Wardlaw D, Urbaniak S. Allograft versus autograft in instrumented posterolateral lumbar spinal fusion. *Spine* 2002;27(15):1599-1603. [Evidence Table Allograft bone4]

The use of allograft bone for spinal fusion does meet the *Group Health Medical Technology Assessment Criteria*.

## **Spinal Fusion**

### **09/2011: MTAC REVIEW**

**Evidence Conclusion:** The 2009 APS guideline recommends that clinicians discuss risks and benefits of surgery as an option for patients with non-radicular low back pain, common degenerative spinal changes, and persistent and disabling symptoms; however, they also note that there was no difference between lumbar fusion and intensive rehabilitation (weak recommendation, moderate-quality evidence). The 2009 NICE guideline also recommends considering a referral for an opinion on spinal fusion for patients who have completed an optimal package of care, including a combined physical and psychological treatment program and still have severe non-specific low back pain for which they would consider surgery.

**Articles:** The literature search did not reveal any new studies that addressed the safety or effectiveness of lumbar fusion for the treatment of chronic low back pain. NICE 2009 Consider referral for an opinion on spinal fusion for people who: Have completed an optimal package of care, including a combined physical and psychological treatment program AND Still have severe non-specific low back pain for which they would consider surgery. American Pain Society (Chou) 2009 In patients with non-radicular low back pain, common degenerative spinal changes, and persistent and disabling symptoms, it is recommended that clinicians discuss risks and benefits of surgery as an option (weak recommendation, moderate-quality evidence). The net benefit of lumbar fusion was moderate compared to standard nonsurgical therapy; however, there was no difference between lumbar fusion

and intensive rehabilitation. The literature search revealed several studies published after the 2009 guidelines that addressed the safety or effectiveness of lumbar (spinal) fusion compared to non-surgical interventions for the treatment of chronic low back pain; however, none of these were selected for review because of severe methodological limitations (small sample size, power was not assessed, high level of crossover, etc.). PubMed was searched from July 2008 (NICE literature search date) or November 2006 (APS/ACP literature search date) through July 2011 with the search terms acupuncture, back pain, spinal manipulation, meditation, massage, mindfulness based stress reduction, multidisciplinary rehabilitation, physical therapy, sacroiliac joint injections, corticosteroid injections, epidural steroid injections, spinal injections, spinal fusion, and surgery with variations. Searches were limited to English-language studies of human subjects. Only randomized controlled trials (RCTs), meta-analyses, and clinical trials were included in the review. Reference lists and the related articles function in PubMed were used to identify additional publications. Studies were excluded if they had severe methodological limitations (e.g. small sample size, power and/or ITT analysis were not performed, etc.) or if pain or functional disability was not a primary or secondary outcome.

Reviewed by the content of care committee and not MTAC.

## **AxialIF**

### **12/16/2013: MTAC REVIEW**

**Evidence Conclusion:** *Efficacy* The literature search revealed five case series that report on outcomes associated with AxialIF. The largest, published in 2011, was a retrospective analysis of 156 patients from 4 clinical sites in the US. Ultimately, the mean pain and ODI scores improved by approximately 63% and 54% respectively ( $P < 0.001$ ) and the overall radiographic fusion rate at 2 years was 94%. The study did not report any adverse events. The patient population was reported to be homogenous, however, the variable nature and progression of the disease compromises the reliability of this claim. Limitations of this study include the retrospective analysis, industry funding as well as selection bias. Outcome measures were not all objective and relied on patient reporting. Only half of the patients were accounted for in the preoperative and postoperative ODI outcome (Tobler, Gerszten et al. 2011). Several smaller case series were also identified and are summarized in a table 1. Ultimately, all of the studies report similar results and conclusions but are subject to the bias of any retrospective series. Further limitations include a lack of control subjects, potential for selection bias as only one of the studies enrolled consecutive patients and unclear study objectives. All studies, with the exception of the publication by Patil and colleagues, received industry funding from TranS1 (Patil, Lindley et al. 2010; Gerszten, Tobler et al. 2012; Marchi, Oliveira et al. 2012). *Safety* Two publications addressed the safety of AxialIF with conflicting results. The first study was a 5-year surveillance study of 9,152 patients (Gundanna, Miller et al. 2011) and the second, a retrospective review of 68 patient records (Lindley, McCullough et al. 2011). Gundanna and colleagues reported minimal complications (1.3%) in their study while Lindley et al. reported high complication rates (23.5%). The observed adverse events across both the studies included pseudoarthrosis, superficial infection, sacral fracture, pelvic hematoma, failure of wound closure, and rectal perforation. Although both studies were designed to be systematic in their investigation, neither study had a control group for comparison and the results are dependent on either spontaneous reporting or the accuracy of medical records. In addition, both of the studies are subject to a variety of bias due to patient selection and industry funding.

**Conclusion:** There is insufficient evidence to determine the efficacy of AxialIF compared to standard fusion procedures. There is insufficient evidence to establish whether the AxialIF is as safe as standard fusion procedures.

**Articles:** Currently, there are no randomized control trials that compare the AxialIF with other approaches to lumbosacral interbody fusion. The literature related to the safety and efficacy is primarily comprised of case series. The following studies were selected for review: Tobler WD, Gerszten PC, Bradley WD, Raley TJ, Nasca RJ and Block JE. Minimally invasive axial presacral L5-S1 interbody fusion. *Spine* 2011;**36**(20):E1296-E1301. [See Evidence Table](#). Gerszten PC, Tobler W, et al. Axial presacral lumbar interbody fusion and percutaneous posterior fixation for stabilization of lumbosacral isthmic spondylolisthesis. *Journal of Spinal Disorders & Techniques* 2012;**25**(2):E36-E40. [See Evidence Table](#). Marchi L, Oliveira L, et al. Results and complications after 2-level axial lumbar interbody fusion with a minimum 2-year follow up. *Journal of Neurosurgery: Spine* 2012;**17**(3):197-192. [See Evidence Table](#). Patil S, Lindley E, et al. Clinical and radiological outcomes of axial lumbar interbody fusion. *Orthopedics* 2010;**33**(12). [See Evidence Table](#) Aryan H, Newman C, et al. Percutaneous axial lumbar interbody fusion (AxialIF) of the L5-S1 segment: initial clinical and radiographic experience. *Minimally Invasive Neurosurgery* 2008;**51**:225-230. [See Evidence Table](#).

The use of AxialIF does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Standers

- Adult Standers
- Pediatric Standers

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

National Coverage Determination (NCD)

[Durable Medical Equipment Reference List \(280.1\)](#)

#### For Non-Medicare

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Supported standing programs are routinely used by therapists as part of a postural management approach in children with severe developmental disabilities (e.g. cerebral palsy, spinal cord injuries, meningomyelocele, osteogenesis imperfecta) as they are unable to stand or walk by themselves due to poor motor control. These programs use assistive devices or adaptive equipment, eg. standers or standing frames that provide external adjustable support, to facilitate an upright position. Standers allow weight bearing activities which are believed to increase bone mineral density (BMD), manage contractures, increase muscle strength and postural control, as well as improve visuals and oral motor skills and social communication. These in turn, may prevent or reduce the children's musculoskeletal problems, increase their independence, and enhance their functional abilities (Gudjonsdottir 2002, Caulton 2003).

### Medical Technology Assessment Committee (MTAC)

#### *Pediatric Standers*

#### **10/16/2012: MTAC REVIEW**

**Evidence Conclusion:** There is insufficient evidence to date to determine the efficacy of standers in reducing risk of fractures among children who are unable to stand independently due to severe developmental disabilities. The published pilot RCT did not study the effect of stander equipment, but examined the effect of increasing standing time in children with cerebral palsy who are already involved in a standing program. In addition, it used bone mineral density, an intermediate outcome, as the primary end point. A more important clinical outcome would be the effect of the program on reducing the risk of bone fracture. Larger RCTs with long-term follow-up are needed to determine the long term safety and efficacy of standers on reducing the risk of fractures in children severe developmental disabilities.

**Articles:** There is very limited published literature on the use of standers for non-ambulant children due to significant developmental disabilities. The search identified a small pilot randomized controlled trial (RCT) that examined the effect of increasing the duration of a standing program on bone mineral density (BMD) in children with cerebral palsy, and another also very small pilot RCT (N=20) that examined the effect of standing on BMD in children with disabling conditions. There was also a number of published small case series with twenty or less participants each that examined the short-term effect of standing frames or prolonged standing on gait, muscle contracture, or BMD in children with cerebral palsy. The following RCT was critically appraised in the 2012 review. Caulton JM, Ward KA, Alsop CW, et al. A randomised controlled trial of standing programme on bone mineral density in non-ambulant children with cerebral palsy. Arch Dis Child. 2004;89;131-135. See [Evidence Table](#).

The use of use of standers to reduce fracture risk does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Pediatric Standers**

#### **02/11/2013: MTAC REVIEW**

**Evidence Conclusion:** There is insufficient evidence to date to determine the efficacy of standers in reducing risk of fractures among children who are unable to stand independently. The published pilot RCT by Caulton and colleagues (2004), did not study the effect of stander equipment, but examined the effect of increasing standing time in children with cerebral palsy who are already involved in a standing program. In addition, it used bone mineral density, an intermediate outcome, as the primary end point. A more important clinical outcome would be the effect of the program on reducing the risk of bone fracture. Ward and colleagues' (2004) RCT included children who were able to stand independently but had limited mobility due to their disability (autism, involuntary movements, limb deformity, and spasticity). 20 children 4-19 years of age were randomized to standing on active (vibrating platform) or placebo devices for 10 minutes/day, 5 days/week for 6 months. The primary outcome was proximal tibial spinal bone mineral density (vTBMD). The compliance rate was only 44%, and the 6 months results showed a net benefit of treatment equal to +15.72 mg/ml (17.7%;  $p=0.0033$ ) for proximal tibial BMD and + 6.72 mg/ml, ( $p = 0.14$ ) for the spine, compared with placebo. Larger RCTs with long-term follow-up, and patient oriented outcomes, are needed to determine the long term safety and efficacy of standers on reducing the risk of fractures in children with developmental disabilities.

**Articles:** There is very limited published literature on the use of standers for non-ambulant children due to significant developmental disabilities. The search identified a small pilot randomized controlled trial (RCT) that examined the effect of increasing the duration of a standing program on bone mineral density (BMD) in children with cerebral palsy, and another also very small pilot RCT (N=20) that examined the effect of standing on BMD in children with disabling conditions. There was also a number of published small case series with twenty or less participants each that examined the short-term effect of standing frames or prolonged standing on gait, muscle contracture, or BMD in children with cerebral palsy. The following RCT was critically appraised in the 2012 review. Caulton JM, Ward KA, Alsop CW, et al. A randomised controlled trial of standing programme on bone mineral density in non-ambulant children with cerebral palsy. *Arch Dis Child*. 2004;89;131-135. See [Evidence Table](#).

The use of standers to improve pulmonary function does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Adult Standers**

#### **BACKGROUND**

Standing frames also known as standers, standing devices, standing systems, or standing aids, are assistive devices that enable non-ambulatory individuals to achieve and maintain an upright posture. These may be used by patients with mild to severe disabilities such as spinal cord injury, traumatic brain injury, cerebral palsy, muscle dystrophy, or other neuromuscular conditions that do not enable the individual to stand independently. They can be used at home, in the workplace, extended care units, assisted living centers, nursing homes, and rehabilitation facilities. Prolonged standing has been investigated over the years for its possible benefits for patients with spinal cord injuries and other disabilities. It is suggested that standing and weight bearing activities may increase bone mineral density and muscle strength, reduce abnormal muscle tone and spasticity, improve circulation, reduce lower limb swelling, improve bowel and bladder function, prevent pressure sores, as well as other potential benefits. Many of these benefits however, are not supported by good quality evidence (Eng 2001, Bagley 2004, Bernhardt 2012).

There are a variety of standing systems. The common types include sit to stand, prone, upright, prone, multi-positioning standers, and standing wheel chairs. Some systems can be changed by the user from a sitting to a standing position; others require the assistance of another person to change its position. Standing systems can generally be divided into three groups: 1. Passive or static standers that remain in one place and cannot be self-propelled, 2. Mobile or dynamic standers that can be propelled by the user if he/she has the ability to do so, and 3. Active standers that can create reciprocal movements of the arms and legs while the patient is standing.

#### **08/17/2015: MTAC REVIEW**

#### **Adult Standers**

**Evidence Conclusion:** There is insufficient evidence to date, to determine the efficacy of standing devices on health outcomes of patients with disabilities or health conditions that render them unable to stand independently. The published RCT conducted by Bagley and colleagues (2005) (Evidence table 1) evaluated the effectiveness of the Oswestry Standing Frame for severely disabled stroke patients. The trial included 140 inpatients in a stroke rehabilitation unit. In addition to undergoing the usual stroke care, the patients were randomized in a 1:1 ratio to receive 14 consecutive treatment with the use of Oswestry standing frame, or to receive 14 consecutive

treatments but without access to the Oswestry standing frame. The primary outcome of the trial was the change in the Rivermead Mobility Index (RMI) from baseline to 6 weeks post stroke. The results of the trial showed no statistically significant difference between the study groups in any of the primary or secondary outcome measures or for resource savings. Larger RCTs with long-term follow-up and patient-oriented outcomes are needed to determine the long term safety and efficacy of standing devices or systems among adults with different health conditions and/or disabilities that do not enable them to stand on their own.

**Articles:** There is very limited published literature on the use of standers for non-ambulatory adults with mild to severe physical disability. The literature search identified one RCT (Bagley et al, 2005) that evaluated the Oswestry standing frame for patients after stroke, and another very small pilot RCT (Allison et al, 2007) that assessed the impact of additional supported standing practice on the functional ability post stroke in 14 patients.

The following trial was selected for critical appraisal: Bagley P, Hudson M, Forster A, Smith J, et al. A randomized trial evaluation of the Oswestry Standing Frame for patients after stroke. *Clin Rehabil.* 2005 June; 19(4):354-364. [See Evidence Table 1.](#)

The use of Adult Standers does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Other Non-Medicare Members

Type Of Transplant	Criteria
<b>Allogenic Bone Marrow/Stem Cells</b>	Has one of the following conditions: 1) Acute leukemia (ALL) 2) Non-refractory acute leukemia (AML and ALL) 3) Chronic myelogenous leukemia (CML) 4) Chemotherapy sensitive lymphoma 5) Myelodysplastic syndrome 6) Chemotherapy sensitive multiple myeloma 7) Aplastic anemia 8) Neuroblastoma 9) Severe combined immuno deficiency (SCID, IgM) 10) Wiscott-Aldrich syndrome 11) Metastatic neuroblastoma 12) Certain conditions where, established, published evidence of efficacy is present and based on the evidence the designated medical staff reviewer has determined coverage should be approved.
<b>Autologous Bone Marrow/Stem Cells</b>	Has one of the following conditions: 1) Acute myelogenous leukemia (AML) 2) Chemotherapy sensitive lymphoma 3) Resistant non-Hodgkin's lymphomas 4) Chemotherapy sensitive Hodgkin's disease (relapsed) 5) Recurrent or refractory neuroblastoma 6) Wilm's Tumor (relapsed, metastatic) 7) Germ cell tumor (relapsed, metastatic) 8) Ewings Sarcoma /Primitive neuroectodermal (PNET) 9) Chemotherapy sensitive or with Durie-Salmon stage II or III newly diagnosed multiple myeloma with age <78 and adequate cardiac, renal, pulmonary and hepatic function
<b>Stem Cell Transplantation for Amyloidosis</b>	Must meet all of the following criteria: 1) Less than 70 years of age

Type Of Transplant	Criteria
	2) No significant cardiac disease: <ul style="list-style-type: none"> <li>a) Ejection fractions greater than 55%;</li> <li>b) Intraventricular septum thickness less than 16 mm;</li> <li>c) Bilirubin less than 2.0.</li> </ul>
<b>Multiple Myeloma</b>	Must meet all of the following criteria: <ul style="list-style-type: none"> <li>1) Member must not have significant co-morbid medical conditions.</li> <li>2) Karnofsky performance score of 60% or greater, or SWOG/ECOG score of 0 - 1; and</li> <li>3) Members should not have had extensive prior chemotherapy or radiation therapy (i.e., more than a year of alkylator-based chemotherapy and/or more than two prior alkylator-based chemotherapies; radiation therapy to no more than 10% of marrow producing bones).</li> <li>4) Adequate liver function; bilirubin, SGOT less than 1.5x normal.</li> <li>5) The member has adequate major organ function:                             <ul style="list-style-type: none"> <li>a) Cardiac function (left ventricular ejection fraction equal or greater than 45% predicted);</li> <li>b) Pulmonary function [forced vital capacity (FVC) / forced expiratory volume (FEV1)/diffusion capacity of the lung for carbon monoxide (DLCO) equal to or greater than 50%];</li> <li>c) Members should not have evidence of cardiac amyloid;</li> <li>d) Members with indolent myeloma, smoldering myeloma, and monoclonal gammopathy of uncertain significance [MGUS] are excluded.</li> </ul> </li> </ul> Does not have one of the following: <ul style="list-style-type: none"> <li>1) Presence of another life-limiting cancer or cancer that may become life-threatening with immunosuppression; or</li> <li>2) Presence of psychiatric disease that would interfere with the member's ability to comply with the therapeutic regimen; or</li> <li>3) Inadequate cardiac, renal, pulmonary, or hepatic function</li> </ul>

Type Of Transplant	Criteria
<p><b>Multiple Myeloma - tandem transplant</b></p>	<p>Must meet all of the following criteria:</p> <ol style="list-style-type: none"> <li>1) Member must not have significant co-morbid medical conditions.</li> <li>2) Karnofsky performance score of 60% or greater, or SWOG/ECOG score of 0 - 1; and</li> <li>3) Members should not have had extensive prior chemotherapy or radiation therapy (i.e., more than a year of alkylator-based chemotherapy and/or more than two prior alkylator-based chemotherapies; radiation therapy to no more than 10% of marrow producing bones).</li> <li>4) Adequate liver function; bilirubin, SGOT less than 1.5x normal.</li> <li>5) The member has adequate major organ function:               <ol style="list-style-type: none"> <li>a) Cardiac function (left ventricular ejection fraction equal or greater than 45% predicted);</li> <li>b) Pulmonary function [forced vital capacity (FVC) / forced expiratory volume (FEV1)/diffusion capacity of the lung for carbon monoxide (DLCO) equal to or greater than 50%];</li> <li>c) Members should not have evidence of cardiac amyloid;</li> </ol> </li> <li>6) Members with indolent myeloma, smoldering myeloma, and monoclonal gammopathy of uncertain significance [MGUS] are excluded.</li> <li>7) Members with Durie-Salmon stage I (one bone lesion), II or III myeloma.</li> <li>8) Planned 1st and 2nd transplantation should be within a 6-month period.</li> </ol> <p>Does not have one of the following:</p> <ol style="list-style-type: none"> <li>1) Presence of another life-limiting cancer or cancer that may become life-threatening with immunosuppression; or</li> <li>2) Presence of psychiatric disease that would interfere with the member's ability to comply with the therapeutic regimen; or</li> <li>3) Inadequate cardiac, renal, pulmonary, or hepatic function</li> </ol>
<p><b>High Dose Chemotherapy with Autologous Stem Cell Rescue for Treating Multiple Sclerosis</b></p> <p><b>High-Dose Chemotherapy with Stem Cell Transplant for Breast Cancer</b></p> <p><b>Scleroderma</b></p>	<p>There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.</p>
<p><b>Non-Myeloablative Stem Cell/Bone Marrow Transplant (Mini Transplant)</b></p>	<p>Nonmyeloablative allogeneic stem cell transplantation (mini-allograft) may be covered in patients who would otherwise meet patient selection criteria for <b>High-Dose Chemotherapy and Allogeneic Stem Cell Transplantation</b>. Persons who are unable to tolerate a conventional allogeneic stem cell transplant may be able to tolerate a milder, non-myeloablative conditioning regimen.</p> <p>Non-myeloablative bone marrow/peripheral stem cell transplantation (mini-allograft) is not covered for any of the following diseases because it has not been established that allogeneic transplant (conventional ASCT or mini-allograft) is effective in treating these conditions:</p> <ul style="list-style-type: none"> <li>• <b>Melanoma and Renal Cell Carcinoma</b></li> <li>• <b>Multiple Myeloma</b></li> </ul> <p>There is insufficient evidence to cover tandem transplantation of high dose chemotherapy with autologous stem cell support followed by nonmyeloablative allogeneic stem cell transplantation.</p>

Type Of Transplant	Criteria
<b>Allogeneic Bone Marrow Transplantation (BMT) in Low-Grade Lymphoma (LGL) and Chronic Lymphocytic Leukemia (CLL)</b>	Because of the lack of evidence, this service will be considered on a case by case basis following a second opinion evaluation. In young patients with rapidly progressing disease requests for coverage should be reviewed via a second opinion, expert case review. The physician reviewer will use the information resulting from the second opinion to determine if coverage should be approved on an exception basis.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

A stem cell transplant is the infusion of healthy stem cells into your body. A stem cell transplant may be necessary if the bone marrow stops working and doesn't produce enough healthy stem cells. Stem cell transplantation is necessary following high dose chemotherapy/radiation for several types of cancers. Stem cells are a type of cell that divide and develop into one of the three main types of cells found in the blood; red blood cells, white blood cells, and platelets.

Although the procedure generally is called a stem cell transplant, it's also known as a bone marrow transplant or an umbilical cord blood transplant, depending on the source of the stem cells. Stem cell transplants can use cells from your own body (autologous stem cell transplant) or they can utilize stem cells from donors (allogenic stem cell transplant).

The first step in the process of stem cell transplantation is the collection of stem cells from a patient or a donor. When a patient's own stem cells are used, they are frozen and stored until needed. Stem cells can be collected from a donor when they are needed. The patient then receives high-dose chemotherapy and the stem cells are infused into the patient's bloodstream. The stem cells travel to the bone marrow and begin to produce new blood cells, replacing the normal cells lost during high-dose chemotherapy.

## Medical Technology Assessment Committee (MTAC)

### *Autologous Stem Cell Transplant (SCT)/Bone Marrow Transplant for Chronic Myeloid Leukemia (CML)*

#### BACKGROUND

Chronic myelogenous leukemia (CML) also referred to as chronic myeloid leukemia, chronic myelocytic leukemia, and chronic granulocyte leukemia, is a malignant disease of the hematopoietic stem cells. Most cases occur in adults, with a median age of approximately 50 years. CML has three stages: Chronic phase, accelerated phase, and blast phase, which is always fatal. Transition from one phase to the other occurs gradually over a period of one year or more however it may take place abruptly and is called the blast crisis. The average survival of CML is 42 months, however after the development of the accelerated phase, survival is usually less than a year, and only a few months after blastic transformation.

There are many treatment options available, yet management of CML remains unsatisfactory. Currently accepted therapies for the chronic phase range from relatively non-toxic oral medications, to alpha interferon-based therapy or aggressive high-dose chemotherapy with allogenic stem transplantation. Conventional chemotherapy usually does not produce a lasting complete remission, nor does it prevent or delay transformation of the disease from an indolent chronic phase to an accelerated phase and blast crisis. High dose therapy, at concentrations much higher than conventional therapy, is highly toxic to the bone marrow and may be able to alter the haematopoietic environment to favor regrowth of normal stem cells. The most effective treatment of CML is high dose

chemotherapy with allogenic bone marrow transplantation, which may result in long-term disease free survival in the majority of patients who receive transplants early in the chronic phase (Meloni 2001). Unfortunately, allogenic stem cell transplantation is limited by donor availability and toxicity of graft-versus-host disease (GVHD), especially in the elderly. Transplant of stem cells derived from a patient's own marrow or peripheral blood (autologous transplant) avoids the need for an HLA-matched donor, has less complications, and shorter hospital stay than allogenic transplantations. Autologous bone marrow transplantation was started at the University of Colorado in 1977, and has been successful in other haematological malignancies.

#### **10/9/2002: MTAC REVIEW**

##### **Autologous Stem Cell Transplant (SCT)/Bone Marrow Transplant for Chronic Myeloid Leukemia (CML)**

**Evidence Conclusion:** The studies reviewed do not provide sufficient evidence to determine the efficacy and outcome of stem cell/ bone marrow transplantation for CML patients. Results of these studies suggest that this treatment modality has a potential to lead to hematologic and cytogenetic response, as well as prolonging survival of younger patients in the first chronic stage. However, the reviewed studies are limited by their design, size, length of follow-up, and lack of a control or comparison group. Their results should be interpreted cautiously. Prospective randomized clinical trials with larger patient sizes, and longer follow-up is needed to assess and compare efficacy of autologous transplantation for CML with other approaches.

The search yielded 79 articles. Articles were selected based on study type. The majority were reviews, opinion pieces, editorials, letters, and commentaries. Some used different adjunct therapies for conditioning, treatment or immunotherapy.

**Articles:** The literature search did not reveal any randomized controlled trials, or meta-analyses. A study that pooled data from 8 marrow transplant center, and four case series with patients who underwent an autograft after intensive chemotherapy, were identified. The studies with the larger size and/ or better methodology were selected for critical appraisal. Khouri IF, Kantarjian HM, Talpaz M, et al. Results of high dose chemotherapy and unpurged autologous stem cell transplantation in 73 patients with chronic myelogenous leukemia. The MD Anderson experience. *Bone marrow transplantation* 1996;17:1775-779. See [Evidence Table](#) McGlave PB, De Fabritis P, Deisseroth A, et al. Autologous transplants chronic myeloid leukemia: results from eight transplant groups. *Lancet* 1994;34:1486-1488. See [Evidence Table](#) Singer IO, Franklin IM, Clark RE, et al. Autologous transplantation in chronic myeloid leukemia using peripheral blood stem cells. *British Journal of Haematology* 1998;102:1359-1362. See [Evidence Table](#)

The use of autologous SCT/BMT in the treatment of CML does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **High Dose Chemotherapy with Autologous Stem Cell Rescue for Treating Multiple Sclerosis**

##### **BACKGROUND**

Multiple Sclerosis (MS) is a progressive debilitating neurological disorder with a relapsing and remitting course of symptoms including tremor. MS is caused by a progressive and selective destruction of myelin that is thought to occur as a result of an autoimmune reaction. It is typically treated with anti-inflammatory and immunosuppressive agents such as high-dose steroids, cyclophosphamide and as a last resort, beta-interferon. The symptomatic improvement seen following immune suppression led investigators to propose treating MS by destroying the immune system with high dose chemotherapy and then restoring immune function by replacement of the patients own stem cells. Patient's stem cells are mobilized by administering cyclophosphamide and then harvested for later reinfusion. High doses of chemotherapeutic agents are then used to destroy the patient's immune system. The previously harvested stem cells are then re-infused and in most cases, restore normal immunologic function.

#### **8/11/1999: MTAC REVIEW**

##### **High Dose Chemotherapy with Autologous Stem Cell Rescue for Treating Multiple Sclerosis**

**Evidence Conclusion:** Evidence identification was conducted by searching MEDLINE from 1995-1999 using terms multiple sclerosis, hematopoietic stem cell transplant, stem cells, and transplantation. The author of the largest case series was contacted to ascertain if there were any studies published which had not been previously identified.

**Articles:** The best, published scientific evidence consists of a case series of 15 patients with a history of progressive MS for a median of 6 yrs and severe disability. Most of the patients were observed for only a few months after treatment; only 3 of the 15 patients were followed for a year or more. Six months after treatment, 3 of 13 patients had improved by at least 1.5 points on the Kurtzke Disability Status Scale (0=normal to 10=death from MS) and 1 patient had worsened by 1 point. The mean improvement was less than 1 point at 6 months. Using the Scripps Neurological Rating Scale (0-100) eight of 13 patients improved by 20 points or more at 6 months. The mean improvement was 22.5 points at 6 months. Transplant-related complications included sepsis and anaphylactic shock. This case series does not prove that high dose chemotherapy with stem cell rescue is an effective treatment for MS. Because some patients who carry the diagnosis of progressive MS may experience

neurologic improvement without treatment, one cannot be certain that the clinical improvement documented in this study was the result of the therapeutic intervention. Fassas A, et al. Peripheral blood stem cell transplantation in the treatment of progressive multiple sclerosis: first results of a pilot study. *Bone Marrow Transplantation* 1997;20:631-8 See [Evidence Table](#)

The use of stem cell transplantation in the treatment of multiple sclerosis does not meet the *Group Health Medical Technology Assessment Criteria*.

### **High-Dose Chemotherapy with Stem Cell Transplant for Breast Cancer**

#### BACKGROUND

The success of high-dose chemotherapy (HDC) for some hematologic cancers stimulated hope that high doses might also improve survival for patients with metastatic breast cancer. The usual approach for the use of high-dose chemotherapy in breast cancer treatment involves the delivery of maximally tolerable doses of a combination of chemotherapy drugs supported by autologous stem or bone marrow cells. In the last 10 years, dozens of phase I and II studies have been reported. There is agreement that HDC is highly toxic, with treatment-related mortality rates in the range of 5% to 30%. There has been serious disagreement, however, about whether existing evidence establishes that the treatment is effective in improving survival and whether the benefits, if they exist, outweigh the harms. The strongest "evidence" of the efficacy of this treatment came from the work of a South African researcher, Dr. Bezwoda. He recently admitted falsifying data in a randomized controlled trial (RCT) in which he had reported that HDC, done in conjunction with bone marrow transplantation, prolonged the lives of some women with advanced breast cancer. None of the other peer-reviewed RCTs have shown a statistically significant advantage for HDC with stem-cell support over conventional chemotherapy. The current Group Health clinical indications include using high-dose chemotherapy for breast cancer treatment. The purpose of this review is to critically appraise the existing literature in order to evaluate the efficacy of this treatment regimen.

#### **6/14/2000: MTAC REVIEW**

### **High-Dose Chemotherapy with Stem Cell Transplant for Breast Cancer**

**Evidence Conclusion:** A critical appraisal of the existing evidence strongly suggests that high-dose chemotherapy with stem or bone marrow cell support is not beneficial in breast cancer treatment. Studies that have shown some benefit, even in a subset of patients, have numerous threats to validity, including selection bias, small sample sizes, and confounding. Furthermore, the procedure is associated with significant morbidity and mortality, a high rate of relapse, and potentially irreversible long-term effects. The available evidence therefore does not permit conclusions about the effectiveness of this treatment. The final results of large, multi-center, randomized trials may help determine the role of HDC in the management of breast cancer.

**Articles:** Articles were selected based on study type. There were four randomized controlled trials (RCTs) comparing HDC with "standard treatment" as well as several prospective studies, and meta-analyses. Since the results from the randomized trials were essentially similar (except for studies by Dr. Bezwoda), evidence tables were created for one randomized controlled trial and one prospective phase II trial— 1 each with favorable and unfavorable findings (attached). Reviews, editorials, and comments were reviewed, but no evidence tables were created. *The articles (RCT) selected for critical appraisal include:* Nieto et al. Phase II trial of high-dose chemotherapy with autologous stem cell transplant for Stage IV Breast Cancer with Minimal Metastatic Disease. *Clinical Cancer Research* 1999 July; 5:1731-1737. See [Evidence Table](#) Staudmauer et al. Conventional-dose chemotherapy compared with high-dose chemotherapy plus autologous hematopoietic stem-cell transplantation for metastatic breast cancer. *NEJM* 2000;342:1069-76. See [Evidence Table](#)

The use of high-dose chemotherapy followed by stem-cell transplant treatment of breast cancer does not meet the *Group Health Medical Technology Assessment Criteria* (fails criteria 2).

### **Multiple Myeloma**

#### BACKGROUND

Multiple myeloma (MM) is a plasma cell neoplasm that accounts for almost 10% of hematologic malignancies, and about 1% of all cancer related deaths. There are approximately 50,000 patients with MM in the United States, and it is estimated that there are more than 15,000 new cases per year. The median age at onset is 66 years, and only 2% of patients are younger than 40 years at diagnosis. Their median survival is around 3 years, but some patients can live longer than 10 years (Hari 2006, Terpos 2005, Levy 2005, Rajkumar 2005). High dose chemotherapy (HDT) with autologous stem cell transplant (ASCT) is regarded as the standard of care for newly diagnosed myeloma in patients less than 65 years of age. This can prolong remission duration, progression free survival, and overall survival in a significant proportion of patients. However, the therapy is not curative, and survivors eventually experience relapse or progression of the disease. Only a few patients who undergo the procedure are free of the disease for more than 10 years. Recurrences are primarily due to the failure of chemotherapy to eradicate all myeloma cells. Once relapse has occurred, survival is limited despite the use of

novel drugs and salvage regimens (Terpos 2005, Hari 2006, Gerull 2005, Bruno 2007). Researchers have found that allogeneic hematopoietic cell transplantation, following high dose conditioning may lead to lower relapse rates and longer remissions, and possibly cure of MM. This is presumably due to the graft versus myeloma effects, in addition to the advantage of a tumor-free graft. However, only a small percentage of patients are candidates for allogeneic transplants because of age, availability of an HLA-matched sibling donor, and adequate organ function. Conventional allogeneic transplantation is also limited by the high transplant-related morbidity and mortality associated with myeloablative conditioning regimens, and graft versus host disease (GVHD). The risk of treatment-related mortality (TRM) could be as high as 30-60% (Bruno 2007, Gerull 2005). Reduced intensity (non-myeloablative) conditioning was thus developed to decrease toxicity and treatment related mortality while maintaining the graft versus tumor effect. However, relapses are frequent when non-myeloablative allogeneic transplantation is used in patients with a relapsed or refractory disease (Harousseau 2005). In the past few years, researchers have been studying the efficacy and feasibility of performing non-myeloablative allogeneic transplantation after one or two procedures of high dose therapy and ASCT. This concept combines the advantage of cytoreduction achieved with the high-dose autologous transplant with the graft versus myeloma effect of the non-myeloablative allogeneic transplant in order to eradicate the minimal residual disease with a goal of long-term disease control, and hopefully cure of MM (Maloney 2003, Hari 2006).

#### **04/10/2002: MTAC REVIEW**

##### **Multiple Myeloma**

**Evidence Conclusion:** The case series reviewed do not provide sufficient evidence to determine the efficacy and outcome of mini stem cell transplantation, for multiple myeloma. In addition to the small sample size of the study reviewed, and the relatively short follow-up, case series provide the lowest grade of evidence; they lack a control or comparison group and are prone to selection bias, and confounding.

The search yielded 59 articles. Articles were selected based on study type. Most of the articles were reviews, opinion pieces, editorials, letters, and commentaries. The literature did not reveal any randomized controlled trials, or meta-analyses. There was only one case series on MM patients who had mini-stem transplantation.

**Articles:** *The following article was critically appraised:* Badros A, et al. High response rate in refractory and poor-risk multiple myeloma after transplantation using a nonmyeloablative conditioning regimen and donor lymphocyte infusions. *Blood* 2001;97:2574-9. See [Evidence Table](#)

The use of mini stem cell transplant in the treatment of multiple myeloma does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **12/05/2005: MTAC REVIEW**

##### **Multiple Myeloma**

**Evidence Conclusion:** Gerull and colleagues (2005) reported the outcomes of 52 MM patients who received non-myeloablative allogeneic transplantation between September 1999 and June 2003, at the University of Heidelberg, Germany. The ages of the patients ranged from 36 to 68 years, and they were followed up for a median of 567 days, (479 days for survivors). At the time of analysis only 24 patients (46%) were alive. The results show that the estimated overall survival at 18 months was 41%, and the estimate progression free survival also at 18 month was 29.4%. 38% developed GVDH grade II-IV, and 70% developed chronic GVHD. This study only presents an analysis of a retrospective data of a heterogeneous group of patients treated at one center, followed up for a relatively short time, and the treatment was not compared to an alternative therapy or no treatment.

**Articles:** Compiled data in Djulbegovic's systematic review on 103 patients with MM show complete response rate of 37%, acute GVHD among 59%, and chronic GVHD among 18% of the patients.

Gerull S, Goerner M, Benner A, et al. Long-term outcome of nonmyeloablative allogeneic transplantation in patients with high –risk multiple myeloma Bone Marrow Transplant 2005;doi: 10.1038/sj.bmt.1705161 See [Evidence Table](#)

The use of non-myeloablative stem cell transplantation (mini-stem cell transplantation) in the treatment of hematologic malignancies, acute myeloid leukemia, myelodysplastic syndrome, multiple myeloma, lymphomas, renal cell carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **08/06/2007: MTAC REVIEW**

##### **Multiple Myeloma**

**Evidence Conclusion:** To date, there is no high quality evidence on the safety and efficacy of mini stem cell transplantation with a preceding autologous hematopoietic cell transplantation for the treatment of multiple myeloma. There are no published randomized controlled trials that compare allografting with non-myeloablative conditioning following a cytoreductive autograft to double (tandem) autologous stem cell transplantation, or to an alternative therapy. The best published evidence to date consists of one nonrandomized controlled trial (Bruno

2007) and another study that compared two series of patients (Garban 2006). Bruno and colleagues' study (2007) recruited 245 patients < 65 years old with stage II or III multiple myeloma, from five centers in Italy. 199 of the participants had at least one sibling, and only 104 received treatment. The patients were not randomized to the treatment groups. Those with an HLA-identical sibling (n=58, 56%) received a myeloablative autograft followed by a nonmyeloablative allograft transplantation, and patients without an HLA identical sibling (n=46, 44%) received two consecutive myeloablative doses conditioning, each followed by an autologous stem cell transplant. The primary endpoints of the study were overall survival and event-free survival. After a median follow-up of 45 months, the overall survival and event free survival were significantly longer in patients who completed the autograft-allograft treatment versus those who completed the high-dose, double autograft treatment. The results of the study also show that there was no significant difference between the two groups in the treatment related deaths, but the autograft-allograft transplantation was associated with high rates of acute and chronic GVHD (43% and 64% respectively). The chronic GVHD was extensive among 36% of the patients in that treatment group. Garban and colleagues (2006) compared the results of two multicenter trials (IFM99-03 and IFM99-04). The studies recruited patients <65 years old with newly diagnosed MM, and with two adverse prognostic factors. After 3-4 cycles of induction regimens, the participants received their first ASCT. Then, according to the availability of an HLA-identical sibling, they either received an allograft with a nonmyeloablative conditioning (IFM99-03 trial) or a second allograft with or without anti-IL-6 monoclonal antibody (IFM99-04 trial). After a relatively short follow-up period (median 24 months) the authors compared the outcomes from both studies. The results showed no significant difference between the two strategies in terms of overall survival or event free survival. Patients were not randomized to one of the two transplantation protocols, and the study was not powered to detect any significant difference between these two treatments. The two studies have their limitations, and it is hard to compare their results because different regimens were used for conditioning, and different intensities of immune suppression drugs were used. Moreover, the participants in Garban's study had a high risk myeloma unlike those in Bruno's study who were at intermediate or good risk. Large randomized controlled trials would provide higher quality evidence the efficacy and safety of allografting with nonmyeloablative conditioning following a cytoreductive autograft, to other alternative therapies e.g. the tandem autograft used in these non-randomized studies.

**Articles:** The search yielded around 140 articles. Several were not related to the current review, and many others were review articles. There were two nonrandomized studies with comparison groups, and several prospective and retrospective case series. The two trials with comparison groups were selected for critical appraisal. Bruno B, Rotta M, Patriarca F, et al. A comparison of allografting with autografting for newly diagnosed myeloma. *NEJM* 2007; 356:1110-1120. See [Evidence Table](#). Garban F, Attal M, Michallet M, et al. Prospective comparison of autologous stem cell transplantation followed by dose-related allograft (IFM99-03 trial) with tandem autologous stem cell transplantation (IFM99-04 trial) in high risk de novo multiple myeloma. *Blood* 2006;107:3474-3480 See [Evidence Table](#).

The use of mini stem cell transplant in the treatment of multiple myeloma meets the *Group Health Medical Technology Assessment Criteria*.

### **Nonablative SCT for Renal Cell Carcinoma and Melanoma**

#### BACKGROUND

Considerable morbidity and mortality are consequences of the myeloblastic chemoradiotherapy utilized in conventional allogeneic marrow transplantation. This has generally restricted such potentially curative treatment to patients <50-55 years with normal organ function. Recent studies indicate that purine-analogue based non-myeloblastic regimens are sufficiently immunosuppressive to facilitate allogeneic donor cell engraftment. Non-ablative (non-myeloblastic) bone marrow transplantation involves engrafting an HLA-matched donor's marrow into a host to obtain a graft versus tumor effect. Engraftment is done with just immunosuppressive therapy (not high dose chemotherapy) initially and then is stopped. This procedure is not FDA-approved, but Dr. Feldman states that FDA approval is not necessary.

#### **10/11/2000: MTAC REVIEW**

#### **Nonablative SCT for Renal Cell Carcinoma and Melanoma**

**Evidence Conclusion:** Given the limitations of the studies presented (small sample sizes, potential selection bias, and possible toxicity associated with the procedure) there is insufficient evidence at this time to determine the efficacy of non-myeloblastic allogeneic peripheral-blood stem-cell transplantation. As stated by one of the investigators "non-myeloblastic allogeneic peripheral-blood stem-cell transplantation should remain an investigational approach for the treatment of metastatic renal-cell carcinoma.

**Articles:** Articles were selected based on study type. There was one prospective study and one case series. Evidence tables were created for these 2 studies (attached). Review articles and commentaries were reviewed, but no evidence tables were created. *The articles selected for critical appraisal include:* Childs et al. Regression of metastatic renal-cell carcinoma after non-myeloblastic allogeneic peripheral-blood stem-cell transplantation.

The use of Non-ablative Stem Cell Transplantation for Melanoma and Renal Cell Carcinoma does not meet the *Group Health Medical Technology Assessment Criteria* (fails criteria 2 for effectiveness).

#### **12/05/2005: MTAC REVIEW**

##### **Nonablative SCT for Renal Cell Carcinoma and Melanoma**

**Evidence Conclusion:** Peccatori and colleagues (2005), analyzed data from 70 patients who received reduced intensity stem cell transplantation for advanced renal cell carcinoma in nine European transplant centers from 1999 to 2003. The authors selected ten variables and entered them in a univariate analysis. Those significantly correlated with survival were entered in a multivariate regression analysis, which suggested three prognostic parameters according to which the authors categorized the study patients as high or low risk groups. After a median follow-up of ten months the median survival (according to Kaplan Meier estimates) was 23 months for the low-risk group, and 3.5 months for the high-risk group. The study population was a highly selected group of patients, and the therapy was not compared to an alternative strategy or to no treatment.

**Articles:** Peccatori J, Barkholt, Demirer, et al. Prognostic factors for survival in patients with advanced renal cell carcinoma undergoing nonmyeloablative allogenic stem cell transplantation. *Cancer* 2005;104:2099-2103. See [Evidence Table](#)

The use of nonmyeloablative stem cell transplantation (mini-stem cell transplantation) in the treatment of hematologic malignancies, acute myeloid leukemia, myelodysplastic syndrome, multiple myeloma, lymphomas, and renal cell carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

#### ***Non-Myeloablative Stem Cell/Bone Marrow Transplant (Mini Transplant)***

##### **BACKGROUND**

Myeloablative combination of high-dose chemo-radiotherapy followed by allogenic hematopoietic stem-cell transplantation (HSCT) is an effective treatment for various hematological malignancies resistant to conventional doses of chemotherapy. Conventional allogenic HSCT involves the use of maximally tolerated myeloablative chemotherapy and/or radiotherapy conditioning regimens to eradicate the underlying disease, while the allograft serves to rescue patients from marrow aplasia induced by the treatment (Georges 2002). However, high-dose chemo/radiotherapy with allogenic HSCT is associated with significant morbidity and mortality due to toxicity of the preparative regimen, the accompanying immunodeficiency, and graft versus host disease (GVHD). The associated toxicity and mortality have limited the use of allogenic HSCT to young medically fit patients. Many patients who may potentially benefit from the treatment are not eligible for the procedure due to age, co-morbid illnesses, poor organ function, or extensive previous chemotherapy. Several hematologic malignancies e.g. acute myelogenous leukemia, chronic myelogenous leukemia, and myeloblastic syndromes peak in the seventh decade of life, which limits the options for these older patients to palliative chemotherapy (Burroughs 2004). There are indications that the main therapeutic effect of allogenic HSCT may not be solely due to the physical elimination of all tumor cells by the high doses of conditioning regimen, but also to T-cell-mediated graft-versus tumor (GVT) or graft versus leukemia (GVL) effect. Researchers also found that donor lymphocyte infusions (DLIs) can re-induce remissions in patients who have relapsed following allogenic transplantation. This has led to the exploration of non-myeloablative allogenic stem cell transplantation (NST) as a safer alternative to conventional high-dose transplant regimens, and as a means to exploit the GVD effect to cure malignancies with elimination of the need for hazardous conditioning. Conditioning regimens are referred to as non-myeloablative if they are not given at a dose that will result in permanent marrow aplasia i.e. will not completely eradicate host hematopoiesis and immunity. They have a potent immunosuppressive effect but are only mildly myelodepressive and commonly result in induction of mixed chimerism (Shimoni, 2002). A truly nonmyeloablative regimen is defined as a regimen that allows relatively prompt hematopoietic recovery (in less than 28 days) without a transplant and upon engraftment mixed chimerism should occur (Khouri, 2004). Clinical data indicate that NST lowers the incidence and severity of GVHD which is main cause of treatment related mortality. NST regimens were originally designed for older patients or any patient ineligible for standard conditioning due to other co-morbidities or risks. Now, they may also be considered for patients where high-dose chemo/radiotherapy is unnecessary. Reduced intensity regimens usually consist of purine analogues e.g. fludarabine combined with alkylating agents such as busulfan, or cyclophosphamide. A second approach which is nonablative, consists of 2 Gy total body irradiation either alone or combination with fludarabine. Mini stem cell transplant was reviewed by MTAC on 4/10/2002, and 6/11/2003 and did not pass MTAC criteria. They studies reviewed were all small case series with short follow-up and no control or comparison groups.

## Non-Myeloablative Stem Cell/Bone Marrow Transplant (Mini Transplant)

**Evidence Conclusion:** There is insufficient published literature to provide evidence on the use of non-myeloablative stem cell/bone marrow transplant for cervical cancer, myeloproliferative disease, HIV patients, severe combined immunodeficiency, Wiskott-Aldrich syndrome, amyloidosis, or other metabolic disorders. There is also insufficient evidence to determine the efficacy and outcome of mini stem cell/ bone marrow transplantation in treating hematological diseases. In addition to the small sample sizes of the series reviewed, and the relatively short follow-up duration, case series provide the lowest grade of evidence; they lack a control or comparison group and are prone to selection and observation bias.

**Articles:** The search yielded almost 600 articles. The majority were reviews, opinion pieces, or dealt with the technical aspects of the procedure. The literature search did not reveal any randomized controlled trials, or non-randomized comparative studies. All were small case series or case reports with small sample sizes. The search did not reveal any studies or reports on non-myeloablative transplantation for cervical cancer, amyloidosis, or other metabolic disorders. There were very few case reports with 1-8 patients each on PNP deficiency, Wiskott-Aldrich syndrome, ADA severe combined immunodeficiency, DiGeorge syndrome, and HIV infection. The search also revealed a series of 50 patients with Fanconi's anemia conditioned with a non-myeloablative regimen before the transplantation, and with six years of follow-up. Most of the series published were on leukemias, lymphomas, and multiple myeloma (MM). Mini transplant for MM was reviewed by the committee in 4/10/2002, and did not pass MTAC criteria. The case series on the individual leukemias and lymphomas were too small. The two largest series that included older patients and/or patients with other co-morbid conditions, with a variety of hematological diseases were selected for critical appraisal, as well as the series on Fanconi's anemia. *The following articles were critically appraised:* McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose toxic therapy with graft-versus-tumor effects. *Blood* 2001;97:3390-3400. See [Evidence Table](#) Niederwieser D, Maris M, Shizuru JA, et al. Low-dose total body irradiation (TBI) and Fludarabine followed by hematopoietic cell transplantation (HCT) from HLA-matched or mismatched unrelated donors and postgrafting immunosuppression with cyclosporine and mycophenolate mofetil (MMF) can induce durable complete chimerism and sustained remissions in patients with hematological diseases. *Blood* 2001;101:1620-1629. See [Evidence Table](#) Socie G, Devergie A, Girinski T, et al. Transplantation for Fanconi's anemia: long-term follow-up of fifty patients transplanted from a sibling donor after low-dose cyclophosphamide and thoraco-abdominal irradiation for conditioning. *British Journal of Hematology* 1998;103:249-255. See [Evidence Table](#)

The use of non-myeloablative stem cell/bone marrow transplant in the treatment of cervical cancer, myeloproliferative disease, HIV patients, severe combined immunodeficiency, Wiskott-Aldrich syndrome, amyloidosis, or other metabolic disorders does not meet the *Group Health Medical Technology Assessment Criteria*.

### 12/05/2005: MTAC REVIEW

## Non-Myeloablative Stem Cell/Bone Marrow Transplant (Mini Transplant)

**Evidence Conclusion:** Hematological malignancies Djulbegovic and colleagues' systematic review included 25 case series with a total of 603 patients with a wide range of hematologic malignancies. Only 4 studies included more than 10 patients with the same malignancy. The authors compiled some extractable data from the heterogeneous studies included, but apparently they did not use standard meta-analysis techniques. The studies had different inclusion/exclusion criteria, used different conditioning, treatment, and immunosuppression regimens, and the patients had variable co-morbid conditions. The authors did not discuss any evaluation of the quality of the studies, or how they pooled the data. The results of the compiled data showed that 44% of the patients had complete response to the treatment, and that 51% developed acute GVHD, and 23% developed chronic GVHD. Some analyses were done for specific diseases. Three recent studies (Alyea 2005, Sorror 2004, and Diaconescu 2004) compared the outcomes of transplantations after nonablative and ablative regimens in different centers in the US. They were not randomized rather retrospective analysis of cohorts of patients selected to receive the nonablative conditioning regimens, and matched controls conditioned with myeloablative regimens. The results of these analyses showed that patients who received the nonablative conditioning had lower transplant related mortality, nonrelapse mortality rates, and experienced less or comparable grade II to IV toxicities despite the fact that they were older, had more advanced diseases, and more co-morbidities. The three studies had specific questions, defined inclusion/exclusion criteria, and comparison groups, yet they were only observational, and subject to bias and confounding. Randomization would have been ideal, but is not an option as patients conditioned with nonablative regimen are not candidates for the standard ablative conditioning. Specific hematologic diseases: [AML](#) Sayer et al's article (2003) reported on 113 patients with AML treated at ten German transplant centers between February 1998 and December 2000, using reduced intensity conditioning regimens. Their ages ranged from 16-67 years, and the survivors had a median follow-up of 12 months (range 46-937 days). The authors analyzed the outcomes of this retrospective series of patients, and did not include a control group. There were multiple baseline variations in the patient and disease characteristics, and according to the authors,

inclusion criteria differed between centers, with no clear or accurate definition for who is or is not eligible for the standard conditioning regimen. The results of the analysis show that the estimated 2-year overall survival, and event free survival after the procedure were 32% and 29% respectively. The rate of acute GVHD grades II-IV was 42%, and that of chronic GVHD was 32.7%. The latter was extensive among 6.5% of the patients. The compiled data in Djulbegovic's systematic review (N=62) showed a 66% complete response rate, 36% acute GVHD, and 23% chronic GVHD. [AML/MDS De Lima and colleagues \(2004\)](#) compared the outcomes of 94 patients with AML or MDS treated with either a reduced intensity or a nonablative conditioning regimen. The average ages were 61 and 54 years in the two regimens respectively, and the median duration of the follow-up was 40 months. It was a retrospective analysis and there were several baseline variations in the patients' and disease characteristics among the recipients of the two regimens, as well as some variations in the source of transplant received. The analysis had the advantage of comparing two regimens but the disadvantage of non-randomization, which is a potential source of selection bias. The regimens were not compared to the conventional ablative regimen. Overall, the results of the study indicate a 3-year actuarial progressive free survival rate of 34%, and overall survival of 27% with no statistically significant difference between the two groups. The rate of acute GVHD grade II-IV was 36%, and that of chronic GVHD was 34% for all patients. Ho and colleagues (2004) presented the results of 62 patients who received a reduced intensity allogeneic hematopoietic stem cell transplant for MDS, and AML with multilineage dysplasia, in one center in UK. The donors were either siblings or unrelated volunteers. The ages of the patients ranged from 5-60 years with a median of 53 years, and they were followed up for a median of 348 days (range 37-1,495 days). The overall survival was 89% at 100 days, 80% at 200 days, and 74% at one year. The corresponding disease free survival rates were 84%, 67% and 62% respectively, and the nonrelapse mortality at one year was 15%. None of the related recipients, and 9% of the unrelated recipients developed acute GVHD. Extensive chronic GVHD developed in only 3% of the population. The nonmyeloablative transplantation was not compared to any other therapeutic strategy, or to no treatment. [Multiple myeloma Gerull and colleagues \(2005\)](#) reported the outcomes of 52 MM patients who received nonmyeloablative allogeneic transplantation between September 1999 and June 2003, at the University of Heidelberg, Germany. The ages of the patients ranged from 36 to 68 years, and they were followed up for a median of 567 days, (479 days for survivors). At the time of analysis only 24 patients (46%) were alive. The results show that the estimated overall survival at 18 months was 41%, and the estimate progression free survival also at 18 month was 29.4%. 38% developed GVDH grade II-IV, and 70% developed chronic GVHD. This study only presents an analysis of a retrospective data of a heterogeneous group of patients treated at one center, followed up for a relatively short time, and the treatment was not compared to an alternative therapy or no treatment. Compiled data in Djulbegovic's systematic review on 103 patients with MM show complete response rate of 37%, acute GVHD among 59%, and chronic GVHD among 18% of the patients. [NHL Khouri and colleagues \(2004\)](#) reported on the results of a prospective cohort of patients treated with nonmyeloablative stem cell transplantation for advanced recurrent NHL after a prior response to conventional treatment study, in one center in Texas. Their ages ranged from 21 –68 years with a median of 55 years. 20 (41%) patients had follicular lymphoma, 15 (31%) had transformed or de novo diffuse large cell lymphoma, and 14 (28%) had mantle cell lymphoma. All had received a prior treatment with a range of 1-4 chemotherapy regimens (median 4), and 17% had failed a previous autologous transplant. The results of the analysis show that hematopoietic recovery occurred within 25 days (median 11 days), 22% had a persistent or progressive disease after transplantation, 20% developed acute GVHD, and 36% developed chronic extensive GVHD. 2% of the patients died within 100 days and 6% after 100 days. The study was small, with potential biases, and no comparison group. Compiled data from Djulbegovic's systematic review on patients with NHL (N=103) show complete response rate of 31%, acute GVHD among 50%, and chronic GVHD among 12% of the patients. [Renal cell carcinoma: Peccatori and colleagues \(2005\)](#), analyzed data from 70 patients who received reduced intensity stem cell transplantation for advanced renal cell carcinoma in nine European transplant centers from 1999 to 2003. The authors selected ten variables and entered them in a univariate analysis. Those significantly correlated with survival were entered in a multivariate regression analysis, which suggested three prognostic parameters according to which the authors categorized the study patients as high or low risk groups. After a median follow-up of ten months the median survival (according to Kaplan Meier estimates) was 23 months for the low-risk group, and 3.5 months for the high-risk group. The study population was a highly selected group of patients, and the therapy was not compared to an alternative strategy or to no treatment. Conclusion: The results of the published studies do not provide strong evidence on the efficacy of nonmyeloablative stem cell transplants in improving the net health outcomes of patients with hematopoietic malignancies. The studies were all observational case series with different selection criteria. Those with comparison groups were retrospective and nonrandomized. There were significant differences in patients' characteristics, disease characteristics and stages, and other co-morbid conditions. Moreover, there was no clear or accurate definition for who is, or is not eligible for the standard conditioning regimen. Multiple conditioning regimens, treatments, and GVHD prophylaxis regimens were used. Randomized controlled trials might not be an option among these patients who are not candidates for transplantation with the conventional conditioning regimens. Overall, the results of existing published studies, with their limitations, indicate good overall survival and disease free survival rates, and reduced regimen-related

toxicities with the nonmyeloablative stem cell transplantations despite the older age of the patients and presence of more co-morbid conditions and/or organ dysfunctions.

The search yielded more than 600 articles. The majority were reviews, opinion pieces, or dealt with the technical aspects of the procedure. The literature did not reveal any randomized controlled trials. One systematic review of case series was identified. Other published studies were small prospective or retrospective case series or case reports, and most lacked control groups. Most studies included patients with a wide range of hematologic malignancies, and only a few included cohorts of patients with a specific disease. Hematological malignancies: The search identified several case series with population sizes ranging from six patients to just over 100. There was one systematic review with some compiling of the results of smaller studies, and several other prospective and retrospective series. The systematic review, and the studies with comparison groups were selected for critical appraisal. *Specific disease results:* Acute myeloid leukemia and myelodysplastic syndrome (AML/ MDS) The search revealed few studies on patients with AML or MDS. The series with comparison groups, large number of patients, and published in full text were reviewed.

**Articles:** The literature search for articles published on MM after the last review revealed a recent case series with 52 patients (Gerull 2005), and smaller series with less than 25 patients. Gerull's study was selected for critical appraisal. Lymphoma: Hodgkin's disease (HD) and Non Hodgkin's lymphoma (NHL): There were few small case series on either HD, and /or NHL. The largest series with 49 patients was selected for the review. Other hematopoietic diseases Studies on other hematologic conditions included small number of patients and were not critically appraised. Renal cell carcinoma (RCC): There were several reports on small case series (sizes ranging from 6-18) of patients with RCC treated with nonmyeloablative stem cell transplantation. Very recently a larger analysis of 70 patients with advanced RCC was published. The latter was critically reviewed. *The following articles were selected for critical appraisal:* Alyea EP, Kim HT, Ho V, et al. The use of nonmyeloablative stem cell transplantation (mini-stem cell transplantation) in the treatment of hematologic malignancies, acute myeloid leukemia, myelodysplastic syndrome, Melanoma and Renal Cell Carcinoma, Multiple Myeloma does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Scleroderma**

### BACKGROUND

Scleroderma is a rare multi-system autoimmune disease notable for a pathologic fibrotic thickening of the skin and abnormalities of the vasculature and visceral organs. It is progressive, debilitating, and often fatal. There is no cure and treatment usually involves anti-inflammatory and immunosuppressive agents such as high dose steroids. The symptomatic improvement seen following immune suppression led investigators to propose treatment of scleroderma by destroying the immune system with high-dose chemotherapy and then restoring immune function by infusing the patient's own stem cells. The patient's stem cells are mobilized by administering cyclophosphamide and then harvested for later reinfusion. High doses of chemotherapeutic agents are then used to destroy the patient's immune system. The previously harvested stem cells are then re-infused and in most cases, restore normal immunologic function.

## 8/11/1999: MTAC REVIEW

### **Scleroderma**

**Evidence Conclusion:** Evidence identification was conducted by searching MEDLINE from 1995-1999 using terms multiple sclerosis, hematopoietic stem cell transplant, stem cells, and transplantation. The author of the largest case series was contacted to ascertain if there were any studies published which had not been previously identified.

**Articles:** The best, published scientific evidence consists of a case series of 15 patients with a history of progressive MS for a median of 6 yrs and severe disability. Most of the patients were observed for only a few months after treatment; only 3 of the 15 patients were followed for a year or more. Six months after treatment, 3 of 13 patients had improved by at least 1.5 points on the Kurtzke Disability Status Scale (0=normal to 10=death from MS) and 1 patient had worsened by 1 point. The mean improvement was less than 1 point at 6 months. Using the Scripps Neurological Rating Scale (0-100) eight of 13 patients improved by 20 points or more at 6 months. The mean improvement was 22.5 points at 6 months. Transplant-related complications included sepsis and anaphylactic shock. This case series does not prove that high dose chemotherapy with stem cell rescue is an effective treatment for MS. Because some patients who carry the diagnosis of progressive MS may experience neurologic improvement without treatment, one cannot be certain that the clinical improvement documented in this study was the result of the therapeutic intervention. Fassas A, et al. Peripheral blood stem cell transplantation in the treatment of progressive multiple sclerosis: first results of a pilot study. *Bone Marrow Transplantation* 1997;20:631-8 See [Evidence Table](#)

The use of stem cell transplantation in the treatment of multiple sclerosis does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Stem Cell Transplantation for Amyloidosis**

#### BACKGROUND

Amyloid is a protein that is made by plasma cells in bone marrow. There are several forms of amyloid; one form is lighter than the others. A disease called amyloidosis occurs when too much of the light form of amyloid is produced and the proteins are deposited in the body's organs and tissues. The most common form is primary (AL) amyloidosis that mainly affects the heart, lungs, skin, tongue, nerves and intestines. The accumulation of amyloid causes progressive disruption of the normal tissue structure and ultimately leads to organ failure. Signs and symptoms of amyloidosis are generally nonspecific and are seen in a small proportion of patients. Many patients have multi-system involvement at diagnosis. The natural history of amyloidosis is that it is fatal within 2 years in about 80% of patients. It is a rare condition, affecting approximately 3000 people in the United States per year (United Kingdom Myeloma Forum, 2004; Gertz & Rajkumar, 2002; MayoClinic.com). The standard treatment for AL amyloidosis is oral melphalan. However, this has a clinical response rate of only about 20% and is not effective for rapidly progressive disease (Dispenzieri et al., 2004; Skinner et al., 2004). The use of high-dose intravenous melphalan, followed by autologous stem cell transplantation was first described in the literature in 1996. Stem cells are collected from the patient's bone marrow before high-dose chemotherapy is administered. Early case series found a substantially higher procedure-related mortality than for patients with multiple myeloma. There is also significant risk associated with stem cell mobilization in patients with AL amyloidosis. However, positive results have been reported in patients who survive the treatment. A United Kingdom guideline does not recommend high-dose chemotherapy and stem cell transplantation for patients with any of the following: over 70 years old, more than two organ systems involved, symptomatic cardiac neuropathy or autonomic neuropathy, dialysis-dependent renal failure or a history of GI bleeding due to amyloid (United Kingdom Myeloma Forum, 2004). The amyloid patients who are eligible for high-dose chemotherapy and stem cell transplantation are a highly select group. Researchers at the Mayo Clinic reviewed their records and found that fewer than 20% of their amyloidosis patients would have theoretically been eligible for the treatment. The researchers point out that, due to the better prognosis of this group compared to other amyloidosis patients, a randomized controlled trial or study with a matched control group is needed to determine efficacy (Gertz & Rajkumar, 2002).

## 10/13/2004: MTAC REVIEW

### **Stem Cell Transplantation for Amyloidosis**

**Evidence Conclusion:** There is evidence from a matched case-control study (Dispenzieri) that high-dose chemotherapy and autologous stem cell transplantation improves survival in patients with amyloidosis. Two-year survival in the Dispenzieri study was 70% in the cases and 40% in controls. Matching reduces, but does not eliminate the potential for selection bias. The evidence is weaker than that provided by a randomized controlled trial which can control for group differences on unmeasured characteristics. There were no appropriate randomized controlled trials or other matched studies. Experts in amyloidosis have stressed the need for randomized or matched studies because of the better prognosis of patients with amyloidosis who are eligible for

high-dose chemotherapy and stem cell transplantation. The Skinner study was a descriptive analysis of one institution's experience over 8 years. It did not match patients and is therefore subject to selection bias. The searched yielded 112 articles, many of which were reviews, opinion pieces, dealt with technical aspects of the treatment or addressed similar treatments or diseases. There was one randomized controlled trial. In the RCT, both groups received high-dose chemotherapy and stem cell transplantation, one initially and the other after two rounds of oral chemotherapy. Since there was no comparison to a different treatment, this study was not reviewed.

**Articles:** The best, most relevant, evidence was a matched case-control study comparing patients who did and did not receive high-dose chemotherapy and stem cell transplantation. This was critically appraised, along with the largest case series. *The two studies reviewed were:* Dispenzieri A, Kyle RA, Lacy MQ et al. Superior survival in primary systemic amyloidosis patients undergoing peripheral blood stem cell transplantation: a case-control study. *Blood* 2004; 103: 3960-3963. See [Evidence Table](#) Skinner M, Sanchorawala V, Seldin DC et al. High-dose melphalan and autologous stem-cell transplantation in patients with AL amyloidosis: An 8-year study. *Ann Intern Med* 2004; 140: 85-93. See [Evidence Table](#)

The use of stem cell transplantation in the treatment of amyloidosis does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Stem Cell Transplantation for Autoimmune Diseases**

### **BACKGROUND**

Autoimmune diseases (ADs) encompass a heterogeneous group of chronic systemic disorders with different genetic, environmental, and individual etiological factors, as well as different prognoses. They are highly prevalent, have a significant morbidity and mortality, and a considerable economic cost to the patients and the community. For most ADs the exact pathophysiology remains unclear and may vary from one disease to another. It is known however, that some immunogenic predisposition combined with environmental triggers is required to initiate most ADs (Gratwohl 2005, Tyndall 2005). Among the categories of autoimmune diseases are neurological disorders, rheumatological disorders, vasculitis, hematological immunocytopenias, gastrointestinal and others. Multiple sclerosis, systemic sclerosis, systemic lupus erythematosus, and rheumatoid arthritis are the most commonly encountered ADs. Multiple sclerosis (MS) is a chronic inflammatory disease that affects the central nervous system. It is the most frequent cause of neurologic disability in young adults in Western countries. MS is thought to be an autoimmune disease, but there are other views for its origin. The disease causes gradual demyelination and axonal degeneration in the brain and spinal cord. The clinical course of MS is widely variable ranging from isolated episodes with no clinical significance to impaired mobility, disability, and reduction of life expectancy in more severe cases (Saccardi 2005). Several therapies have been utilized, but currently immunosuppression and immunomodulation are the only recognized forms of therapy. Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune disease that affects predominantly young women and may range from a relatively mild condition to a severe life threatening disease involving major organs such as the kidney, brain, lung, or the hematopoietic system. Renal involvement is the most common severe manifestation; it occurs in 30-50% of patients and has a 9-25% rate of end-stage renal failure. Lupus has no cure, but in the majority of cases it is responsive to treatment with immunosuppression and steroids. It was reported that more than half of the patients have permanent organ damage, much of which is due to, or increased by corticosteroids (Petri 2006). The disease often pursues a relapsing or refractory course that results in poor quality of life and reduced survival (Jayne 2004). Systemic sclerosis (SSc) also known as scleroderma, is a clinically heterogeneous autoimmune disease characterized by excessive collagen deposits in the skin and internal organs. It was found that rapidly progressive SSc, both in the cutaneous and diffuse forms, has a 5-year survival rate of 20-80%, and a 10-year survival rate of 15-65% (Farge 2004). Various treatments were tried, but none has been proven effective in preventing disease progression or reversing fibrosis. Rheumatoid arthritis (RA) is a chronic systemic inflammatory autoimmune disease of undetermined etiology that affects about 1% of the population (Snowden 2004). It primarily involves the synovial membranes and articular structures of multiple joints leading to substantial pain, joint destruction, and loss of mobility. RA often affects extra-articular tissues throughout the body including the skin, blood vessels, muscles, heart, and lungs. It is a disorder for which there is no cure, and current treatment methods focus on relieving pain, reducing inflammation, slowing joint damage and improving function, and sense of well-being. Patients with severe diseases however may not be controlled by the conventional methods used. In general, immunosuppression and immunomodulation are the basic therapeutic strategies for autoimmune diseases, and are usually successful. However, certain patients do not respond to these therapies, and require more toxic drugs to achieve or maintain remissions (Gratwohl A, 2005). The ability to use immunosuppressive or cytotoxic therapy over longer periods of time is limited due to infections, bone marrow toxicity, and secondary malignancy. In the last decade, hematopoietic stem cell transplantation (HSCT) after intense immunosuppression has been proposed as a possible strategy for the treatment of severe or refractory autoimmune diseases. HSCT is a short name for a complex multi-step treatment aimed at resetting the dysregulated immune system of patients with severe autoimmune diseases. Various protocols have been tried

depending on the underlying disease and experience of the transplant centers. The majority were based on autologous HSCT which is a 3-step procedure involving collection of hemopoietic stem cells (HSCs), treating the patient with a conditioning regimen to eliminate self-reacting lymphocytes within the body, and finally re-infusion of the previously frozen autologous stem cells. The source of stem cells may be bone marrow, cord blood, or peripheral blood. Peripheral blood stem cells harvest contains more progenitor and mature lymphocytes and gives more rapid hematological and immunological reconstitution. It is also simpler to collect than bone marrow harvests, and do not require general anesthesia (Tyndall 2005). Once mobilized, the stem cells are harvested, manipulated, and may be cryopreserved. The conditioning regimens used are designed to specifically target the lymphocytes (lymphoablative regimens) or to destroy the entire hematopoietic bone marrow compartment (myeloablative regimen). However, the goal of autologous HSCT for AD is to generate new self-tolerant lymphocytes after elimination of self or autoreactive lymphocytes within the patient, rather than ablate and reconstitute the entire hematopoietic compartment (Burt 2006). A major difference between lymphoablative and myeloablative regimens is the use of total body irradiation. The latter may have deleterious effects among patients especially those with SSc as radiation can cause microvascular damage. After conditioning the patient, the graft is thawed and infused. Hematological reconstitution occurs in 10-12 days, and immunological reconstitution takes longer. HSCT for autoimmune diseases is still in its experimental stages, it has a learning curve, and some researchers are concerned that it might not be feasible, or too toxic in immunosuppressed patients with organ involvement from the underlying AD.

#### **04/2/2007: MTAC REVIEW**

##### **Stem Cell Transplantation for Autoimmune Diseases**

**Evidence Conclusion:** The use of hematopoietic stem cell transplantation in the treatment of severe refractory autoimmune diseases is still in the experimental phase. All published studies were case reports or small case series that assessed the feasibility, tolerance, and efficacy of the transplant for patients with ADs. None included a control or comparison group. These cases were registered in databases, the largest of which is The European Bone Marrow transplant/European league against Rheumatism (EBMT/EULAR) registry. Gratwohl, and colleagues (2005), analyzed the data recorded in the EBMT registry up to 2003. It included records for 473 patients treated in 110 transplant centers in 21 countries in Europe and Australia. This has the advantage of studying the efficacy and safety of the procedure in a larger series of patients, but has several limitations including the variations between these centers in the eligibility criteria, patient characteristics, autoimmune disorders and stage of the disease, protocol and techniques of the transplant, and experience in performing the procedure as well as others. Moreover the analysis did not include a control or comparison group that received an alternative or no treatment. The results of the analysis show that the overall treatment mortality was 7% and with large differences between the ADs (20% for immune thrombocytopenia, 14% for SLE, and 2% for rheumatoid arthritis). The results also show that the more aggressive conditioning regimen was statistically associated with slowing down of the disease progression, but was also associated with a significantly higher treatment related mortality. In conclusion the published studies to date do not provide sufficient evidence to determine the efficacy and safety and long term net health outcome of stem cell transplantation in the treatment of autoimmune diseases. All studies on HSCT published to date are phase I-II clinical trials (only case series with no controls). Phase III RCTs are underway in US and Europe, and none has been completed and reported to date. The published reports are mostly on one or two individual cases or small case series that either included patients with a specific autoimmune disease, or grouped patients with different ADs who underwent an autologous HSCT. The inclusion/exclusion criteria, patient characteristics, protocol, and technique of the procedure, as well as the population size and duration of follow-up varied between the trials. The population sizes of the case series ranged from as low as 8 patients with miscellaneous ADs in one study with 12 months of follow-up, to 50 patients with systemic lupus erythematosus who were followed up for a mean of 29 months. The majority of the published reports collected their data from databases, and had overlapping population. The largest database is The European Bone Marrow transplant/European League Against Rheumatism (EBMT/EULAR) International Stem Cell Project database. Other databases for stem transplantation include the International Bone Marrow Transplantation (IBMTR) registry, and the Autologous Blood and Marrow Transplant Registry (ABMTR) in the US, the Sylvia Lawry Center, Munich, Germany database, and the International Autoimmune Diseases stem cell Database in Basel, Switzerland.

**Articles:** There is insufficient literature on reduced intensity conditioning and allogenic HSCT. The article (Gratwohl 2005) that analyzed data on the efficacy and toxicity of HSCT recorded in the EBMT database was critically appraised. Gratwohl A, Bocelli-Tyndall C, Fassa A, et al. Autologous hematopoietic stem cell transplantation for autoimmune diseases. *Bone Marrow Transplantation* 2005; 35:869-879. See [Evidence Table](#)

The use of stem cell transplantation in the treatment of autoimmune disorders does not meet the *Group Health Medical Technology Assessment Criteria*.

## Allogeneic Bone Marrow Transplantation (BMT) in Low-Grade Lymphoma (LGL) and Chronic Lymphocytic Leukemia (CLL)

### BACKGROUND

Low grade lymphomas (LGL) are indolent malignancies with a high rate of initial response to treatment and median survival duration of 7-10 years. Radiation therapy or the combination of radiation and chemotherapy can produce durable remissions in some patients with stage I, II, or III disease. Patients with an advanced, recurrent or refractory disease have a poor prognosis. The use of myeloablative therapy and autologous BMT showed positive results among patients with recurrent disease, but not among those with an extensive bone marrow involvement or refractory disease. Allogeneic BMT is viewed as an attractive option to treat younger patients with refractory or recurrent disease, with the idea that donor lymphoid cells can potentially mediate a graft versus lymphoma (GVL) effect, and achieve a long term disease control. Chronic lymphocytic leukemia (CLL) is the most common form of leukemia in Europe and North America. Although it is generally considered a disease of the elderly, it is increasingly recognized in younger patients. CLL is characterized by the heterogeneity in clinical behavior and life expectancy for those affected by it. Treatment options for CLL are the use of steroids, alkylating agents, or observation. Bone marrow transplantation is not a standard therapy but autologous and allogeneic transplants are increasingly being used. BMT which induces high remission rates, yet a small percentage of durable remissions, is an appealing treatment strategy for younger patients. The use of tumor free grafts constitutes an obvious advantage of allogeneic over autologous bone transplantation. The allogeneic transplantation however, has considerable treatment-related complications and mortality, particularly graft-versus-host disease (GVHD) and infections. Other reasons for the infrequent use of allogeneic BMT are the frequent lack of a matched sibling donor and the higher cost of care. Many questions regarding patient selection, efficacy and outcome are still unresolved. Description: Before BMT, patients are conditioned with total body irradiation (TBI) containing regimens, which may also include cyclophosphamide. After the infusion of the bone marrow, immune suppression is generally used for GVHD. The bone marrow source is human leukocyte antigen (HLA) matched sibling, syngeneic donor, or HLA matched unrelated donor.

### 12/12/2001: MTAC REVIEW

#### Allogeneic Bone Marrow Transplantation (BMT) in Low-Grade Lymphoma (LGL) and Chronic Lymphocytic Leukemia (CLL)

**Evidence Conclusion:** The case series reviewed do not provide sufficient evidence to determine the efficacy and outcome of allogeneic bone marrow transplantation, for low-grade lymphoma, and chronic lymphocytic leukemia. Case series provide the least grade of evidence; they lack a control or comparison group and are prone to selection bias, and confounding. The search yielded 161 articles. Articles were selected based on study type. Most of the articles were reviews, opinion pieces, editorials, letters, and commentaries.

**Articles:** The literature did not reveal any randomized controlled trials, or meta-analyses, only clinical reports and case series. Evidence tables were created for the following articles: van Besien, K ; et al. Allogeneic bone marrow transplantation for low-grade lymphoma. *Blood* 1998; 92: 1832-6 See [Evidence Table](#) Toze CL, Shepherd JD, et al. Allogeneic bone marrow transplantation for low-grade lymphoma and chronic lymphocytic leukemia. *Bone Marrow Transplantation* 2000; 25: 605-612. See [Evidence Table](#)

The use of allogeneic bone marrow transplantation in the treatment of low-grade lymphoma, and chronic lymphocytic leukemia does not meet the *Group Health Medical Technology Assessment Criteria*.

## Codes

CPT: 38240, 38241, S2150

## Clinical Review Criteria

### Stereotactic Radiation (Radiosurgery/Focused Beam/Gamma Knife)

- CyberKnife Robotic Radiosurgery System
- Fractionated Stereotactic Radiotherapy
- Multiple Brain Metastatic Lesions (5 or more brain metastatic lesions)
- Proton Beam Therapy for Prostate Cancer

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Local Coverage Determination (LCD)

[Stereotactic Radiosurgery \(SRS\) and Stereotactic Body Radiation Therapy \(SBRT\) \(L34151\)](#)

And for facility-based services billed using a UB form, see [Stereotactic Radiosurgery \(SRS\) and Stereotactic Body Radiation Therapy \(SBRT\) \(L34136\)](#).

#### For Non-Medicare Members

Group Health has elected to use the Stereotactic Radiosurgery (GHC-0423) MCG\* for medical necessity determinations.

**MCG\*are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Most recent medical oncology notes
- Most recent radiation oncology notes
- Most recent imaging (i.e. CT/MRI)

Service	Criteria Used
<ul style="list-style-type: none"> <li>▪ Multiple Brain Metastatic Lesions (5 or more brain metastatic lesions)</li> <li>▪ Stereotactic Body Radiation Therapy (SBRT) for Prostate Cancer</li> </ul>	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Radiosurgery can be defined as the stereotactic (precision) delivery of multiple cross-fired radiation beams to a point or volume within a configured space (Chang 2003). Stereotactic radiosurgery may also be described as a method to destroy targets using single high doses of focused ionizing radiation, administered using stereotactic guidance (Niranjan 2001). It is a combination of minimally invasive technologies administered by a multidisciplinary team consisting of surgeons, oncologists, medical physicists, and engineers.

Stereotactic radiosurgery (SRS) was originally designed to produce functional lesions in the brain. It then evolved to target benign tumors and vascular malformations in surgically inaccessible locations. These indications are

continuously expanding with the rapidly evolving technology of radiosurgical systems. Currently it has become an alternative to microsurgery and conventional radiation therapy in the treatment of many lesions in the base of the skull. It is used for vascular, tumor, and functional brain surgery, including arteriovenous malformations, pituitary adenomas, acoustic neuromas, and meningiomas, as well as brain metastases. Radiosurgery was initially limited to the brain because of the requirement of a stereotactic frame attached to the skull to provide a coordinate system for tumor localization. Recent advances however, allow radiosurgical treatment throughout the body without such frames.

A variety of methods have been developed to provide a reference system for the localization study to determine the target coordinates, including fixed frame and frameless systems, removable frame systems, and rigid masks.

Treatment can be repeated any number of times with equal precision as the target is calculated from the position of gold markers. Regardless of the number of sessions, these procedures consist of the following components:

- Head position stabilization (attachment of a frame or frameless)
- Imaging for localization (CT, MRI, or angiography, etc)
- Computer assisted tumor localization
- Treatment planning – number of isocenters, number, placement and length of arcs, beam size and weight, etc.
- Isodose distributions, dosage prescription and calculation
- Setup and quality assurance testing
- Simulation of prescribed arcs or fixed portals
- Stereotactic intervention or treatment itself

Gamma knife, the prototype of stereotactic radiosurgery was first clinically used in 1967. It developed rapidly from the earlier A-units to B units, and in 1999 to Model C that has a robotic engineering. With the gamma knife, the patient's head is placed within a large metal collimator consisting of a dome-shaped shell with holes that transmit the radiation to the center point. A stereotactic frame is anchored to the skull with four screws that penetrate the outer table to position the head so that the desired target is at the center of the collimator. The use of the frame limited the use of the gamma knife to head lesions, and to patients who could tolerate the rigid frame fixation. Moreover, the use of fractionated treatments that extended for several days was impractical with the frame fixation (Giller 2005).

The CyberKnife is a recently developed frameless stereotactic system that consists of a modified linear accelerator mounted on a robotic arm that moves slowly around the patient. It delivers several beams of radiation at each of many stopping points while minimizing radiation exposure of surrounding tissue (Quinn 2001). Stereotactic precision is achieved without a rigid frame by means of two diagnostic x-ray cameras mounted in the CyberKnife vault and are used to acquire real-time images of the patient's internal anatomy during treatment. Any patient motion is detected by these images, and the information is used by the robot to compensate and keep the linear acceleration on target. Treatment time ranges from 45-60 minutes and can be given in one fraction, or several fractions with smaller doses given over several days, depending on the condition being treated and the size of the affected area.

The use of the CyberKnife for radiosurgery of organs other than the brain is more challenging and requires several technical refinements. When used for spinal lesions for example, it requires the placement of internal small 2-mm stainless steel screws in the spinal lamina adjacent to the target site as "fiducial markers" (Giller 2005).

Radiosurgery has its advantages as well as risks. It is non invasive, and can treat poor surgical candidates, and tumors inaccessible to surgery. Moreover, it can safely deliver higher doses of radiation than those used in conventional radiotherapy, while sparing the surrounding tissues from the high levels of radiation. It can thus be more effective in treating radioresistant and recurrent tumors, and may be used as a boost to conventional radiotherapy. On the other hand, its was reported that its efficacy is lower and risk of complications higher in larger tumors, or those that were previously treated with radiation. Another limitation is the sensitivity of the optic nerve and chiasma to radiosurgical doses. There is also the risk of radionecrosis which is a combination of cytotoxic and microvascular tissue injury within the treated field due to radiation. This may be delayed for months, asymptomatic, severe, and /or persistent (Giller 2005).

The CyberKnife was cleared by the FDA in October 2001 for radiosurgery for lesions, tumors, and other conditions in any anatomical site.

Trigeminal neuralgia (tic douloureux) is a disorder of the fifth cranial (trigeminal) nerve that causes episodes of intense, stabbing pain (separated by pain-free periods) in the areas of the face where the branches of the nerve are distributed.

The general approach to treating this disorder is to begin treatment with pharmacological agents and to initiate surgical treatment if medical treatment fails. There are 3 categories of surgical options: 1) Percutaneous procedures (glycerol injection commonly used at GHC); 2) Microvascular decompression; 3) Focused beam radiosurgery (gamma knife, LINAC). According to the MRU, GHC patients currently referred for radiosurgery on a case-by-case basis).

In gamma knife radiosurgery, magnetic resonance imaging (MRI) is used to identify the trigeminal nerve root. Subsequently, a single 4-mm isocenter of radiation is delivered to the trigeminal nerve root (just posterior to the pons). The radiation dose is 70-90 Gy. No surgical incisions are made.

### ***Gamma Knife in the treatment of Trigeminal Neuralgia***

**04/12/2000: MTAC REVIEW**

**Evidence Conclusion:** Since this topic was last reviewed in 1997, there have been two moderately sized case series articles published examining gamma knife radiosurgery on trigeminal neuralgia. A substantial proportion of patients improved after treatment with low rates of adverse outcomes. Case series have numerous threats to validity and provide weak evidence. If patients with trigeminal neuralgia are known to uniformly experience unrelenting pain, however, the improvement reported in these papers is more suggestive of efficacy. Even in this situation, it is not known whether alternate treatments might be as or more effective than gamma knife radiosurgery. If pain episodes tend to occur infrequently, case series results are less impressive because many patients would likely have been in remission during the initial follow-up period.

**Articles:** Articles were selected based on study type. For gamma knife therapy, there were no randomized control trials or meta-analyses. Several case series were sub-sets of subsequent case series. The largest and most comprehensive case series that had not been previously reviewed for the 1997 CPC evaluation were selected for critical appraisal and evidence tables were created (Kondziolka, D, Perez, B, Flickinger, JC, Habeck, M, Lunsford, D. Gamma knife radiosurgery for trigeminal neuralgia. Arch Neurol 1998; 55: 1524-1528. Young, RF, Vermeulen, S, Posewitz, A. Gamma knife radiosurgery for the treatment of trigeminal neuralgia. Stereotact Funct Neurosurg 1998; 70 (suppl 1): 192-199). The search on LINAC did not yield any additional articles. One book chapter on LINAC was located. This reported on a case series with 10 patients and was not included in this review due to the small sample size. Young, RF, Vermeulen, S, Posewitz, A. Gamma knife radiosurgery for the treatment of trigeminal neuralgia. Stereotact Funct Neurosurg 1998; 70 (suppl 1): 192-199. See [Evidence Table](#). Kondziolka, D, Perez, B, Flickinger, JC, Habeck, M, Lunsford, D. Gammaknife radiosurgery for trigeminal neuralgia. Arch Neurol 1998; 55: 1524-1528. See [Evidence Table](#).

The use of Gamma Knife in the treatment of Trigeminal Neuralgia does not meet the *Group Health Medical Technology Assessment Criteria*.

### ***CyberKnife Robotic Radiosurgery System***

**06/05/2006: MTAC REVIEW**

**Evidence Conclusion:** CyberKnife; There were no published meta-analyses or randomized controlled trials on the CyberKnife radiosurgery system. There were only case reports and small case series with no control or comparison groups. Case series have numerous threats to validity and provide the weakest grade of evidence, Chang, et al reported on their experience with radiosurgical treatment with the CyberKnife among 61 patients treated in their center at Stanford University over 3 years, and who had at least 36 months of follow-up. The treatment was not compared to an alternative therapy. Data were collected both prospectively and retrospectively, and the main outcome was the tumor response and hearing preservation. The authors did not discuss any inclusion/exclusion criteria, included a heterogeneous group of patients, and two fractionation regimens for the therapy were used. After 36 months of observation, the tumor size decreased among 48% of the patients, was stable among 50%, and increased in size in 2%. Ninety percent of those with those with measurable hearing

maintained their hearing level after treatment. Gerszten and colleagues reported their experience with CyberKnife radiosurgery for spinal lesions among 115 patients with several variations in their baseline characteristics and indications for the treatment. It was also a case series with no control or comparison group and potential selection and observation biases. The median follow-up duration was 18 months, and the outcome was improvement in pain, and tumor control. The results of the series indicate that 94% of the patients presenting with significant pain described an improvement in their pain using a 10-point scale after one month of the treatment. The condition did not progress among those who received the therapy as the primary treatment modality or those who had undergone previous surgery. In conclusion the published literature to date does not provide sufficient evidence to determine the efficacy of Cyberknife for stereotactic radiosurgery for lesions or tumors in various anatomical sites.

**Articles:** The search yielded 71 articles. There were no meta-analyses or randomized control trials on CyberKnife robotic surgery. There were several small case reports and series that dealt with the technology for the treatment of several lesions in different parts of the body including pituitary tumors, extracranial lesions, metastatic brain tumors, acoustic neuromas, trigeminal neuralgia, spinal lesions, lung, renal, and prostate cancer. Gerstzen et al, published two articles on the same series of patients. The largest and most comprehensive case series, and/or the series with long-term follow-up were selected for critical appraisal. Chang SD, Gibbs IC, Sakamoto GT. Staged stereotactic irradiation for acoustic neuromas. *Neurosurgery*. 2005;56:1245-1263. See [Evidence Table](#). Gerszten PC, Ozhasoglu C, Burton SA, et al. Evaluation of CyberKnife frameless real-time image-guided stereotactic radiosurgery for spinal lesions. *Stereotact Funct Neurosurg*. 2003; 81:84-89. See [Evidence Table](#). Gerszten PC, Ozhasoglu C, Burton SA, et al. CyberKnife frameless stereotactic radiosurgery for spinal lesions: Clinical experience in 125 cases. *Neurosurgery*. 2004; 55:89-99. See [Evidence Table](#).

The use of CyberKnife Robotic Radiosurgery System in the treatment of lesions, tumors, and other conditions in any anatomical site does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Gamma Knife in the treatment of five or more brain metastatic lesions**

#### **02/09/2015: MTAC REVIEW**

**Evidence Conclusion:** To date, there is no direct evidence from randomized controlled trials to determine that stereotactic radiosurgery alone or in combination with WBRT for patients with more than 4 brain metastases leads to better or equivalent outcomes to those of WBRT as regards overall survival, local recurrence, need for salvage therapy, neurological functioning, quality of life, or other outcomes. The best published evidence consists of a recent large prospective observational study of patients with one to 10 brain metastases (Yamamoto et al, 2014), two case-matched studies conducted by the same principal author and colleagues, that compared SRS treatment results for patients with 1-4 versus  $\geq 5$  tumors and 2-9 vs.  $>10$  brain metastases (Yamamoto et al, 2013 & 2014 respectively), and a number of retrospective analyses of patients for multiple brain metastases treated with SRS used alone or in conjunction with surgical excision or WBRT. The prospective study conducted by Yamamoto and colleagues (2014, Evidence table 1) included 1,194 patients with 1-10 newly diagnosed brain metastasis, with a maximum lesion volume  $<15$  mL, and a Karnofsky performance status (KPS) score of  $\geq 70$ . All patients received standard stereotactic radiosurgery and the primary outcome was overall survival for which the non-inferiority margin for the comparison of outcomes in patients with two to four brain metastases with those of patients with five to ten brain metastases was set as the value of the upper 95% CI for a hazard ratio (HR) of 1.30. The results of the analysis showed a median overall survival after stereotactic radiosurgery of 13.9 months in the patients with one brain metastasis, 10.8 months for those with 2-4 metastases, and 10.8 months among those with 5-10 lesions). Overall survival did not differ between the patients with two to four vs. those with 5-10 lesions (HR 0.97, 95% CI 0.81-1.18). This was less than the value of non-inferiority margin set by the authors a priori. The same group of investigators performed two retrospective case matched-studies to examine whether treatment results of SRS alone for patient with five or more brain metastases differ from those for patients with 1-4 metastases in one study, and for patients with 2-9 versus 10 or more lesions in the other study (Yamamoto et al 2013, 2014). Overall the analysis comparing outcomes of SRS in patients with more than 5 metastases versus 1-4 showed a minimal, but statistically significant higher survival in patients with 1-4 versus  $\geq 5$  metastases. There were no significant differences between the subgroups in other outcomes including death due to progression of brain disease, need for salvage WBRT, salvage surgery, repeat SRS for new tumors, neurological deterioration, or SRS-related complications. Generally similar results were observed with the comparison of outcomes among patients with 2-9 versus 10 or more brain metastases. The studies had their shortcomings including the inherent limitations of retrospective studies, as well as limitations in analyses performed. The great majority of published observational retrospective studies suggest that the number of brain metastases (exceeding one lesion) had no statistically significant impact on overall survival among patients treated with SRS given alone or in combination with WBRT. These retrospective studies include the largest series (Karlsson et al 2009) with data for 1,885 patients with 1-8 metastases treated over 30 years. The results of the analysis indicate that the median overall survival did not differ significantly between those with 2, 3-4, 5-8 or  $>8$  brain metastatic lesions; but patients with one brain metastasis

survived longer than those with multiple brain metastases. Prospective randomized controlled trials are needed to determine the efficacy of SRS with or without surgery for multiple brain metastases compared to WBRT alone or following surgical excision of the lesions. A randomized controlled study of neurocognitive outcomes in patients with five or more brain metastases treated with radiosurgery or whole-brain radiotherapy is underway. The primary aim of this study is to compare the change in neurocognitive function outcome between baseline and 6 months in WBRT versus SRS treatment groups. Conclusion: There is insufficient evidence to determine that SRS with or without whole brain radiation therapy (WBRT) has non-inferior, equivalent, or superior outcomes to WBRT in the management of patients with five or more brain metastases. There is insufficient direct evidence to determine that the outcomes of SRS in patients with five or more brain metastases are non-inferior or equivalent to those in patients with 1-4 brain metastases.

**Articles:** The literature search revealed over 400 articles on the use of SRS for brain metastases. The majority of published articles were studies evaluating the use of the technology for one to four brain lesions, studies comparing different radiation doses, and articles on the technical aspects of the technology. The search did not identify any randomized controlled trial (RCT) that compared SRS with or without WBRT versus WBRT. Almost all the studies that examined the efficacy of SRS in patients with five or more brain lesions were retrospective, observational studies with no comparison groups. There was one recently published prospective, observational study conducted in Japan (Yamamoto, et al, 2014) among patients with up to 10 brain metastases, and two case-matched retrospective studies conducted by the same group of principal authors comparing the SRS results for patients with 1-4 versus  $\geq 5$  tumors in one study, and 2-9 versus 10 or more lesions in the other. The Prospective study and the case matched study comparing outcomes of SRS for 1-4 versus  $\geq 5$  brain metastases were critically appraised. The results of the retrospective studies published in the last 8 years were summarized and presented in [Table 3](#). Yamamoto M, Serizawa T, Shuto T, et al, Stereotactic radiosurgery for patients with multiple brain metastases (JLKG0901): A multi-institutional prospective observational study. *Lancet Oncol*. 2014 April; 15(4): 387–395. [Evidence tables 1 and 2](#). Yamamoto M, Kawabe T, Sato Y, et al. A case-matched study of stereotactic radiosurgery for patients with multiple brain metastases: comparing treatment results for 1-4 vs  $\geq 5$  tumors: clinical article. *J Neurosurg*. 2013 Jun; 118(6):1258-1268. [Evidence tables 1 and 2](#).

The use of Gamma Knife in the treatment of five or more brain metastatic lesions does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Stereotactic Body Radiation Therapy (SBRT) for Prostate Cancer**

### **BACKGROUND**

Prostate cancer is one of the most common cancers, and the second leading cause of cancer death in men in the US. There are many treatment options for a localized disease, and each has its advantages and side effects. The choice of intervention should be considered carefully, balancing the benefits and harms as they relate to the patient's age, overall health, and personal preferences. External beam radiation therapy (EBRT) is one of the standard treatment options for localized prostate cancer and research shows that there is a dose response for biochemical relapse-free survival. However, the increase in radiation dose to the prostate also results in an increase in exposure to the adjacent organs at risk (namely the bladder, urethra, and rectum). The National Comprehensive Cancer Network (NCCN) Prostate Cancer Guideline (2014) states that doses of 75.6–79.2 Gy in conventional fractions to the prostate are appropriate for patients with low-risk cancers, and that patients with intermediate- or high-risk disease should receive doses up to 81.0 Gy. Several advanced techniques have been developed within the last two decades to deliver these high doses of radiation to the prostate while sparing the surrounding normal tissues. Currently intensity-modulated radiation therapy (IMRT) is the most common EBRT modality used for the treatment of localized prostate cancer. IMRT involves the external delivery of multiple beams of radiation that conform to the shape of the tumor, and where the intensity of each beam can be modulated in order to spare the surrounding healthy tissue. IMRT is typically delivered in 38-45 fractions (treatment sessions) and requires 7-9 weeks of treatment (Parthan 2012, Yamazaki 2014, NCCN 2014). Slowly proliferating prostate cancer cells are thought to have a unique radiobiology that is characterized by a low  $\alpha/\beta$  ratio (around 1.5 Gy as opposed to about 10 Gy for other cancers). This assumption was first promoted in 1999 by Brenner and Hall, based on their observation of 367 patients from two centers. They noted that this low  $\alpha/\beta$  ratio of prostate cancer is comparable or lower than that for late-responding normal tissue (experiments on rodents suggest that  $\alpha/\beta$  ratio for the rectum is 4-6 Gy). This suggests that prostate cancer cells have a high degree of sensitivity to dose per fraction, and that the use of fewer high-dose per fraction radiation treatments (hypofractionation) would improve local tumor control. This theory is controversial, supported by some investigators and questioned by others, yet it provided the biologic rationale in favor of hypofractionated radiotherapy for localized prostate cancer (Brenner 1999, Freeman 2011, McBride 2012, Bolzicco 2013, Cabrera 2013, Katz 2013, Oliai 2013, Mangoni 2014, Tan 2014). Hypofractionation may be defined as moderate (2.4-4 Gy per fraction) or extreme (6.5-10 Gy per fraction). Extreme hypofractionation with high-dose-rate brachytherapy (HDR-BT) has been used in some centers for the treatment of prostate cancer, either as a monotherapy or in combination with EBRT. HDR-BT therapy however, is

not widely adopted due to its relatively invasive nature, need for hospitalization, anesthesia, resources, and technical expertise for the planning and delivery of therapy. It also requires prolonged bed rest that increases the risk of infection and thromboembolism (Jabbari 2012, Fukudo 2014, Koh 2014). Stereotactic radiation therapy refers to non-surgical techniques that deliver precisely-targeted (within a few millimeters) external beam photon radiotherapy. Stereotactic techniques are often used to deliver much higher doses per treatment (in only a single or few treatments), compared to traditional radiation therapy. Stereotactic radiosurgery (SRS) was initially developed to treat small brain tumors and functional abnormalities of the brain. Stereotactic body radiotherapy (SBRT) has recently emerged, and is highly marketed, as a non-invasive alternative to HDR-BT for delivering hypofractionated radiotherapy to the prostate. The term 'stereotactic' means precise positioning of the target within three-dimensional space, and the term 'body' is used to distinguish the technique from the current terminology of SRS used for brain tumors. SRS and SBRT rely on several technologies: 1. Three-dimensional imaging and localization techniques that determine the exact coordinates of the target within the body, 2. Systems to immobilize and carefully position the patient and maintain it during therapy, 3. Highly focused gamma-ray or x-ray beams that converge on a tumor or abnormality, and 4. Image-guided radiation therapy to improve the precision and accuracy of the treatment (Freeman 2011, Radiology Info.org, Aneja 2014, Tan 2014). SBRT for prostate cancer delivers the entire course of therapy in 4-5 visits over 2-2.5 weeks, compared with up to 45 fractions over 9 weeks with conventional fractionation. Thus, it may be more convenient to patients, potentially improve their adherence to therapy, reduce staff and machine burden, and according to a number of analyses (based on modeling), may be less costly than EBRT. However, the use of SBRT for prostate cancer is an area of controversy in the radiation oncology community, and is still regarded by many as an experimental treatment. The mechanism of cell kill with large hypofractionated doses is not fully understood in vivo, and many radiation oncologists have concerns over the potential toxicity of the very high ablative doses delivered per fraction, as well as the risk of disease recurrence (Hodges 2012, Parthan 2012, Cabrera 2013, Seison 2013, Tan 2014). CyberKnife® (Accuray Incorporated, Sunnyvale, CA) is one of the devices used for delivering SBRT. It is a non-gantry-based frameless robotic stereotactic radiation delivery system that consists of a 6MV linear accelerator mounted on a robotic arm, with two orthogonal X-ray imagers to track the inserted gold fiducial markers (GFM) and perform real-time corrections for target repositioning during treatment. CyberKnife delivers hundreds of individualized circular beams with a targeting error of less than 1 mm. allowing the safe delivery of highly conformal treatment plans. To date, CyberKnife has been used to treat tumors of the head and neck, lung, kidney, liver, pancreas, and prostate. The CyberKnife SBRT treatment protocol has two principal phases; treatment planning and treatment delivery. The treatment planning phase involves the implanting of three to four gold fiducial markers (GFMs) in the apex, intermediate lateral zone, and base of the prostate using TRUS for image guided positioning and motion tracking, followed by treatment planning using CT to differentiate the prostate and proximal seminal vesicles from the surrounding tissue. Treatment is then delivered to the prostate by the CyberKnife system in four or five fractions to a total of 34 -39 Gy, given on consecutive or alternating days, according to the study protocol (Freeman 2011, Chen 2013, Seisen 2013). CyberKnife was previously reviewed by MTAC in 2006 for the treatment of lesions or tumors in any anatomical site and did not meet MTAC evaluation criteria. The current review is limited to the use of CyberKnife SBRT for the treatment of prostate cancer, based on a request for coverage of the technology.

## **10/20/2014: MTAC REVIEW**

### **Stereotactic Body Radiation Therapy (SBRT)**

**Evidence Conclusion:** There is insufficient published evidence to date, to determine the long-term safety and effectiveness of SBRT compared to other conventional radiation therapy regimens used for the treatment of localized prostate cancer. The published literature includes a number of phase I and phase II feasibility trials conducted in several centers in the US (Virginia Mason Medical Center, Stanford University, Naples Florida, Georgetown University, Philadelphia CyberKnife Center, and Winthrop University). The population sizes varied between studies from 40 patients in the Stanford trial to 304 in the Winthrop trial. The longest median follow-up duration reported to date was 5 years, and data were collected prospectively or retrospectively. Patients included in the studies were newly diagnosed with biopsy-proven prostate cancer with no evidence of metastases. The majority of participants were low risk, a lower proportion at intermediate risk, and a few at high risk based on NCCN or D'Amico risk stratification criteria. Most studies described a protocol using five fractions of 7-7.25 Gy, for a total dose of 35-36.25 Gy. In one study (Oliai et al, 2013) the dose was 37.5 Gy in two thirds of the participants. The treatment was delivered either in consecutive days or every other day. In the majority of studies, androgen deprivation therapy was administered at the discretion of the treating urologist. The main endpoints of these observational studies were the PSA response, biochemical relapse free survival (bRFS), and the toxicity associated with SBRT. **Conclusion:** Overall the results of the published small observational phase I and II trials indicate that SBRT has favorable outcomes in terms of short-term biochemical control, and with acceptable toxicity. However, the literature does not provide sufficient evidence to determine the comparative effectiveness of SBRT to other conventional radiotherapy techniques, or the durability of the observed biochemical control and low toxicity associated with the treatment beyond 3-5 years. The published studies did not examine the long-term

safety of SBRT or its clinical effects in terms of disease-free survival, metastases-free survival, or overall survival. Larger trials with longer follow-up duration are required to evaluate the long-term safety and effects of SBRT, especially that late toxicity could be worse with extreme hypofractionation compared to the conventional hypofractionation. A number of RCTs involving extreme hypofractionation are underway, and may provide more evidence on the safety and efficacy of SBRT compared to conventional therapies for the treatment of localized prostate cancer. However, it will be several years before the results of these trials are published. These ongoing studies are: PACE (Prostate Advances in Comparative Evidence) is an ongoing international randomized phase III study comparing SBRT using Cyberknife, radical prostatectomy, and IMRT (78 Gy in 39 fractions) for low and intermediate risk prostate cancer. HYPO-RT-PC (Hypofractionated radiotherapy of intermediate risk localized prostate cancer) is a Swedish phase III trial that will compare 78Gy in 39 fractions delivered with IMRT over 8 weeks vs. SBRT 42.7 Gy in 7 fractions of 6.1 Gy over 2.5 weeks. RTOG 0938 is a randomised phase II trial that compares the health related side effects of 2 hypofractionation regimens (36.25 Gy delivered twice weekly for a total of 5 treatment sessions (7.25Gy /session) over 15-17 days versus 51.6 Gy delivered in 12 daily treatment sessions (4.3Gy per session) over 16-18 days) for low-risk patients.

**Articles:** The literature search revealed over 200 articles, the majority of which were reviews, description of hypofractionation radiation therapy, or studies that were unrelated to the current review. No randomized controlled trials (RCTs) comparing SBRT to conventional EBRT regimens or low dose brachytherapy for low-risk prostate cancer were identified. The published empirical studies on the use of the technology for prostate cancer were only phase I and phase II feasibility trials conducted in a number of centers in US and overseas. The search also revealed a pooled analysis (King et al, 2013) of the results of the phase II trials conducted in 8 institutions participating in a consortium for prostate SBRT, as well as a number of published systematic reviews (with no meta-analyses) for hypofractionation therapy in general, or SBRT for the treatment of localized prostate cancer. The pooled analysis by King and colleagues, and the larger phase II trials with the longest follow-up duration were selected for critical appraisal: King CR, Brooks JD, Gill H, et al. Long-term outcomes from a prospective trial of stereotactic body radiotherapy for low-risk prostate cancer. *Int J Radiat Oncol Biol Phys.* 2012; 82:877-882. See [Evidence Table 1](#). King CR, Freeman D, Kaplan I, et al. Stereotactic body radiotherapy for localized prostate cancer: pooled analysis from a multi-institutional consortium of prospective phase II trials. *Radiation Oncol.* 2013;109:217-221. Local Coverage Article	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Flatfoot is a progressive developmental or acquired deformity characterized by plantar medial rotation of the talus, decrease in the medial arch height, and supination and abduction of the forefoot. The posterior tibial tendon may weaken and tear and the talo-navicular capsule, the tibio-navicular ligament, the spring ligament, the long and short plantar ligaments and the plantar aponeurosis may become stretched. There is a shift in the load from lateral column to the medial column, which may cause the medial arch to flatten further (Arangio 2007).

Flexible flatfoot is also referred to as “collapsing pes valgo planus” in which collapsing refers to the flexibility of the deformity, pes refers to the foot, planus refers to the flattened arch, and vulgus refers to the everted calcaneus (Forg 2001). It is one of the most common foot deformities in adults and can cause pain, fatigue, night cramps, and abnormal gait.

A vast majority of flexible flatfeet can be controlled with functional orthoses, but the worst deformities may require surgical intervention to reconstruct the foot deformity and reduce posterior tendon dysfunction. Many surgical procedures as tendon and muscle lengthening, osteotomies, arthrodesis, and arthroereisis have been described (Saxena 2007).

Arthroereisis was developed more than 30 years ago to be used in combination with other bone and soft tissue procedures. It involves placing various shaped implants beneath the talus to limit excessive eversion while preserving inversion. The implants are intended to block forward, downward and medial displacement of the talus, thus allowing normal subtalar joint motion but blocking excessive pronation. They do not replace reconstructive surgery, but are used in conjunction with other operative soft-tissue and bony procedures (Needleman 2006, Saxena 2007).

The operative procedure includes inserting the arthroereisis implant after correcting all parts of the flatfoot deformity and associated conditions in sequence; ankle, hindfoot, midfoot and forefoot. To date there are at least four cylindrical metallic implants (composed of titanium alloys) designed to be placed under the talus in the tarsal canal and sinus tarsi lesion. They range from 6 -14 mm in width, and 12-18 mm in length. The Futura Biomedical Subtalar Peg Implant, the Maxwell-Brancheau Arthroereisis (MBA) Sinus Tarsi Implant, the Kalix device, and the

HyProCure Sinus Tarsi implant are all approved by the Food and Drug Administration for use as an internal support to primary surgical interventions in the treatment of flatfoot. The devices are contraindicated in cases of active local infection, allergic reactions to foreign bodies, poor or insufficient bone stock, the presence of clinical or functional abnormalities that would prevent the potential of achieving good results, or other conditions that may place the patient at risk.

## Medical Technology Assessment Committee (MTAC)

### Subtalar Arthroereisis

#### 06/04/2007: MTAC REVIEW

**Evidence Conclusion:** There is insufficient published evidence to determine the efficacy and safety of Arthroereisis in the treatment of flexible flatfeet in adults. The published studies on the technology are only small case series with no comparison groups to compare the outcomes of the intervention to alternative therapies.

**Articles:** The search revealed around twenty articles on subtalar arthroereisis for the correction of flatfeet in adults. There were no randomized or non-randomized controlled trials that compared the procedure with an alternative therapy. The majority of the published articles reported on experimental studies performed on cadavers. The reports on human adult patients were either case reports or case series with less than 25 patients. The largest were two case series (Needleman 2006, and Viladot 2003) with 23 and 21 patients respectively, and each on a different arthroereisis implant. Both were critically appraised. Needleman RL. A surgical approach for flexible flatfeet in adults including a subtalar arthroereisis with MBA Sinus tarsi Implant. *Foot & Ankle International* 2006;27:9-18. See [Evidence Table](#). Viladot R, Pons M, Alvarez F, et al. Subtalar arthroereisis for posterior tibial tendon dysfunction. A preliminary report. *Foot & Ankle International* 2003;24:600-606. See [Evidence Table](#).

The use of Subtalar Arthroereisis in the treatment of Pes Planus does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

###### Group 2 Pressure Reducing Support Surfaces:

Alternating Pressure and Low Air Loss Mattresses and Overlays

A group 2 support surface is considered medically necessary DME if the member meets **ONE of the following:**

- A. The member must meet **ALL of the following:**
  - 1. The member has multiple stage II (partial thickness skin loss) pressure ulcers located on the trunk or pelvis.
  - 2. The member has been on a comprehensive ulcer treatment program<sup>†</sup> for at least the past month, which has included the use of an appropriate group 1 support surface.
  - 3. The member's ulcers have worsened or remained the same over the past month.
- B. The member has large or multiple stage III (full thickness tissue loss) or stage IV (deep tissue destruction) pressure ulcer(s) on the trunk or pelvis; or
- C. The member has had a recent myocutaneous flap or skin graft for a pressure ulcer on the trunk or pelvis (surgery within the past 60 days) and has been on a group 2 or 3 support surface immediately prior to a recent discharge from a hospital or nursing facility (discharge within the past 30 days).

<sup>†</sup> The comprehensive ulcer treatment described in criterion 2 above should generally include:

- Appropriate management of moisture/incontinence;
- Appropriate turning and positioning;
- Appropriate wound care (for stage II, III, or IV ulcer);
- Education of the member and caregiver on the prevention and/or management of pressure ulcers;
- Nutritional assessment and intervention consistent with the overall plan of care;
- Regular assessment by the nurse, physician, or other licensed healthcare practitioner (usually at least weekly for a member with a stage III or stage IV ulcer).

If the member is on a group 2 surface, there should be a care plan established by the physician or home care nurse, which includes the above elements.

When a group 2 support surface is prescribed for a myocutaneous flap or skin graft, continued use is generally considered medically necessary for up to 60 days from the date of surgery.

Use of a group 2 support surface is considered medically necessary until the ulcer is healed or, if healing does not continue, there is documentation in the medical record to show: (i) other aspects of the care plan are being modified to promote healing, or (ii) the use of the alternating pressure mattress is medically necessary for wound management.

A group 2 support surface is considered experimental and investigational when these criteria are not met because of insufficient evidence in the peer-reviewed literature.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Pressure relieving support surfaces are designed to prevent or promote the healing of pressure ulcers by reducing or eliminating tissue interface pressure. Most of these devices reduce interface pressure by conforming to the contours of the body so that pressure is distributed over a larger surface area rather than concentrated on a more circumscribed location. This clinical policy is consistent with Medicare DME MAC guidelines.

## Clinical Review Criteria

### Treatment of Migraine Headaches

- Surgical Deactivation of Trigger Sites

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

No related national or local coverage decision document found.

##### For Non-Medicare Members

Group Health has elected to use the MCG\* Migraine Headache, Surgical Treatment (A-0578) for medical necessity determinations.

The MCG\* are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 2 years of neurology notes
- Most recent clinical note from requesting provider

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Migraine headache is a common primary headache disorders that is characterized by a variety of symptoms such as nausea, vomiting, visual disturbances, and sensitivity to light and sounds. In the United States, approximately 18% of women and 6% of men have experienced at least one migraine in the previous year. Standard treatment for migraine involves identification and avoidance of triggers, and the use of pharmacotherapy to treat acute attacks and prevent further attacks (Goadsby 2010, Silberstein 2004).

Surgical treatment for migraine headache has been proposed for patients who are not receiving adequate benefit from standard treatment options. This approach was originally discovered as an unanticipated benefit of cosmetic surgery. The first step to determining whether the patient is a candidate for surgery is to identify trigger sites. Most investigators use Botox to identify the trigger site; however, local nerve blocks can also be used. Patients who experience complete elimination or at least 50% improvement in intensity and/or frequency of headaches are considered candidates for surgery. The surgical approach varies by trigger site and involves removal of certain facial muscles, severing of a facial nerve, and/or surgical modification of the sinuses (Kung 2011).

#### Medical Technology Assessment Committee (MTAC)

##### *Surgical Deactivation of Trigger Sites for Treatment of Migraine Headaches*

##### **02/11/2013: MTAC REVIEW**

**Evidence Conclusion:** A RCT that included 125 subjects evaluated the safety and efficacy of surgical deactivation of migraine headache trigger sites. Patients in the treatment group were injected with Botox to identify trigger sites. Patients were eligible for surgery if they experienced at least 50% improvement in the intensity and/or frequency of headaches from the Botox lasting at least 4 weeks. Ninety-one patients out of the 100 patients in the treatment group underwent surgery. Patients in the control group receive injections of saline. After one year 31 patients in the treatment group and 3 patients in the control group experienced complete elimination. Both groups experienced significant improvement in headache intensity and duration compared to baseline; however, only the treatment group experienced a significant improvement in headache frequency. Compared to the control group, patients who received surgery experienced significantly greater reductions in headache frequency, intensity, and

duration at one year. The most common surgical complications were: nasal dryness, rhinorrhea, recurrence of septal deviation, scalp itching, and minor hair loss. This study had several limitations: the inclusion and exclusion criteria were not provided, an ITT analysis was not performed, power was not assessed, the outcome data was self-reported, and it is not stated whether patients were taking pharmacotherapy during the trial (Guyuron 2005).

<b>Headache outcomes at 1 year (Guyuron 2005)</b>			
	Treatment	Control	P-value
	Number (%)		
Complete elimination	31 (35)	3 (15.8)	<0.001
Significant improvement*	82 (92)	0 (0)	<0.001
	Mean ± SE		
Frequency (migraine/month)	3.8 ± 0.4	10.2 ± 1.7	<0.001
Intensity (0 to 10, most severe)	4.0 ± 0.3	7.0 ± 0.3	<0.001
Duration (hour)	0.35 ± 0.05	0.99 ± 0.2	0.007

\*At least 50% improvement in intensity, frequency, and/or duration.

Patients in the treatment group were followed for 5-years to determine the long-term safety and efficacy of surgery. Ten patients in the treatment group who underwent additional surgery were excluded from the analysis, leaving 69 patients. Results from this observational follow-up study suggest that the improvements in headache frequency, duration, and intensity that were achieved at 1 year were maintained at 5 years (Guyuron 2011).

<b>Headache outcomes at baseline, 1 year, and 5 years (Guyuron 2011)</b>			
	Baseline	Year 1	Year 5
	Number (%)		
Complete elimination	NA	N=89 31 (35)	N=69 20 (29)
Significant improvement*	NA	82 (92)	61(88)
	Mean ± SD		
Frequency (migraine/month)	10.9 ± 7.5	4.0 ± 6.4	4.0 ± 5.3
Intensity [0 to 10 (most severe)]	8.5 ± 1.2	4.0 ± 3.3	4.5 ± 3.2
Duration (days)	1.4 ± 1.4	0.42 ± 0.8	0.31 ± 0.9

\*At least 50% improvement in intensity, frequency, and/or duration.

A more recent RCT that included 75 subjects also evaluated the safety and efficacy of surgical deactivation of migraine headache trigger sites. Patients underwent injections of Botox to identify the trigger site. Patients who experienced complete elimination or at least 50% improvement in intensity and/or frequency of headaches were candidates for surgery. Patients were then randomized to receive either surgery based on migraine trigger site (frontal, temporal, or occipital) or sham surgery. Twenty-eight (57%) patients who underwent surgery experienced complete elimination compared to 1 (4%) who underwent sham surgery. Both groups experienced significant improvements in headache frequency and intensity from baseline. The treatment group also experienced a significant improvement in headache duration from baseline. The treatment group experienced significantly greater reductions in headache frequency and intensity compared to the control group at one year. There was no significant difference between the treatment and the control group in headache duration. The most common adverse events were temporary hollowing and intense itching. This trial had several limitations: it was a small trial and power was not assessed, outcomes were self-reported, and it is not stated whether patients were taking pharmacotherapy during the trial (Guyuron 2009).

<b>Change from baseline to 1 year (Guyuron 2009)</b>			
	Treatment	Control	P-Value
	Number (%)		
Complete elimination	28 (57.1)	1 (3.8)	<0.001
Significant improvement*	41 (83.7)	15 (57.7)	0.014
	Mean ± SD		
Frequency (headaches/month)	-7.4† ± 5.8	-3.5† ± 5.4	0.005
Intensity (1 to 10)	-3.0† ± 3.5	-1.3† ± 2.9	0.03
Duration (days)	-0.30† ± 0.46	-0.87 ± 4.5	0.43

\*At least 50% improvement in intensity, frequency and/or duration.

†Significant improvement from baseline.

**Conclusion:** Results from two RCTs with methodological limitations suggest that surgical treatment for migraine headaches may improve migraine headache frequency, intensity, and durations, and results in more patients

achieving complete elimination compare to control (not surgery or sham surgery). However, the safety and efficacy of surgical treatment for migraine headaches compared to standard therapy is unknown and there is limited data on the long-term efficacy of this procedure.

**Articles:** Several observational studies and two randomized controlled trials (RCTs) were identified that evaluated the safety and efficacy of surgical treatment of migraine headaches. The two RCTs and a follow-up study of one of the RCTs were selected for review. All of these studies were conducted by the same investigator.

The following studies were selected for review: Guyuron B, Kriegler JS, Davis J, Amini SB. Comprehensive surgical treatment of migraine headaches. *Plast Reconstr Surg.* 2005;115:1-9. See [Evidence Table](#). Guyuron B, Kriegler JS, Davis J, Amini SB. Five-year outcome of surgical treatment of migraine headaches. *Plast Reconstr Surg.* 2011;127:603-608. See [Evidence Table](#). Guyuron B, Reed D, Kriegler JS, Davis J, Pashmini N, Amini S. A placebo-controlled surgical trial of the treatment of migraine headaches. *Plast Reconstr Surg.* 2009;124:461-468. See [Evidence Table](#).

The use of Surgical Deactivation of Trigger Sites for Treatment of Migraine Headaches does not meet *the Group Health Medical Technology Assessment Criteria*.

#### Criteria

##### For Medicare Members

Local Coverage Determination (LCD)

[Brachytherapy: Non-Intracoronary \(L24281\)](#)

##### For Non-Medicare Members

- I. The use of Yttrium-90 (90Y) microsphere radioembolization (SIR-Spheres® or TheraSphere®) is medically necessary if **ONE of the following** is met:
  - A. Unresectable metastatic liver tumors from primary colorectal cancer (CRC)
  - B. Unresectable liver-only or liver-dominant metastases from neuroendocrine tumors (NET) (e.g. carcinoid, islet cell tumor/pancreatic endocrine tumor) and **ALL** of the following:
    1. The disease is diffuse\* and symptomatic (\*For this medical policy, the term “diffuse” disease is defined as tumor tissue spread throughout the affected organ (e.g., diffuse liver disease)
    2. Only in persons who have failed systemic therapy with octreotide to control carcinoid syndrome (e.g., debilitating flushing, wheezing and diarrhea)
  - C. Unresectable primary hepatocellular carcinoma (HCC)
- II. Yttrium-90 (90Y) microsphere radioembolization is not covered for any other indication because its clinical utility has not been established.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world, and the third most common cause of cancer-related mortality. It is responsible for more than half a million deaths across the globe each year. Treatment options for patients diagnosed with hepatocellular carcinoma (HCC) are limited. Less than 15% are candidates for surgical resection at presentation, and the use of external beam radiation is limited due to the intolerance of normal liver parenchyma to tumoricidal radiation doses (the dose required to destroy solid tumors (>70 Gy) is much higher than the liver tolerance dose of 35 Gy). In addition, systematic chemotherapy was found to have little impact on survival and negative impact on the health-related quality of life due to the toxicity to other organs and systems. These limitations have led to the emergence of local and regional treatments such as radiofrequency ablation, local administration of cytostatic drugs like hepatic arterial infusion and isolated hepatic infusion, or intrarterial embolization techniques such as transarterial chemo-embolization and selective intrarterial radioembolization therapy (Steel 2003, Salem 2004, Ibrahim 2008, Bult 2009, Riaz 2009).

Yttrium-90 (90Y) intra-arterial radiotherapy also known as radioembolization, is an emerging technique for the treatment of patients with unresectable primary or metastatic liver tumors. It is a minimally invasive catheter-based therapy that delivers internal radiation via the arterial vessels that feed the tumor. The technology takes advantage of the dual blood supply of the liver as the normal hepatic tissue obtains more than 70% of its blood supply through the portal vein, while intrahepatic malignancies derive their blood supply almost entirely from the hepatic artery i.e. arterial rather than portal circulation. The concept of intra-arterial radioembolization was first explored by injecting yttrium-90 containing microspheres in the hepatic artery of rabbits with liver tumor. The first clinical trial on selected patients was conducted in the mid 1980s, but was discontinued due to the several patient deaths of myelosuppressions due to leaching (leakage) of the microspheres (Vente 2009).

In an attempt to overcome the problem of leaching, yttrium containing solid glass microspheres were developed (TheraSphere®, MDS Nordion, Ottawa, Ontario, Canada). These consist of microscopic glass beads 20-30 µ in diameter embedded with the radionuclide yttrium-90. The glass microspheres are delivered into the liver tumor through a catheter placed into the hepatic artery and subsequently get lodged in the microvasculature surrounding the tumor. Their size causes them to be trapped in the tumor capillary bed where they deliver very high irradiation doses to the tumors while sparing the surrounding liver parenchyma. Once inside the liver neither the medical personnel nor the family members can be irradiated. The microspheres are not biodegradable; they have a half-life of 64.1 hours (2.67 days) and emit pure beta-radiation with a mean tissue penetration of 2.5 mm and a maximum of 1 cm. The therapy is given as an outpatient interventional radiology procedure, and lasts from 30 to 40 minutes (Carr 2004, Ibrahim 2008, Bult 2009).

Another 90Y product available for clinical use is SIR-Spheres® (SIRTeX Medical Ltd., Sydney, Australia). These consist of biodegradable resin-based microspheres containing Yttrium-90 (90Y) and have an average size of 35 µ in diameter. Upon administration of the spheres in vivo, they are permanently implanted. Similar to TheraSphere, SIR-Spheres emit pure β-radiation with a half life of 2.67 days. Both types of microspheres have shown to preferentially localize to abnormally vascularized liver tumors, where they exert intense localized radiation, while limiting radiation exposure to the uninvolved hepatic parenchyma (Ibrahim 2008, Bult 2009).

Radioembolization is not without complications; it may lead to post-radioembolization syndrome which includes fatigue, nausea, vomiting, anorexia, fever, abdominal pain and cachexia. More serious adverse events include radiation induced liver toxicity, vascular injury when introducing the catheter, radiation pneumonitis from microspheres shunting around the liver and into the lungs, and gastrointestinal tract ulceration. Absolute contraindications for the use of 90Y microspheres include pretreatment with 99mTc macroaggregated albumin scan demonstrating significant hepatopulmonary shunts, and inability to prevent deposition of the microspheres to the gastrointestinal tract with modern catheter techniques (Ibrahim 2008, Riaz 2009).

TheraSphere (MDS Nordion, Ottawa, Canada) was approved by the FDA in 1999 under the Humanitarian Device Exemption Guidelines for the treatment of unresectable hepatocellular carcinoma.

SIR-Spheres® (SIRTeX Medical Ltd., Sydney, Australia) received FDA premarket approved in 2002 for the treatment of colorectal cancer metastasized in the liver with adjuvant floxuridine administered via the hepatic artery.

## Medical Technology Assessment Committee (MTAC)

### ***Therasphere in the Treatment of Unresectable Hepatocellular Carcinoma***

#### **04/10/2002: MTAC REVIEW**

**Evidence Conclusion:** There is insufficient published evidence to determine the effectiveness of Therasphere for the treatment of unresectable hepatocellular carcinoma (HCC). Many of the empirical studies were done with animals. Only small case series (four studies, each with n<20) with human populations were available.

**Articles:** The search yielded 24 articles, many of which dealt with technical aspects of the procedure. There were no randomized controlled trials or meta-analyses. There were several case series, all with small sample sizes (n<20). None of the empirical articles were considered of sufficient quality to be evaluated.

The use of Therasphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **06/05/2006: MTAC REVIEW**

### ***Therasphere in the Treatment of Unresectable Hepatocellular Carcinoma***

**Evidence Conclusion:** The empirical studies published before the previous MTAC review of the TheraSphere in 2002, were very small case series with less than 20 patients. For this review the literature search identified a small comparative non-controlled trial and few additional relatively larger series, many of which were published by the same group of investigators. In the comparative trial 28 patients received either TheraSphere therapy or Cisplatin. The patients were not randomized to the treatment groups, the study was unblinded, and the authors did not discuss how the patients were selected for each of the two therapies. The trial was not powered to detect significant differences between the study groups, had a short follow-up duration, and the 6-months data were available for only 50% of the patients. Its results indicate that patients treated with 90-Yttrium microspheres reported significantly higher scores on physical, functional, and social well-being vs. those treated with cisplatin. There was no significant difference in survival between the two groups according to Kaplan Meier curves.

The other case series reviewed was relatively small, had no control or comparison group, included a heterogeneous group of patients with different comorbidities, and the therapy received was not uniform for all patients. Its results indicate that 47% of the patients and 51% of the lesions had a greater than 50% reduction in size. The median survival was 20.8 months among non-high risk patients, and 11.1 month for those at high risk. In conclusion, the evidence published after the previous review is still insufficient to determine the effectiveness and safety of TheraSphere for the treatment of unresectable hepatocellular carcinoma (HCC).

**Articles:** The search yielded 27 articles, many of which dealt with technical aspects of the procedure. No randomized controlled trials or meta-analyses were identified. There was a small non-randomized cohort study that compared TheraSphere treatment with Cisplatin, as well as several small prospective and retrospective case series with sizes ranging from 15 to less than 90 patients. The study with a comparison group, as well as a prospective case series with no patient overlap with the comparative trial, and clinically important outcomes, were selected for critical appraisal. Steel J, Baum A, and Carr B. Quality of life in patients diagnosed with primary hepatocellular carcinoma: hepatic arterial infusion of cisplatin versus 90-Yttrium microspheres (TheraSphere)® *Psycho-Oncology* 2004;13;73-79. See [Evidence Table](#). Salem R, Lewandowski RJ, Atassi B, et al. Treatment of unresectable hepatocellular carcinoma with use of <sup>90</sup>Y microspheres (TheraSphere): safety, tumor response, and survival *J Vasc Interv Radiol.* 2005;16:1627-1639 See [Evidence Table](#).

The use of Therasphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

### 07/06/2010: MTAC REVIEW

#### **Therasphere in the Treatment of Unresectable Hepatocellular Carcinoma**

**Evidence Conclusion:** *TheraSphere* The literature search did not reveal any published randomized controlled trials on TheraSphere after the last 2006 review. At the time the published empirical studies consisted of one small comparative non-randomized trial with 28 patients and a number of case series, many of which were published by the same group of investigators. In the comparative trial, 28 patients received either TheraSphere therapy or cisplatin. The patients were not randomized to the treatment groups, the study was unblinded, and the authors did not discuss how the patients were selected for each of the two therapies. The trial was not powered to detect significant differences between treatments, had a short follow-up duration, and the 6-month data were available for only 50% of the patients. Its results indicate that patients treated with Yttrium-90 microspheres reported significantly higher scores on physical, functional, and social well-being vs. those treated with cisplatin. There was no significant difference in survival between the two groups according to Kaplan Meier curves. The recently published meta-analysis (Vente 2009) pooled the results of the case series with no comparison or control group and do not provide any additional evidence to determine the efficacy and safety of TheraSphere in the treatment of unresectable hepatocellular carcinoma. *Sir-spheres:* The results of the two randomized trials on Sir-Spheres (Gray 2001 and Van Hazel 2004) provide some but insufficient evidence on the benefits of Sir-Spheres combined with regional chemotherapy vs. regional chemotherapy alone in improving the response rate and time to progression. The common toxicities associated with the treatment were generally mild and the rate of grade 3 and 4 toxicities did not differ significantly between the treatment arms in Gray et al's trial. These results, however may not be generalized as the chemotherapies used in the trials are not the standard regimens currently used as a first-line treatment, and the response rates in the control arms (0% in Gray et al's trial and 18% in Van Hazel and colleagues trial) were much lower than usually observed. Moreover, the trials were too small, and had insufficient power to determine whether radioembolization has any mortality benefit. **Conclusion:** There is insufficient published evidence to determine efficacy and toxicity of TheraSphere in the treatment of unresectable liver cancer when given alone or in combination with systemic or regional chemotherapy. There is insufficient published evidence to determine the efficacy and toxicity of Sir-Spheres in the treatment of liver metastases from colorectal cancer when given alone or in combination with systemic or regional chemotherapy. Larger RCTs are randomizing patients to first line chemotherapy with or without <sup>90</sup>Y microsphere radioembolization are currently underway and may provide more evidence on the benefits of adding radioembolization therapy to first line chemotherapy.

**Articles:** The literature search yielded around 200 articles; many were review articles or publications that dealt with technical aspects of the procedure. There was one meta-analysis of studies (Vente 2009) on patients with primary or secondary liver malignancies treated with <sup>90</sup>Y glass or resin microspheres, and another Cochrane review (Townsend 2009) of RCTs on radioembolization for liver metastases from colorectal cancer. Vente meta-analysis pooled the data from case series, but presented a summary result for each of the RCTs separately. The Cochrane review also presented the results of the same 2 trials separately. The search also identified two phase-2 randomized trials conducted by the same research group in Australia that compared Sir-Spheres plus chemotherapy vs. chemotherapy alone for treating patients with liver metastases from primary colorectal cancer. The first published RCT (Gray 2001) compared Sir-Spheres with regional chemotherapy vs. regional chemotherapy alone in 74 patients, and the second (Van Hazel 2004) compared Sir-Spheres combined with

systemic chemotherapy vs. systemic chemotherapy alone in 21 patients. The two trials were included in both meta-analyses. The search did not reveal any randomized controlled trials on TheraSphere. The majority of other published studies were prospective or retrospective case series including patients with HCC or hepatic metastatic colorectal cancer (mCRC). A small number of case series reported on patient with liver metastases secondary to neuroendocrine or breast cancers. The following meta-analysis and the larger RCT were selected for critical appraisal: Vente MAD, Wondergem M, van den Bosch MAAJ, et al. Yttrium-90 microsphere radioembolization for the treatment of liver malignancies: a structured meta-analysis. *Europ Radiol* 2009;19:951-959. See [Evidence Table](#). Gray B, Van Hazel G, Burton M, et al. Randomized trial of SIR-Spheres® plus chemotherapy vs. chemotherapy alone for treating patients with liver metastases from primary large bowel cancer. *Ann Oncol* 2001;12:1711-1720. See [Evidence Table](#).

The use of Therasphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of SIRsphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

## 02/13/2012: MTAC REVIEW

### **Therasphere in the Treatment of Unresectable Hepatocellular Carcinoma**

**Evidence Conclusion:** The best evidence published to date, after the last 2010 MTAC review, consisted of one small phase III randomized controlled trial on radioembolization using SIR-Spheres in patients with liver metastatic colorectal cancer, and two comparative efficacy analyses conducted to compare of the safety and efficacy of yttrium 90 (<sup>90</sup>Y) radioembolization in patients with unresectable hepatocellular carcinoma. In all published series and studies the radioembolization were performed by highly trained professionals in specialized centers.

**TheraSphere:** Salem and colleagues (2011) recently published a comparative analysis of the outcomes of two relatively large cohorts of patients (total N= 463) with unresectable HCC who were treated in a single center with either transarterial chemotherapy (TACE) or radioembolization using <sup>90</sup>Y microspheres (TheraSphere). The study was not a randomized trial, nor designed to determine equivalence between the two therapies. The authors indicated that treatment response and survival were calculated from first treatment, and follow-up duration was longer for TACE. They also explained that patients undergoing TACE were younger and more likely to receive it as a bridge to transplantation. The overall results of the analysis showed longer time to progression with radioembolization using <sup>90</sup>Y microspheres. There was no significant difference between the two therapies in time to response or survival. The study was not designed as an equivalence study, and lack of significant difference does not indicate that the two therapies are equivalent. An analysis performed by the authors showed that a randomized trial with over a 1000 patients would be required to establish equivalence in survival. There were no statistically significant differences in major toxicities between the two therapies. Patients treated with chemoembolization were more likely to experience abdominal pain and higher hepatic transaminase elevation. Lance et al's (2011) comparative analysis only included 73 patients treated with either chemoembolization or radioembolization with glass or resin <sup>90</sup>Y microspheres. The results did not show survival advantage with radioembolization, but found higher rates of hospitalization in the chemoembolization group due to the postembolization syndrome.

**Sir-Sphere:** Hendlisz and colleagues' (2010), RCT compared the efficacy and safety of intravenous fluorouracil (FU) given alone or with of intra-arterial 90Y-resin microspheres (SirSpheres) in 46 patients with liver-limited metastatic colorectal cancer (mCRC) who failed other chemotherapies. The trial was randomized, controlled, and multicenter. However, it was conducted among a highly selected group of patients; it was not blinded, and allowed patients in the FU alone group who had documented progression to cross-over to the radioembolization plus FU group at the investigators' discretion. As a result 70% of those in the FU alone group also received radioembolization, which is significant source of bias, but the authors performed an intention to treat analysis (ITT), ie. analyzed the patients in the groups they were randomized to. The overall results of the study indicate that radioembolization with yttrium 90 resin microspheres in addition to intravenous fluorouracil significantly improved the response to therapy and time to liver progression compared to FU alone among the selected patients included in the trial. Radioembolization was not associated with more toxicity than chemoembolization. The effect on survival was not statistically significant, which could be attributed to the small sample size, especially with the high cross-over that could have improved the outcomes in the FU only group.

**Articles:** The literature search for studies published after the last review revealed one Phase III trial that compared IV fluorouracil infusion alone or with radioembolization with SIR-Spheres for a specific indication, two retrospective comparative analyses that compared radioembolization with TheraSphere vs. transcatheter chemoembolization, and a number of retrospective and prospective single center case series with different population sizes. The largest case series and the larger comparative analyses were published by the same group of authors (Salem et al. 2010, 2011) and had a potential population overlap. The comparative analysis, as well as the Phase III trial, were selected for critical appraisal. Salem R, Lewandowski RJ, Kulik L, et al. Radioembolization results in longer time-to-progression and reduced toxicity compared with chemoembolization in patients with hepatocellular

carcinoma. *Gastroenterology*. 2011;140:497-507. See [Evidence Table](#). Hendlisz A, den Eynde M V, Peeters M, et al. Phase III trial comparing protracted intravenous fluorouracil infusion alone or with yttrium-90 resin microspheres radioembolization for liver-limited metastatic colorectal cancer refractory to standard chemotherapy. *J Clin Oncol*. 2010;28:3687-3694. See [Evidence Table](#).

The use of Therasphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of SIRsphere in the treatment of unresectable hepatocellular carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Tinnitus Masking/Retraining Therapy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Codes for auditory assessment and rehabilitation are covered.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Tinnitus is the perception of sound in the absence of an acoustic source (Luxon 1993). The perceived sound can vary from simple sounds such as whistling or humming to complex sounds such as music. Tinnitus may be perceived as a single sound or multiple sounds, unilateral or bilateral, within the head or outside the body, and intermittently or constantly. The American Tinnitus Association estimates that 50 million Americans have some degree of tinnitus with about 16 million of those experiencing significant enough symptoms to seek medical care and 2 million of them suffering so much that it ultimately interrupts normal day to day function. Tinnitus can occur at any age but its incidence increases by the age of 40 and peaks between 65 to 79 years (Hobson, Chisholm et al. 2012). The tinnitus experience is consistently higher among men and is strongly related to hearing loss but may be experienced by individuals with normal hearing as well. Acute tinnitus, which can last for days or weeks, may be caused by ear infection, medication, ear wax, exposure to excessive sound or changes in blood pressure. Chronic tinnitus, experienced by 10 to 15% of adults, persists for six or more months and may be caused by almost any disorder involving the outer, middle or inner ear, or the auditory nerve (Davis, Paki et al. 2007). In any case, tinnitus can be debilitating because it is difficult to describe, predict and manage and can lead to disruption of sleep, inability to concentrate, and depression.

Tinnitus is not a condition itself, rather, it is a symptom of an underlying condition and, therefore, management should include diagnosis and elimination of the factors precipitating tinnitus. In many cases, the cause of tinnitus cannot be identified warranting treatment of the symptom itself. At present, no universal treatment has been found effective in all patients and options are heavily dependent on the severity and perception of the condition. Treatment might range from counseling and dietary modification to acupuncture and relaxation therapy. Optimal management techniques seek to minimize the detrimental effects on activities of daily life and might include a variety of strategies. The use of medications and surgical interventions are rarely successful.

Tinnitus masking instruments have been clinically employed for alleviating symptoms for decades. These devices are worn behind or in either the same or the opposite ear affected by tinnitus and generate a noise based on the principle of distraction. The idea being that the level of noise, usually white noise, is introduced and can reduce the contrast between the tinnitus signal and background activity in the auditory system, with a decrease in the patient's perception of their tinnitus (Vernon 1977). The characteristics and circumstances of the tinnitus determine the kind of masking noise and instruments that might bring relief. No side effects or significant morbidities have been

reported, to date, from the use of maskers or hearing aids as treatment for tinnitus and no substantial risks of sound therapy have been demonstrated.

Tinnitus instruments such as maskers and hearing aids are approved by the Food and Drug Administration (2009) for alleviating the symptoms associated with tinnitus and are classified as a Class III device.

## Medical Technology Assessment Committee (MTAC)

### Tinnitus Masking Devices

#### 02/10/1999: MTAC Review

**Evidence Conclusion:** *Masking:* One small randomized controlled crossover study reports no decrease in self report of tinnitus intensity but statistically significant improvement in both specific and non specific effects of masking on tinnitus. Another study of patients randomized to masking or hearing aid devices and then allowed to choose which device to continue using demonstrated that 60% chose to continue using a masking device and 20% discontinued the use of any device. *Retraining Therapy:* A single small RCT demonstrated a statistically significant reduction (1 point improvement on a 10 point visual analogue scale) in subjective tinnitus loudness and discomfort following behavioral training as compared to a no treatment control group.

The use of Tinnitus Masking Devices for treatment of tinnitus does not meet *Group Health Medical Technology Assessment Criteria*.

### Tinnitus Masking Devices

#### 6/17/2013: MTAC REVIEW

**Evidence Conclusion:** Henry et al 2006 study recruited 800 US military veterans via advertisements. Following screening, 172 candidates were enrolled into the study; those not eligible were not convinced that their tinnitus was sufficiently severe or they were not motivated to comply with the study requirements. A further 49 subjects were excluded in secondary screening resulting in a total of one hundred and twenty-three patients commencing treatment. Candidates were quasi-randomly assigned to a tinnitus masking (TM) device or tinnitus retraining therapy group (TRT). The mean age in the sound therapy group was 61 (SD 9.6) and in the tinnitus retraining group it was 58.7 (SD 10.5). Baseline audiometry was performed and the Tinnitus Handicap Inventory (THI), Tinnitus Handicap Questionnaire (THQ) and Tinnitus Severity Index (TSI) were administered. Both groups used a combination of noise generators, hearing aids and combination instruments. Audiometry and questionnaires were evaluated at 3, 6, 12 and 18 months. The results show that for patients with 'moderate' problems, sound therapy resulted in a statistically significant improvement in the THQ at six months but tinnitus retraining therapy (TRT) appeared to offer superior results. For patients who described their tinnitus as a 'big' problem, there was an across the board significant improvement in the three instruments at all time points except three months, which is comparable to the TRT group. Looking at the effect sizes, for sound therapy these ranged from 0.18 to 0.59 in the 'moderate group and did not show a systematic improvement over time. For those with a 'big' problem, the effect sizes for sound therapy ranged from 0.46 to 0.86 and whereas the THI and TSI improved over time the THQ effect size remained unchanged. For those with a 'very big' problem the effect of sound therapy seemed greater at three months, with a trend of effect sizes becoming progressively smaller through 18 months. Based on effect size, both groups showed considerable improvement overall but whereas the benefits of sound therapy tended to remain constant over time, the effect of tinnitus retraining improved incrementally. Currently, the literature on maskers and/or hearing aids for the treatment of tinnitus in adults is limited. First and foremost, the lack of an established universal tool for baseline and follow-up assessment of outcome measures restricts the ability to produce valid data and make comparisons. Additionally, due to the often "off label" use of hearing aids as tinnitus treatments there has been a dearth of driving forces for undertaking large randomized controlled trials. Henry and colleague's study demonstrates some of these limitations; although the study claims to be controlled, the two groups being investigated do not make an attempt to treat both groups similarly. Different instruments are used across the study, and even within each group, and patient contact time differs by 1.4 hours between the TM and TRT groups. In addition to these limitations, the study was quasi-randomized which allows for a greater risk of selection bias. The study also notes that the devices were more

apt to break in the TRT group compared to the TM group and variation in treatment specialists for each method might result in clinician differences. While some of the studies included in the Cochrane Review report that patients experienced a decrease in tinnitus with use of masking devices there is no conclusive evidence to validate the effectiveness. On the whole, the studies included in the review demonstrate either no or limited improvement in tinnitus perception. Furthermore, the quality of the studies are, generally, low. With several different devices employed throughout the studies and marked methodological heterogeneity including numerous measures of evaluation of tinnitus severity and outcome all with different scores, scales, tests and questionnaires, comparisons and further analysis are complicated. Small sample sizes also contribute to the low quality leading to the inability to generalize findings.

**Conclusions:** Although some patients report a decrease in tinnitus with the use of masking devices, there is no conclusive evidence from randomized trials to demonstrate effectiveness. The limited data from the included studies show that sound therapy on its own is of unproven benefit in the treatment of tinnitus, although the effect may be better than placebo. Thus far, no adverse outcomes or significant morbidity from using sound-generating (masking) devices have been reported, and furthermore, the literature is unable to demonstrate any substantial risks.

**Articles:** Henry JA, Schechter MA, Zaugg TL, Griest S, Jastreboff PJ, Vernon JA, Kaelin C, Meikle MB, Lyons KS, Stewart BJ. Clinical trial to compare tinnitus masking and tinnitus retraining therapy. *Acta Oto-Laryngologica*, 2006;126:64-69. [See Evidence Table](#)

The use of Tinnitus Masking Devices for treatment of tinnitus does not meet *Group Health Medical Technology Assessment Criteria*.

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Transcatheter Aortic Valve Replacement (TAVR) (20.32)</a>
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

\*Medicare requires that TAVR only be used for FDA approved conditions. The FDA has approved TAVR for use in members who cannot undergo, or are at high risk for open heart surgery as determined by their heart team (a cardiologist and surgeon). TAVR is not approved for use in members that have low or intermediate risk as determined by their heart team.

\*For Medicare members requesting, Valve in Valve, please see Group Health criteria below.

#### For Non-Medicare Members

- I. Transcatheter Aortic Valve Replacement (TAVR)
  - A. Transcatheter aortic valve replacement is medically necessary when **ALL of the following** are true:
    1. Use of an FDA approved device
    2. Documentation of severe, symptomatic aortic valve stenosis
    3. Ejection fraction >20%
    4. Documentation that the patient has **ONE of the following**:
      - a. The patient is either high risk for SAVR or not a candidate for SAVR, as judged by at least two cardiovascular specialists (cardiologist and/or cardiac surgeon) in a face to face evaluation.
      - b. Risk of  $\geq 8\%$  as defined by the Society of Thoracic Surgeons operative risk scoring (<http://riskcalc.sts.org>) and there is documentation in the medical record to support this risk score.
      - c. Judgment of the heart team that there is  $\geq 15\%$  risk of mortality for surgical aortic valve replacement and there is documentation in the medical record to support this mortality risk scoring.
- II. Valve-in Valve Transcatheter Aortic Valve Implantation
  - A. Valve in Valve TAVR is medically necessary when **ALL of the following** are met:
    1. Use of an FDA approved device
    2. The patient (preoperatively and postoperatively) is under the care of a heart team: a cohesive, multi-disciplinary, team of medical professionals.
    3. Documentation of a failed aortic tissue prosthesis resulting in symptomatic stenosis or regurgitation.
    4. Ejection fraction >20%.
    5. Documentation that the patient has **ONE of the following**:
      - a. The patient is either high risk or not a candidate for repeat surgical aortic valve replacement, as judged by at least two cardiovascular specialists (cardiologist and/or cardiac surgeon) in a face to face evaluation.
      - b. Risk of  $\geq 8\%$  as defined by the Society of Thoracic Surgeons operative risk scoring (<http://riskcalc.sts.org>) and there is documentation in the medical record to support this risk score.

- c. Judgment of the heart team that there is  $\geq 15\%$  risk of mortality for repeat surgical aortic valve replacement and there is documentation in the medical record to support this mortality risk scoring.

All other indications are not covered as there is insufficient evidence to support effectiveness.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Aortic stenosis (AS) is one of the most frequent degenerative valve diseases in developed countries with a prevalence of approximately 5% in individuals over the age of 75 years. The absolute numbers continue to increase with the increase in life expectancy. Aortic stenosis has a long latency period followed by a rapid progression after the appearance of symptoms. It is estimated that up to 2.9% of adults between the ages of 75 and 86 years have severe aortic stenosis, and that the two year mortality among adults with severe symptoms is as high as 50% (Leon 2010, Rajani 2011, Amonn 2012).

Currently, surgical aortic valve replacement (SAVR) is the treatment of choice in patients with symptomatic severe aortic stenosis in the absence of severe co-morbid conditions. It is the only treatment that has been shown to reduce symptoms and improve functional status and survival in patients with severe aortic stenosis. The conventional surgical aortic valve replacement is performed via sternotomy using cardiopulmonary bypass. The procedure is associated with low operative mortality; however, at least 30% of the patients with severe symptomatic aortic valve stenosis are not suitable candidates for open SAVR due to advanced age, left ventricular dysfunction, concomitant coronary artery disease, and/or other pre-existing conditions. Historically these high surgical risk patients were treated with palliative medical therapy or aortic valve balloon valvuloplasty (BAV) (Leon 2010, Rajani 2011, Amonn 2012, Staubach 2012).

Transcatheter aortic valve replacement (TAVR) has emerged as an alternative minimally invasive treatment option for elderly patients with aortic stenosis who are at high surgical risk. The first transcatheter aortic valve implantation in humans was performed by Alain Cribier in France ten years ago, and has developed rapidly and tremendously since then. Over 50,000 patients in 500 European centers have undergone the procedure after two prosthetic valves (Edwards SAPIEN and Medtronic CoreValve) was approved by the Conformité Européenne (CE) in 2007. TAVR involves the insertion of a bioprosthetic aortic valve through a catheter and implanting it within the diseased native aortic valve. Patients are treated off-pump i.e. on a beating heart, and the new prosthesis is implanted within the calcified native valve leaflets that remain in place while being squeezed aside. In most patients the prosthetic valve is inserted through the groin and advanced to the heart using X-ray guidance (retrograde approach). In patients who cannot undergo catheterization of the femoral artery due to vessel disease, the valve can be delivered from the left ventricular apex (antegrade approach) through a small chest incision between the ribs (Amonn 2012, Walther 2012).

Currently, TAVR is indicated for the management of high-risk patients with severe aortic stenosis who are not candidates for open surgical valve replacement. However, some patients are at too high risk even for TAVR, and patient selection plays a crucial role in the success of the procedure. Patients have to be evaluated thoroughly for their risk and anatomical suitability for the procedure. A heart team comprised of clinical cardiologists, cardiac surgeons, interventionalists, anesthesiologists, geriatricians, and imaging specialists, is essential for the patient selection and performance of the procedure. The collaboration of such a multidisciplinary team is reported to be a key to the success of the procedure and achievement of optimal clinical outcomes (Piazza 2012, Vahanian 2012).

TAVR is not without complications; the increased risk of stroke is a significant safety concern of the procedure. Other major vascular complications, valve embolization, complete heart block, and moderate to severe paravalvular aortic regurgitation have also been reported. In addition, once the transcatheter aortic valve is implanted, it cannot be removed, and may lead to performing other risky procedures. Researchers are investigating different approaches to reduce the occurrence of these TAVR-related complications e.g. through better screening of the candidates for the intervention; refinement of the implantable devices and their delivery systems; improving the techniques in valve sizing and positioning; use of embolic protection devices as cerebral filters, carotid filters, or membrane covering of the carotid ostia; modification of periprocedure and postoperative antiplatelet strategies; use of antiarrhythmic treatment, and others (Vahanian 2012, Cribier 2012).

Over the years, different prostheses have become available for performing TAVR. The Edward SAPIEN (Edwards Lifesciences, Irvine, CA, USA) prosthesis consists of bovine pericardial leaflets mounted on a balloon-expandable cobalt-chromium stent. It is available in 2 sizes (23 mm and 26 mm) and can be inserted by either the retrograde

or antegrade approach. The prosthesis was approved by the US Food and Drug Administration in 2011 based on data from the inoperable cohort of PARTNER study, for its use patients with severe aortic stenosis who have been determined by a cardiac surgeon to be inoperable for open aortic valve replacement, and in whom existing co-morbidities would not preclude the expected benefit from correction of the aortic stenosis (FDA website). The FDA requested two post-approval studies to assess the long-term safety and effectiveness of the TAVR, as well as adherence to the indication of SAPIEN utilization. Other devices including the COREValve® (Medtronic, Minneapolis, MN, USA), ACURATE TATM valve, and JenaValve™, have received CE approval, but have not been approved by the USA FDA to date.

## Medical Technology Assessment Committee (MTAC)

### Transcatheter Aortic Valve Replacement (TAVR)

#### 6/18/2012: MTAC REVIEW

**Evidence Conclusion:** The PARTNER (Placement of AoRTic traNcathetER valves) trial is the first prospective, multicenter, randomized, controlled trial that compared TAVR in inoperable and high-risk operable patients with severe symptomatic aortic stenosis to surgical or non-surgical treatments. PARTNER consisted of two trials individually powered and with all-cause mortality at one year, as the primary endpoint in each: PARTNER Cohort A trial had a non-inferiority design and involved a high-risk operable population in whom both the transcatheter and surgical aortic valve replacement were clinically acceptable. PARTNER Cohort B was designed as a superiority trial and was conducted upon a very high-risk patient population considered unsuitable for open surgery. The trial had valid methodology; it was randomized, controlled, multicenter, had sufficient power to detect significant differences for the mortality endpoint, and the analysis was based on intention to treat. However, it was conducted among a highly selected group of patients, in highly selected centers, and performed by physicians with high expertise in the implantation technique, all of which may limit generalization of the results. In addition, it was sponsored by the aortic valve manufacturer (Edwards Lifesciences) who funded the study, participated in the selection and management of the sites, as well as the collection and monitoring of the data. Transcatheter aortic valve replacement has a learning curve, and the aortic valve prosthesis used in the PARTNER trial was the first generation device, both of which may not reflect the outcomes of the procedure with the current generations of the device and the gained operator experience in their implantation. PARTNER Cohort B [Evidence Table](#) Inoperable Cohort B patients (N=358) were randomized to receive standard medical therapy including balloon aortic valvuloplasty or to undergo TAVR using Edward SAPIEN heart valve system. The primary endpoint was the rate of death from any cause at one year. The results of the trial showed a 19% absolute mortality reduction at one year after TAVR with a number needed to treat of 5. Cardiac symptoms also improved significantly in the TAVR group. TAVR however, was associated with higher rates of stroke/TIA, vascular events, and bleeding (NNH with TAVR was 20 for stroke or TIA, 7 for major vascular complications, and 8 for major bleeding). 2-year outcomes of the trial (Makkar et al, 2012) showed that the rate of death from any cause, death from cardiovascular causes, and rate of hospitalization for cardiac reasons were all significantly lower in the TAVR group vs. standard therapy group. The death from any cause at 2 years was 68.0% in the standard therapy group and 43.3% in the TAVR group. The calculated NNT with TAVR was 4 to prevent one death and 3 to prevent one cardiac death in 2 years. As regards the adverse events, the rate of stroke was higher at 2 years in the TAVR vs. standard therapy (13.8% vs. 5.5%, p=0.01). The authors explained that the excess of stroke in the TAVR in the first 30 days was attributed to greater number of ischemic strokes in that group. Beyond 30 days and up to 2 years, the higher rate of stroke was attributable to hemorrhagic events. Echocardiographic analyses showed that the early hemodynamic benefits of TAVR were sustained at 2 years (sustained increase in aortic valve area, and a decrease in aortic valve gradient with no worsening in paravalvular regurgitation). PARTNER Cohort A [Evidence Table](#) High-risk operable patients (N=699) were randomized to undergo either TAVR using Edward SAPIEN valve or traditional surgical aortic replacement (SAVR). The results of the trial showed no significant difference in survival between the two procedures. The primary endpoint was rate of death from any cause at one year. Cohort A study was designed as a noninferiority trial to determine whether transcatheter replacement of the aortic valve is not inferior to surgical replacement of the valve. It was not designed to demonstrate that the two interventions are equivalent. The results of the trial showed that TAVR was non-inferior to SAVR for all-cause mortality in one year. Patients in TAVR had a lower risk of major bleeding (NNT 5 in one year), and better improvement than surgical replacement group in cardiac symptoms and 6-minute walk distance at 30 days. These differences were insignificant by the end of the year. On the other hand, the TAVR patients had an increased risk of stroke or TIA (NNH=13) and more major vascular events (NNH=13) than those in the SAVR group. The authors explained that the differences in stroke appeared in the first few days or weeks after TAVR most likely due to the increased liberation atherothrombotic debris from the aorta or the valve causing embolic ischemic strokes. 2-year outcomes of Cohort A (Kodali et al, 2012) showed that between year one and year two there were 32 additional deaths in the TAVR group and 25 in the SAVR group (statistically insignificant difference at 2 years, p=0.78). It also showed that by the end of 2 years the overall incidence of neurological events (stroke and TIA) was higher in the TAVR group (11.2%, vs. 6.5% in the SAVR group, but the difference did not reach a statistically insignificant level (p=0.05). After the first year, the major vascular complications and major bleeding were uncommon in the two groups,

maintaining the difference observed at 1 year. Electrocardiographic analysis at 2 years showed no significant changes in the valve areas or mean gradients. Moderate or severe paravalvular aortic regurgitation was more frequent after TAVR than SAVR at both one and 2 years ( $p < 0.001$  for both comparisons). The presence of aortic regurgitation (mild, moderate, or severe vs., none or trace) was associated with an increase in late mortality (hazard ratio 2.11; 95% CI 1.43-3.10,  $p < 0.001$ ). Conclusion: PARTNER Cohort A showed that transcatheter aortic valve replacement was non-inferior to open heart surgical aortic valve replacement for all-cause mortality at one year in patients with severe aortic stenosis at high-risk of operation. PARTNER Cohort B showed a 19% absolute mortality reduction at one year after transcatheter aortic valve replacement (number needed to treat of 5) when compared to standard medical therapy in patients with severe aortic stenosis and symptoms who are not suitable candidates for surgery. In the two cohorts TAVR was associated with a higher risk of neurological and cardiovascular events. The follow-up duration in the two cohorts of PARTNER may be insufficient to determine long-term safety and durability of the prosthesis, and whether the benefits observed with TAVR will be sustained over time.

**Articles:** The literature search revealed several publications on the PARTNER trial; another small trial (STACCATO trial); a meta-analysis that pooled the results of 16 heterogeneous studies; and a large number of case series, feasibility studies, and registry data. The pivotal PARTNER trial was selected for critical appraisal. The STACCATO study, a randomized controlled trial conducted on operable elderly patients with aortic stenosis, was not selected for critical appraisal due to its small size and premature termination. The meta-analysis was not reviewed further due to the heterogeneity of studies it included. The following studies were critically appraised: Leon MB, Smith CR, Mack M, for the PARTNER Trial Investigators. Transcatheter aortic-valve implantation for aortic stenosis in patients who cannot undergo surgery. *N Engl J Med.* 2010 ;363:1597-607. See [Evidence Table](#) Smith CR, Leon MB, Mark MJ, for the PARTNER trial Investigators. Transcatheter versus surgical aortic-valve replacement in high-risk patients. *N Engl J Med.* 2011;364:2187-2198. See [Evidence Table](#)

The use of TAVR does meet the *Group Health Medical Technology Assessment Criteria*.

### **Valve-in Valve Transcatheter Aortic Valve Implantation (VI-TAVI) in Failed Bioprosthetic Aortic Valves [Transcatheter Valve-in Valve Implantation (TAVIV), transcatheter aortic valve in surgical aortic valve (TAV-in-SAV)]**

#### **BACKGROUND**

Degenerative aortic stenosis is one of the most common and most serious acquired valvular heart diseases among adults. Surgical aortic valve replacement (SAVR) has been the standard treatment for symptomatic severe aortic stenosis for over forty years. SAVR is an open heart procedure that involves removing the diseased aortic valve and replacing it with either a man-made mechanical valve or a biological valve. Mechanical valves are strong and long-lasting, but patients receiving them will need to use a blood thinning medication for the rest of their lives. In the last two decades, there has been a shift toward the use of biological (bioprosthetic) valve implants rather than mechanical valves. These are tissue valves made from human aortic valves (homografts) or more commonly from animal tissue (xenografts). The latter are made from porcine valve leaflets, bovine pericardium, or less frequently from porcine pericardium. Surgical bioprostheses are commonly stratified into stented and stentless valves. Compared with mechanical valves, bioprosthetic valves are associated with a lower risk of thromboembolic events and do not require long-term anticoagulation. However, these tissue valves have a limited durability, and the majority deteriorates within 10-20 years leading to structural dysfunction. Valve failure may present as stenosis due to calcification, pannus or thrombosis; regurgitation secondary to wear and tear or infection; or as a combination of both stenosis and regurgitation (Seiffert 2010, Bapat 2012, Webb 2013, Dvir 2014).

Treatment of patients with failed bioprosthetic valve is a clinical challenge. Re-operation is considered the standard of care, but a repeat cardiac surgery is associated with high risk of morbidity and mortality, not only of the complexity of the procedure, but also because of the comorbidities and advanced age of the patients who usually need it. The operative mortality for elective redo valve surgery is reported to range from 2-7%, and may increase to more than 30% among those at high-risk. Patients who are considered inoperable have no other effective treatment option; supportive medical therapy is associated with poor prognosis, and balloon valvuloplasty is not recommended for stenotic bioprosthetic valves due to the high risk of tearing of the leaflets (Seiffert 2010, Bapat 2012, Dvir 2014).

Transcatheter aortic valve replacement (TAVR), also known as transcatheter aortic valve implantation (TAVI) has become an alternative less invasive treatment modality for patients with severe native aortic valve stenosis who are at high surgical risk due to advanced age, significant comorbidities, frailty, prior chest radiation and other factors. The current widespread use and success of TAVI in high-risk patients together with the major

complications of redo aortic valve surgery in these patients; have led to considering the valve-in-valve TAVI (VIV-TAVI) (also referred to as TAV-in-SAV) approach as an option for patients with degenerated failed bioprosthetic heart valve. TAVI is performed with a beating heart and avoids the risks associated with using cardioplegia and cardiopulmonary bypass during redo surgery. Currently, the main transcatheter valves used for valve-in-valve procedures are the Edwards SAPIEN or SAPIEN XT (Edwards Lifesciences, Irvine, California), and the CoreValve (Medtronic, Minneapolis, Minnesota) (Eggebrecht 2011, Linke 2012, Dvir 2014).

Edwards SAPIEN XT Transcatheter Heart Valve (SAPIEN XT THV) system consists of a transcatheter aortic valve and the accessories used to implant it. The valve is made of cow tissue attached to a balloon-expandable, cobalt-chromium frame for support, and comes in three sizes: 23 mm, 26 mm, and 29 mm. The valve is compressed and placed on the end of a balloon catheter, which is then inserted through either the femoral artery or a small cut between the ribs and advanced through the blood vessels until it reaches the failed valve. The SAPIEN XT valve is then expanded with the balloon until it anchors to the failed valve (valve-in-valve). Once the new valve is in place, it opens and closes properly, allowing the blood to flow in the correct direction. According to the FDA The Edwards SAPIEN XT THV is indicated for patients with symptomatic heart disease due to either severe native calcific aortic stenosis, or more recently (in 2015) due failure of a surgical bioprosthetic aortic valve who are judged by a heart team to be at high or greater risk for open surgical therapy (i.e. Society of Thoracic Surgeons operative risk score  $\geq 8\%$  or at a  $\geq 15\%$  risk of mortality at 30 days). It is contraindicated in patients who cannot tolerate an anticoagulation/antiplatelet regimen, have a mechanical artificial aortic valve, or have active bacterial endocarditis or other active infections in the heart or elsewhere (FDA and the manufacturer's webpages).

The CoreValve system consists of a catheter-based artificial aortic heart valve and the accessories used to implant it. The valve is made of pig tissue attached to a flexible, self-expanding, nickel-titanium frame for support. The CoreValve is compressed and placed on the end of a delivery catheter, which is then inserted through the femoral artery. If the femoral arteries are not suitable, the valve can be inserted through other arteries or through the aorta. The catheter is pushed through the blood vessels until it reaches the diseased aortic valve. The valve is then released from the catheter, expands on its own and anchors to the diseased valve. The CoreValve functions the same as a normal valve, allowing the blood flow in the correct direction. The CoreValve System had been previously approved by the FDA to treat patients whose native aortic valve has become severely narrowed as a result of calcium buildup and who are considered to be at "extreme risk" or "high risk" for surgical aortic valve replacement. In March 2015 the FDA expanded the use of CoreValve system for aortic valve-in valve replacement inpatients who need replacement of a failed tissue aortic valve, but are at extreme or high risk of death or serious complications from traditional open-heart surgery based on the judgement of a heart medical team. The CoreValve System use is contraindicated in patients with a mechanical aortic heart valve, have any infection, cannot tolerate blood thinning medicines; or have sensitivity to titanium or nickel or contrast media (FDA News Release March 30, 2015).

Reported adverse events with of VIV-TAVI include death, stroke, acute kidney injury, myocardial infarction, major bleeding, and the need for a permanent pacemaker. Other limitations associated with VIV-TAVI are the increase risk of coronary obstruction (especially in patients with stentless valves); high residual gradients which may result from under expansion of the result transcatheter heart valve in smaller surgical bioprosthesis; and paravalvular leaks between the surgical and transcatheter valves. Successful outcome of the VIV procedure is thus dependent on patient selection, knowledge of prior cardiac surgery, internal diameter and material of the degenerated bioprosthetic valve as well as mode of valve failure, anticipation of complication, procedural planning, and experience of the cardiac team with TAVI (Bapat 2012, Webb 2013, Verhoye 2015, Phan 2016)

In 2015, the US Food and Drug administration (FDA) expanded the approved use of the SAPIEN XT (Edwards Lifesciences) and CoreValve System (Medtronic) to include "valve-in-valve" repair in patients who failed surgical bioprosthetic heart and are at high or extreme risk for complications associated with traditional open-heart surgery.

#### **06/20/2016: MTAC REVIEW**

**Evidence Conclusion:** The published studies on transcatheter valve-in-valve implantation in a failed surgical bioprosthetic valve, as well as the two unpublished pivotal studies submitted to the FDA, were all descriptive, observational series that aimed at evaluating the feasibility, safety, and short-term outcomes of the procedure. The vast majority of the published studies was conducted in European countries and evaluated the Edwards SAPIEN or the CoreValve systems. The VIVID registry was initiated in 2010 to collect retrospective and prospective data on VIV-TAVI procedures performed in different centers worldwide.

#### **Safety and outcomes of VIV-TAVI in patients with failed prosthetic aortic valve**

The data provided in the meta-analyses as well as that collected in the international VIVID registry (Evidence Tables 1-3) indicate that the patients selected for valve-in-valve implantation due to a failed aortic bioprosthetic valve had a high risk profile. Their mean age was 77.5-78 years, and their mean logistic EuroSCORE (European System for Cardiac Operative Risk Evaluation) was 31-31.3. According to the pooled data presented in Phan and colleagues' (2016) meta-analysis, 74.8% of the patients had a history of hypertension, 27.3% diabetes, 44.6%, chronic kidney disease, 50% coronary artery disease, 26.3% peripheral vascular disease, and 12.4% had a history of stroke. The following table summarizes the pooled results of the two published meta-analyses, and the aggregated data from the VIVID registry (more details and subanalyses are provided in evidence tables

	<b>Chen et al's, meta-analysis (2016) N=15 studies on aortic VIV (861 patients) Rate % (95% CI)</b>	<b>Phan et al's meta-analysis (2016) N=18 studies (823 patients) Pooled weighted estimate (95% CI)</b>	<b>Dvir, et al's VIVID registry (2014) N=459 patients Rate %</b>
<b>Early/preoperative complications</b>			
30-day mortality	6.9% (4.3-10.0)	6.4% (4.8-8.2)	7.6%
Major stroke	1.8% (1.0-2.8)	2.0% (1.0-3.0)	1.7%
Major bleeding	5.5% (4.0-7.2)	4.6% (1.7-7.4)	8.1%
Myocardial infarction	--	3.0% (1.0-5.0)	--
Major vascular complication	--	5.4% (2.6-8.1)	9.2%
Acute renal failure	6.7% (5.1-8.6)	7.0% (5.1-8.9)	7.4%
Need for permanent pacemaker	7.6% (5.9-9.6)	6.5% (4.3-8.7)	8.3%
Post-operative mean gradient (mmHg)	--	15.2 (95% CI; 13.4-17.1)	15.8 ±8.9 **
<b>Late complications</b>			
1-year mortality	16.5% (12.0-21.6)	12.6% (5.6-21.4)*	16.6%

1-3).

#### *Combined results of published studies on VIV-TAVI in patients with failed bioprosthetic aortic valves*

\*Mortality rate at latest follow-up

\*\*Post-procedural gradients were assessed in 429 patients in VIVID registry. It was moderately elevated (mean  $\geq 20$  mmHg) among 26.8% of the patients, and was more common with the balloon expandable vs. self-expandable devices, and with small surgical valves.

- AV regurgitation: at least moderate degree in 5.4% (VIVID registry),
- Paravalvular leak: Mild in 13.1%, moderate in 3.5% (Phan meta-analysis)
  - The majority of studies were conducted in Europe.
  - The studies were single-center or multicenter observational series with population sizes ranging from 11 to 50.
  - Most surgical bioprosthetic valves were stented (~ 82% vs 18% stentless), which may limit generalization of the results. VIV in stentless valves is reported to be a more challenging procedure.
  - The two meta-analyses included the patients in the VIVID registry. There might be a potential of duplication of some results as it is unclear if the registry comprised data on patients included in the individual studies.
  - The follow-up duration was generally insufficient to determine the long-term efficacy and the durability of the VIV implant.
  - Subgroup analysis of data in the VIVID registry showed that patients with small surgical valves (label size <20 mm), and with stenosis as the mechanism of failure, had lower survival and worse outcomes. A multivariate analysis showed that surgical valve label size, type of valve failure, transapical access and STS score were significantly correlated with the overall 1-year mortality.

The FDA approval for the extended use of each of the Medtronic CoreValve and the Edwards SAPIEN in patients with failed prosthetic valves was based on the TAV-in-SAV registries for each of the two VIV systems (Data on methodology, analysis and results of the studies submitted to the FDA, were obtained from the FDA web pages). Both were prospective, non-randomized, observational studies that enrolled patients with

symptomatic, failed bioprosthetic valves, and with an estimated harm exceeding the benefits (operative risk of death or serious irreversible complications as 50%) according to the judgement of a cardiologist and two cardiac surgeons (Evidence Tables 4 and 5).

**VIV-TAVI versus conventional reoperation for replacing failing bioprosthetic aortic valve**

There are no published studies, to date, that directly compared VIV-TAVI versus the conventional reoperation to replace the failing aortic bioprosthetic valve. However, it might not be feasible or ethical to directly compare VIV-TAVI to a redo surgery in high-risk patients with symptomatic degenerated bioprosthetic valve who are not suitable candidates for a repeat cardiac surgery that carries a high morbidity and mortality risk. Indirect comparisons between outcomes and safety VIV-TAVI and redo conventional aortic valve replacement (cAVR) in failed bioprosthetic aortic valves, were performed retrospectively by Phan and colleagues' meta-analysis (2016), and by Erlebach et al (2015) in a small retrospective study.

Phan and colleagues (Evidence Table 2) pooled the results of 18 observational studies (8 prospective and 10 retrospective) on VIV-TAVI and 6 studies on redo conventional aortic valve replacement (cAVR). Patients were not randomized to the interventions, and those in the VIV-TAVI were older and had significantly higher baseline morbidities. The population sizes were small and there were significant heterogeneity between the studies. The results of the analysis suggest that VIV-TAVI was associated with lower risk of stroke and bleeding and a higher risk of moderate paravalvular leak (PVL) compared to cAVR. There were no significant differences between the two procedures in the perioperative mortality. No sub-group analyses were performed to determine whether the outcomes varied according to mechanism or type of bioprosthetic valve failure, or other variables. The authors concluded that lower quality evidence suggests that VIV-TAVI may achieve similar hemodynamic outcomes while significantly reduces the risk of stroke and bleeding vs. redo cAVR, but with an increased rate of moderate PVL. They noted that RCTs and prospective registries are needed to compare the two procedures and examine the long-term effectiveness of VIV-TAVI.

Erlebach and colleagues (2015) retrospectively compared the outcomes of all patients after a valve-in-valve transcatheter aortic valve in surgical aortic valve (TAV-in-SAV) versus standard reoperation (surgical redo operation (SAV-in-SAV). Patient characteristics, preoperative data, post-procedural complications, and 30-day mortality were collected from a database that included data for 210 consecutive patients undergoing SAV-in-SAV from January 2001 to October 2014, and TAV-in-SAV starting from 2007. 108 patients were excluded if they had endocarditis, previous mechanical valves or TAVI, and or concomitant cardiac surgery. The analysis included 52 patients in the SAV-in-SAV group and 50 in TAV-in-SAV. This was a retrospective analysis of data for two groups of patients without randomization or matching. Patients in the TAV-in-SAV had a higher risk profile; they were significantly older, had higher mean logistic EuroSCORE, lower mean left ventricular ejection fraction, worse NYHA functional class, and higher rates of history of stroke, CAD, prior CABG, atrial fibrillation, and pulmonary hypertension than those in the SAV-in-SAV group.

Analysis of the results showed the following:

Outcomes	TAV-in-SAV N=50	SAV-in-SAV N=52	P value
30 day-all cause mortality, n (%)	2 4%	0	0.238
Kaplan-Meier 1-year survival	83%	96%	<b>&lt;0.001</b>
Stroke, n (%)	2 4%	1 2%	0.614
Myocardial infarction, n (%)	1 2%	1 2%	0.490
Need for pacemaker implantation, n (%)	3 6%	11 21%	<b>0.042</b>
Post-procedural new dialysis, n (%)	6 12%	1 2%	0.057
Blood transfusion (liter)	0.7±1.1	0.5±1.0	0.346
Aortic regurgitation, n (%)	10 20%	3 6%	0.614
Paravalvular leak	9	0	
Mean AV gradient (mmHg)	18.8 ±8.7	13.8 ±5.4	<b>0.008</b>

All TAVI patients were grouped together and no subgroup analyses were made to determine the impact of the size of the failed valve, nature of failure, or the access route of TAVI on the outcome of the VIV procedures.

The study was a retrospective analysis of a small group of patients with significant differences in their baseline characteristics and risk profile. The results of this study as well as those of Phan et al's meta-analysis should be interpreted with caution due to the lack of randomization, matching of patients, or adjusting for the confounding factors all of which may have an effect on the results.

**Conclusion:**

- There is fair evidence from a number of observational studies that valve-in-valve implant in a failed aortic prosthetic valve is feasible and relatively safe.
- There is insufficient direct evidence to determine whether the outcomes of valve-in-valve implantation in a failed aortic prosthetic valve are equivalent or superior to the outcomes of a redo conventional operation to replace the valve.
- There is insufficient published evidence to determine the long-term efficacy and durability of valve-in-valve implant in a failed aortic prosthetic valve.

**Articles:** The literature search for studies on valve-in-valve transcatheter aortic valve replacement in high risk patients with failed bioprosthetic valves identified a number of observational studies and case series from single institutions as well as registries for patients receiving a VIV-TAVI in various countries (Canadian registry, German registry, Italian registry, Germany/Switzerland registry, and a global registry that collects data form more than 60 countries worldwide). A recent systematic review with meta-analyses (Chen 2016) pooled the results of studies reporting on clinical outcomes of transcatheter VIV in failed surgical bioprosthetic aortic and mitral valves. Two other systematic reviews (with no meta-analyses) that summarized the results of studies on VIV-TAVI published through July 2014 were also identified (Tourmousoglou, et al, 2015, and Raval et al, 2014). To date, there are no published randomized controlled trials that directly compared the VIV-TAVI to surgical reoperation in patients with failed bioprosthetic aortic valves. The search identified a recent systematic review and meta-analysis (Phan, et al, 2016) that indirectly compared VIV-TAVI versus surgical valve redo operation (i.e. TAV-in-SAV versus SAV-in-SAV), and Erlebach et al, 2015 study that compared retrospective data on postoperative outcomes for patients with failing bioprosthetic valve who received a VIV-TAVI or underwent a redo aortic surgery in a single center in the period from January 2001 through October 2014. The two United States pivotal studies that were the basis of the FDA approvals of the systems are not published to data, but are available at the FDA website. The meta-analysis that pooled the results of the cohort studies on VIV-TAVI and the analysis that compared VIV-TAVI with reoperation, as well as the global VIVID registries and the two pivotal studies submitted to the FDA were selected for critical appraisal. Chen HL, Liu K. Clinical outcomes for transcatheter valve-in-valve in treating surgical bioprosthetic dysfunction: A meta-analysis. *Int J Cardiol.* 2016 Mar 18; 212:138-141. (See Evidence Table 1) Phan K, Zhao DF, Wang N, et al. Transcatheter valve-in-valve implantation versus re-operative conventional aortic valve replacement: a systematic review. *J Thorac Dis.* 2016 Jan; 8 (1):E83-93. (See Evidence Table 2) Dvir D, Webb JG, Bleiziffer S, et al. Transcatheter aortic valve implantation in failed bioprosthetic surgical valves. *JAMA.* 2014 Jul; 312(2):162-170. (See Evidence Table 3).

The use of Valve-in Valve Transcatheter Aortic Valve Implantation does meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Transient Elastography for Evaluating Liver Fibrosis

- FibroScan® System
- Shear Wave Elastography

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	For code 0346T: <a href="#">Non-Covered Services (L35008)</a> . And for facility-based services billed using a UB form, see <a href="#">Non-Covered Services (L34886)</a>
Local Coverage Article	For code 91200 – Covered without review
Local Coverage Article	None

##### For Non-Medicare Members

GHC will cover Transient Elastography (TE) (e.g. Fibroscan, Shear-Wave Elastography) once every six months, as medically necessary to assess the degree of liver fibrosis and cirrhosis in an individual with chronic liver disease. Performance of transient elastography within 6 months following a liver biopsy is considered not medically necessary. The test must be prescribed by or in consultation with a gastroenterologist, Hepatologist, infectious disease specialist or GHC CIM physician.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Liver fibrosis is the natural wound healing response to parenchymal injury in almost all chronic liver diseases (CLDs) including chronic hepatitis B or hepatitis C virus infections (HBV and HCV), chronic alcohol abuse, autoimmune disease, and non-alcoholic fatty liver disease. Without appropriate intervention, liver fibrosis progresses and eventually results in liver cirrhosis and its various complications including hepatocellular carcinoma (HCC). The progression to cirrhosis has three main characteristics; 1. It takes a very long time (as long as 20-30 years), 2. It does not cause symptoms, and 3. Severe fibrosis cannot be reliably identified with standard laboratory tests. Thus CLDs may remain unrecognized for many years until the patient develops complications or cancer (Wong 2008, Chon 2012, Fabrellas 2013, Singh 2013).

The early recognition of chronic liver disease and the accurate assessment of the extent of liver fibrosis and its progression are thus very important for making treatment decisions, surveillance for early detection of HCC, as well as predicting the prognosis and therapeutic outcomes. The true gold standard is the histological analysis of large surgical biopsies, which is impossible to obtain in routine practice. Percutaneous liver biopsy is currently considered the gold standard for diagnosing liver fibrosis and assessing its severity. However, it is an imperfect gold standard; the specimen obtained by the biopsy represents only 1/50,000 of the liver parenchyma and may miss up to 30% of the lesions. It is also limited by its invasiveness, expense, sampling error, heterogeneity of fibrosis throughout the liver, intra-and inter-variability in interpretation, and potential life-threatening complications. In addition, it is impractical to perform repeated biopsies within a short time in order to monitor the dynamic changes in liver fibrosis or disease progression. Several quantitative and qualitative classification systems are

used for interpreting the histological findings of liver biopsies. METAVIR score, a semiquantitative classification system, was specifically designed and validated for patients with hepatitis C, but is commonly used for estimating liver fibrosis due to other etiologies. It consists of activity and fibrosis scores; the latter is assessed on a five point scale (F0, no fibrosis; F1, portal fibrosis; F2, periportal fibrosis or rare portal-portal septa; F3, fibrous septa with architectural distortion, no obvious cirrhosis (bridging fibrosis); and F4, definite cirrhosis. This last stage of F4 includes patients with a wide range of severity. The activity score is graded according to the intensity of necroinflammatory lesions (A0 for no activity, A1 for mild activity, A2 for moderate activity, and A3 for severe activity) (Wong 2008, Anastasiou, 2010, Degos 2010, Sanchez-Conde 2010, Jung 2012, Poynard 2012).

Due to the limitations of liver biopsy, noninvasive tools and procedures such as transient elastography, magnetic resonance elastography, and several serum biomarkers have been developed as surrogates to measure liver fibrosis and to monitor its progression and potential response to therapy.

Transient elastography (TE) (FibroScan®, Echosens, Paris, France) was developed in France in the early 2000s and has gained increased attention since then. It is an ultrasound-based modality that quantitatively assesses liver stiffness (LS) as a surrogate for fibrosis. The basic principle of TE is that the propagation velocity of a wave through a homogenous tissue is proportional to its elasticity, which is correlated with the amount of fibrosis in the liver. TE consists of an ultrasound transducer mounted on the axis of the vibrator, which produces vibration of a mild amplitude and low frequency (50 Hz), consequently inducing elastic shear wave that propagates through the liver. Pulse-echo ultrasound follows the propagation of the shear wave and measures the velocity, which is related to the liver tissue stiffness. It is reported that the velocity of elastic waves is faster in fibrotic liver than normal livers. In order to obtain valid and reproducible measurements, the probe should be placed at the center of the right lobe of the liver, two intercostal spaces below the upper liver margin, and at the level of the anterior or middle axillary line, with the patient lying in dorsal decubitus with the right arm in maximal abduction. The operator, assisted by time motion ultrasound images, locates the probe on a liver portion at least 6 cm thick free of large vascular structures and the gall bladder, then presses the probe button to begin the measurement. For a reliable evaluation, the manufacturer recommends that at least ten valid measurements should be obtained, and their median value calculated and considered representative of liver elasticity. The success rate is calculated as the number of valid measurements divided by total number of measurements. Examinations with a 70% success rate are considered reliable. The results are immediately obtained and are expressed as kilopascals (KPa) (range 2.5-75 KPa). The interquartile range <30% of the median indicates a high-quality result (Poggio 2009, Jung 2012, Myers 2012, Bonder 2014).

TE has been studied for the assessment of fibrosis in patients with HBV, HCV, HCV and HIV co-infected patients, cholestatic liver disease, non-alcoholic fatty liver disease, portal hypertension, spleen fibrosis, and other conditions. It is simple to use, well tolerated by most patients, rapid, and can be easily incorporated in outpatient settings. However, the accuracy and reliability of the scan may be affected by several factors including obesity and associated factors e.g. the thoracic fold thickness, waist circumference, subcutaneous adipose tissue, and the distance between the skin and liver capsule. Nonfibrotic histological features of the liver as necroinflammation and fatty liver, may also overestimate the liver stiffness. Other factors that may be associated with unreliable measurement included female gender, older age, and shorter height. The reported failed and unreliable measurements of transient elastography was as high as 29% ( Jung 2012, Myers 2012, Sirli 2013, Bonder 2014).

FibroScan® received FDA clearance in April 2013 as a noninvasive aid to clinical management of patients with liver disease.

## Medical Technology Assessment Committee (MTAC)

### *Transient Elastography*

#### 04/21/2014: MTAC REVIEW

**Evidence Conclusion:** *Accuracy of TE in staging liver fibrosis* The published studies and meta-analyses indicate that TE is less accurate than liver biopsy in assessing liver fibrosis. However, its accuracy may be considered excellent for F4 and strong for F<sub>≥3</sub> fibrosis due to any etiology. It has a lower accuracy in detecting fibrosis at earlier stages, and for staging liver fibrosis due to HBV compared to HCV infections. The published studies estimated the diagnostic accuracy of TE in staging liver fibrosis by calculating sensitivity, specificity and the areas under the receiver operator curves (AUROC) using percutaneous liver biopsy as the gold standard. The authors of the studies did not incorporate in their inclusion criteria a maximum interval between liver biopsy and TE in order to minimize difference due to progression of the disease. Liver biopsy is not a perfect gold standard, and the potential error in histological staging makes it difficult to evaluate a non-invasive marker correctly. In addition, there are no optimal or validated standard thresholds for the various fibrosis stages or for different etiologies of fibrosis. The stiffness cut-off values for TE for each fibrosis stage varied across studies that calculated these values based on their own cohort after data collection and were not validated externally. There was a wide range and overlap of cut-offs between different fibrosis stage, in the published studies and meta-analyses (see table below).

### Cut-off values for staging fibrosis used in different meta-analyses

	Steadman 2013	Tsochatzis 2011	Chon 2012
<b>All etiologies</b>			
F <sub>≥2</sub>	7.4 ± 1.5	7.3 ± 1.4 (4.0-10.1)	
F <sub>≥3</sub>	9.9 ± 2.4	10.2 ± 1.9 (7.3-15.4)

### Predictive value of liver stiffness measurement using TE

Singh and colleagues, 2013 ([evidence table 2](#)) conducted a meta-analysis of 17 cohort studies (N= 7,058 patients) with chronic liver disease to evaluate the association between liver stiffness measurements (LSM) using TE and outcomes of the disease. The pooled results of the analysis showed a significant association between baseline LSM with the risk of hepatic decompensation, hepatocellular carcinoma, death, or a composite of these outcomes. There was a significant heterogeneity among studies in the magnitude of effect, and the authors of the meta-analysis indicated that the heterogeneity could not be explained by variations in study locations, etiologies and stages of chronic liver disease, techniques to measure liver stiffness, adjustment for covariates, or method of calculating relationship in the meta-analysis. In addition there were variations between the patients in their clinical condition, treatment of underlying condition, follow-up duration, and evaluation, and other potential confounding factors. The patients were managed differently according to their baseline LSM. The authors also indicated that they calculated the RR assuming a log-linear relationship across the ranges of 1.5-75 kPa, which might not be the case at all levels of stiffness.

Association between baseline liver stiffness measurement (LSM) and outcomes  
(Singh 2013)

Outcomes	N studies	Risk ratio (95% CI)
Hepatic decompensation	6	1.07 (1.03-1.11)
Hepatocellular carcinoma	9	1.11 (1.05-1.18)
Risk of mortality	5	1.22 (1.05-1.43)
Composite liver-related outcomes	7	1.32 (1.16-1.51)

Vergniol and colleagues, 2014 ([Evidence table 3](#)) conducted a prospective study to assess the prognostic value of 3-year liver stiffness measurement in 1,025 patients with chronic hepatitis C. The authors concluded that the three-year changes of liver stiffness measurement have a strong predictive value for long-term survival in patients with chronic hepatic C. Based on their findings the authors recommended a clinical algorithm using baseline liver stiffness, its evolution, and SVR achievement for the prediction of prognosis and management of patients with chronic hepatitis C. The study was large and had 3-years follow-up duration, but it only evaluated survival prediction and did not estimate the risk of HCC, or other CLD related morbidities e.g. ascites, portal hypertension,

and bleeding varices. In addition patients with potentially bad prognosis were excluded from the study, which may limit generalization of the results.

Poynard and colleagues (2014) pooled the data for three large prospective cohorts (EPIC, Paris, and Bordeaux) to assess the performance of TE and FibroTest for predicting the steps in fibrosis progression from F0 to death. The three cohorts combined included 3,927 patients with chronic hepatitis C with a wide severity spectrum (26% cirrhotics) and without complications at baseline. Follow-up was 5 years in EPIC cohort and 10 years in the Paris and Bordeaux cohorts. The results of the analysis showed that TE was predictive of severe complications (including primary liver cancer) and deaths independent of treatment response. The probability of severe complications at different predetermined TE cutoff values increased from 1.6% in TE cutoff F0 to 71% at F4.3. The authors did not find significant difference between TE and FibroTest for the prediction of severe complications, primary liver cancer, and overall mortality. Combination of the two tests had slightly higher predictive value.

Prediction of complications based on TE predetermined cutoff (Poynard et al, (2014))

Baseline TE kPa	Severe complications* Defining stage F4.3 % (95% CI)	Primary liver cancer % (95% CI)	Liver-related events % (95% CI)	Deaths % (95% CI)
F0 (0-≤5)	1.6% (0.3-2.8)	0% (0.0)	2.5% (0.9-4.1)	3.7% (0.9-6.5)
F1 (5-≤7.1)	5.0 % (2.8-7.3)	1.0% (0.2-1.9)	10.5% (5.4-15.7)	4.2% (1.9-6.6)
F2 (>7.1-≤9.5)	11.0% (1.7-20.2)	2.1% (0-4.7)	40.6% (3.4-77.8)	3.5% (1.2-5.7)
F3(>9.5-≤12.5)	25.7 (0.0-58.8)	24.6 % (0-58.2)	19.6% (6.0-33.2)	11.8% (4.8-18.9)
F4.1(>12.5-≤20)	23.4 (13.9-75.8)	12.7% (4.5-21.0)	62.1% (35.8-88.5)	20.3% (8.6-32.0)
F4.2(>20-≤50)	55.9 (36.0-75.8)	33.6% (13.6-53.5)	77.1% (60.1-94.2)	30.3% (20.4-40.0)
F4.3(>50-175)	71.0 (26.7-100)	58.7% (0.5-100)	100% (26.0-100)	14.8% (0.0-34.0)

Prognostic performance of TE (AUROCs) for the prediction of first severe complications defining Cirrhosis (F4.3) (Poynard et al, 2014)

	Severe complications* Defining stage F4.3 AUROC (95% CI)	Primary liver cancer AUROC (95% CI)	Liver-related events AUROC (95% CI)	Deaths AUROC (95% CI)
Baseline TE	78 (73-832)	87 (82-90)	79 (75-83)	75 (69-80)
Fibrosis progression rate	59 (53-64)	57 (48-65)	57 (51-62)	59 (51-66)

\*Including primary liver cancer bleeding, and hepatic insufficiency (ascites, jaundice, encephalopathy, or Child C)

### Use of TE in monitoring dynamic changes in liver fibrosis during antiviral treatment

In patients with chronic hepatitis C The results of three prospective studies; Vergniol 2009 ([evidence table 4](#)), Ogawa 2009, and Wang 2010, indicate that patients with CHC treated with peg-interferon (or conventional interferon)/ribavirin-based therapy had significantly reduced TE values at the end of follow-up.

Vergniol et al's study (2009) showed that TE values fell in all treated patients irrespective of the SVR. Ogawa and colleagues (2009) reported that patients with no SVR but with a biochemical response had a greater reduction in TE than those with non-biochemical response. Wang et al's study (2010) showed that 60% of SVR and 47% of non-SVR patients had decreases in their liver stiffness measured by TE. The reduction was statistically significant only for those with SVR. The results of these studies demonstrate a reduction in liver stiffness among patients with HCV treated with interferon-based therapy. The reduction in TE values was significant among patients with sustained viral response. However, the studies did not pair TE with liver biopsy to determine if the reduction in liver stiffness was associated with regression in fibrosis. The studies also, did not correlate observed changes in TE values with long-term endpoint related to liver fibrosis such as decompensation events, HCC development, or liver-related deaths. In patients with chronic hepatitis B Changes in TE values during antiviral therapy in patients with hepatitis B virus were mainly studied among Asian patients. In a prospective cohort study, Fung and colleagues (2011) examined changes in the liver stiffness among 426 selected patients with chronic hepatitis B. All patients underwent transient elastography at baseline and after 3 years. Hepatitis serology, viral load and routine liver biochemistry were monitored regularly. A total of 110 (26%) patients were treated with oral antiviral therapy, and 316 (74%) did not receive antiviral therapy. The results showed a significant decline in the liver stiffness measurement using transient elastography (TE), between the two time points in all participants combined, and in the treated and untreated subgroups. Within the treated subgroup, the reduction in liver stiffness was only observed in patients who had elevated alanine aminotransferase (ALT) at baseline and subsequent normalization after 3 years. For the untreated group, the decline in TE values was only observed in patients in whom the ALT remained normal at both time points. No liver biopsies were performed, which makes it hard to determine whether the decline in TE values was due to liver fibrosis regression or normalization of ALT. Multivariate analysis showed that the factors associated with a significant decline in liver stiffness of  $\geq 1$  kPa in hepatitis B antigen positive patients were higher ALT and higher AST levels at initial TE, lower ALT at follow-up TE, and antiviral therapy.

Two other small prospective studies (Enomoto 2010 and Lim 2011) and one small retrospective study (Kim 2010) also examined the usefulness of TE as a tool for monitoring the degree of liver stiffness as a surrogate to fibrosis during antiviral therapy in patients with chronic hepatitis B. Liver stiffness was measured by TE at baseline and after antiviral treatment. The studies did not include control groups that did not receive antiviral therapy. Liver biopsy to confirm any regression in fibrosis was only performed in a subset of 15 patients in Lim' et al's study and 4 patients in Kim et al's study. The overall results of these studies showed a significant decrease in liver stiffness with antiviral therapy for hepatitis B infection. The absence of comparisons with paired liver biopsy makes it hard to conclude that the reduction in liver stiffness was due to regression in liver fibrosis. Lim and colleagues' (2011) study that compared serial TE values with paired liver biopsies among a subgroup of 15 (25%) patients, reported that the reduction in TE values correlated significantly with improved necroinflammatory scores.

**Conclusion:** The published studies on the diagnostic accuracy of TE in staging liver fibrosis show that compared to liver biopsy, TE has an excellent accuracy for detecting liver cirrhosis (F4). However, a negative TE test does not excluded cirrhosis. TE has lower accuracy at earlier stages of liver fibrosis when antiviral treatment would be optimally performed to stop or slow the progression of fibrosis due to viral hepatitis. There are no validated cutoff values for the various fibrosis stages or for different etiologies of fibrosis. There is fair evidence that baseline measurements of liver stiffness and its changes during antiviral therapy may be useful in predicting severe complications and mortality in patients with viral hepatitis C. According to Vergniol 2014, SVR should be taken into consideration when predicting prognosis. There is insufficient evidence to determine whether the reduction in TE values after antiviral therapy is due to the regression in fibrosis or resolution of tissue inflammation (necroinflammatory activity).

**Articles:** The literature search revealed over 300 articles on transient elastography for liver disease, many of which were unrelated to the current review. There were 8 systematic reviews with meta-analyses and a large number of observational studies that examined the diagnostic accuracy of transient elastography for detecting and staging liver fibrosis in patients with chronic viral hepatitis, and alcohol or non-alcohol related liver disease. The literature search also identified two meta-analyses of longitudinal studies that examined the prognostic accuracy of TE in patients with hepatitis B or C, one more recent prognostic study, and few small to moderate size cohort studies that evaluated the clinical usefulness of TE for monitoring potential fibrosis regression during antiviral treatment in patients with chronic hepatic B or C. The more recent, valid, and inclusive meta-analyses on the diagnostic and prognostic accuracies as well as the larger and more valid study on the use of TE for monitoring the effect of antiviral treatment for patients with hepatitis C were selected for critical appraisal. Steadman R, Myers RP, Leggett L, et al. A health technology assessment of transient elastography in adult liver disease. *Can J Gastroenterol.* 2013;27:149-158. ## Clinical Review Criteria Transition of Care

- Continuing Care with Terminated Practitioners
- Continuing Care with Providers outside of the Member's GHC Health Plan Network for new enrollees

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Medicare

#### Manuals

#### [Chapter 4 – Benefits and Beneficiary Protections – 110.1.2 Significant Changes to Networks](#)

### Criteria

- I. This policy applies to both **Medicare and Non-Medicare** Members
  - A. Continued coverage with a non-network provider may be covered when **All of the following** criteria are met:
    1. The most recent documentation of care provided by the treating practitioner/clinic must be provided and support need for ongoing care.
    2. Discontinuity could cause a recurrence or worsening of the condition under treatment and interfere with anticipated outcomes based on clinical notes and reviewer's clinical judgment.
    3. The member is undergoing an active\* course of treatment for a chronic or acute medical condition with this requested provider. In this circumstance, the member will be permitted to receive coverage until the acute phase is resolved or up to 90 calendar days or, whichever is shorter.
  - B. Has a qualifying situation that in the Group Health Medical Director judgment would place the patient's current health status at risk if care is transitioned from the current provider.
    1. Examples of qualifying situations may include but are not limited to:
      - The member is in their second or third trimester of pregnancy. In this case, the member will be permitted to receive continued coverage with her previously established obstetric provider for the remainder of her pregnancy through the postpartum period (six weeks after the delivery date).
      - In a course of chemotherapy or radiation therapy (initiation of a second course with a different chemotherapy agent can be transitioned to a new provider)
      - Receiving outpatient intravenous therapy for a resolving condition (e.g. antibiotics for infection) until the condition is resolved or up to 6 weeks; whichever is shorter.
      - In the process of staged surgical procedure, where the stages will be completed within 60 days.
      - Receiving Outpatient or Intensive Outpatient (IOP) treatment for chemical dependency or substance use disorders, and in the program of care for greater than 2 weeks. If approved, Transition Care may be approved for no more than 60 days.
      - Receiving Acute Residential or Partial Hospital treatment for chemical dependency or substance use disorders, and in the program of care for greater than 1 week. If approved, Transition Care may be approved for no more than 30 days.
      - Outpatient Mental Health services where time is required to transition to an in-network provider. If approved, Transition Care may be approved for no more than 3 visits within 30 days.
      - Post-operative period (no more than 90 days)
      - Inpatient hospitalization where the discharge is expected to occur in 2 days. Longer stays for medically stable patients may be transferred to a contracted facility.
      - Specialty services where time is required to transition to an in-network provider (one visit)
      - Transplant patient already listed at a non-preferred hospital, may stay until transplant occurs
      - Post acute non-operative fracture care (no more than 90 days)
  - C. Does not have one of the situations below that will be redirected to an in-network provider:
    1. Scheduled elective procedure following enrollment to a Group Health plan

2. Physical examination
3. Elective service and procedures
4. Second opinion evaluations
5. Home care services
6. Routine monitoring of a chronic condition

D. Has completed a Transition of Care request form within 30 days of enrollment in a Group Health plan (only required for new enrollees).

\* An active course of treatment is defined as a program of planned services to correct or treat a diagnosed condition for a defined number of services or treatment period until care is completed or a transfer of care with relevant clinical information required to ensure continuity can be initiated.

The above criteria do not include routine monitoring for a chronic condition.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

**Transition of Care for New Enrollees:** The criteria were developed to promote consistency in identifying the clinical situations where the practitioner may continue to provide care for a Group Health enrollee for the time required to complete the course of treatment. Group Health will assist members in planning for continued care in selected case-specific situations where the member is changing from another health plan to a Group Health plan.

**Terminated Providers:** When a practitioner is ending his/her contract with Group Health, care must be safely transitioned or transferred to another Group Health contracted or Group Health Permanente practitioner in the same or similar specialty. When the Group Health member is in an active course of treatment, the transition to a contracted or Group Health Permanente practitioner of the same or similar specialty may be delayed until treatment has been completed.

The criteria assume that the contract termination with the provider was not based on a professional review action and that the provider is remaining in the local area and is not retired.

##### For Non-Medicare Members

Medical necessity review is not required for this service.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Transmyocardial revascularization (TMR) is a new treatment modality under evaluation in patients with severely symptomatic, diffuse coronary artery disease in whom the potential for medical or interventional management has been exhausted. Patients with end-stage coronary disease have a high morbidity and mortality due to cardiac events and other preexisting diseases.

TMR uses laser ablation to create transmural channels in ischemic myocardium by placing channels or holes in the oxygen-deprived heart muscle with the goal of restoring perfusion to the areas of the heart that are not being reached by diseased or clogged arteries. Initial clinical trials of TMR in patients with chronic intractable angina have shown promising results: more than two thirds of TMR-treated patients experience an average reduction in angina symptoms and improved exercise tolerance. The exact mechanism of action for TMR is unclear, but possible explanations for favorable outcomes include mediation of direct blood flow between the left ventricular cavity and ischemic myocardium, improved perfusion by angiogenesis, an anesthetic effect by nerve destruction, and a potential placebo effect.

In August 1998, the FDA fully approved CO<sub>2</sub> laser TMR for the sole therapy of patients with class III and IV angina. HCFA has also approved this therapy for Medicare patients as of 7/1/99. The Cardiology group would like to know whether TMR might be indicated for other GHC patients as well.

#### Medical Technology Assessment Committee (MTAC)

##### Transmyocardial Laser Revascularization

###### 11/11/1998: MTAC REVIEW

**Evidence Conclusion:** The FDA approved the Heart Laser® manufactured by PLC Systems in August of 1998. Its approved indication is to treat patients with coronary artery disease who have chest pain (angina) that cannot be controlled by medication or effectively treated by Percutaneous Transluminal Balloon Angioplasty (PTCA) or other surgical methods.

The use of transmyocardial laser revascularization does not meet the *Group Health Medical Technology Assessment Criteria*.

###### 06/14/2000: MTAC REVIEW

##### Transmyocardial Laser Revascularization

**Evidence Conclusion:** TMR appears to relieve angina and may also improve exercise tolerance in patients with refractory ischemia who may not be candidates for other therapies. However, there are a number of unresolved issues from the literature, including: questionable validity of some of the RCTs, statistical significance versus clinical significance, ultimate patient group that would benefit, lack of standardization of perioperative management, potential for high rate of adverse events associated with the procedure, mechanism of action unclear, subjective outcome data. Given these uncertainties, the efficacy and safety of TMR cannot be fully determined from the evidence available so far. Larger randomized controlled trials with careful attention to patient selection and randomization, appropriate endpoints, and adverse effects (some of which are ongoing), may provide further information regarding the efficacy and safety of this procedure and the patient subgroup that is most likely to benefit from this treatment modality.

**Articles:** Articles were selected based on study type. There were five randomized controlled trials (RCTs) comparing TMR with “standard treatment” and several prospective studies. Evidence tables were created for 3 randomized controlled trials, and are attached. Reviews, editorials, and comments were reviewed, but no evidence tables were created. Schofield et al. Transmyocardial laser revascularization in patients with refractory angina: a randomized controlled trial. Lancet 1999; 353:519-24. See [Evidence Table](#). Burkoff et al. Transmyocardial laser revascularization compared with continued medical therapy for treatment of refractory angina pectoris: a prospective randomized trial. Lancet 1999; 354:885-90. See [Evidence Table](#). March et al. Transmyocardial laser revascularization with the CO<sub>2</sub> laser: one year results of a randomized controlled trial. Seminars in Thoracic and Cardiovascular Surgery 1999; 11(1):12-18. See [Evidence Table](#).

The use of transmyocardial laser revascularization does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

Treatment	Criteria Used
<b>Positive Airway Pressure Devices</b>	<p>Has one of the following indications:</p> <ol style="list-style-type: none"> <li>1) AHI of 15 events or greater per hour</li> <li>2) AHI between 5 and 15 events per hour with documented excessive daytime sleepiness, impaired cognition, mood disorders or insomnia, or documented hypertension, ischemic heart disease or history of stroke.</li> <li>3) A Sleep Apnea Clinical Score (SACS) greater than 15 and meets all of the following:               <ol style="list-style-type: none"> <li>a) Completed a baseline Stanford Sleepiness Score</li> <li>b) Completed a 3 night autotitration PAP</li> <li>c) Reported one of the following:                   <ol style="list-style-type: none"> <li>i) A positive response to initial autotitration*</li> <li>ii) A negative response to initial autotitration but has completed a polysomnography test and met either of the two initial criteria above.</li> </ol> </li> </ol> </li> </ol> <p><i>*If there is a positive response to initial autotitration, subsequent polysomnography is only covered if documentation in the medical records indicates the study is medically necessary.</i></p> <p>The AHI (Apnea-Hypopnea Index) is equal to the average number of episodes of apnea and hypopnea per hour and must be based on a minimum of 2 hours of sleep recorded by polysomnography using actual recorded hours of sleep (not projected or extrapolated).</p> <p>Apnea is defined as a cessation of airflow for at least 10 seconds. Hypopnea is defined as an abnormal respiratory event lasting at least 10 seconds with at least a 30% reduction in thoracoabdominal movement or airflow as compared to baseline, and with at least a 4% oxygen desaturation.</p> <p>Respiratory disturbance index is a term previously used for the measure to</p>

Treatment	Criteria Used
	determine eligibility for PAP. It used the same parameters as the AHI. The more current term is AHI. Because some coverage requests are received with an RDI, the definition is included to help reviewers.
<b>Hypoglossal Nerve Stimulation</b>  <b>Nasal Expiratory Positive Airway Pressure for Obstructive Sleep Apnea</b>  <b>Pillar Implants for Obstructive Sleep Apnea and Snoring</b>  <b>Oral pressure therapy (OPT) for the treatment of obstructive sleep apnea</b>	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
<b>Laser Treatments for Snoring and OSA</b>	See the <a href="#">criteria document for all laser treatments for snoring and OSA</a> .
<b>Maxillo-mandibular Advancement Surgery for Sleep Apnea</b>  <b>Geniohyoid Advancement Myotomy Combined with Hyoid Re-Suspension</b>	<p>Group Health has elected to use the Maxillomandibular Osteotomy and Advancement Surgery (A-0248) MCG* for medical necessity determinations.</p> <p><b>If requesting this service, please send the following documentation to support medical necessity:</b></p> <ul style="list-style-type: none"> <li>• For sleep related issues, please send initial sleep study and all follow up notes.</li> <li>• For congenital malformation, submit all cranial facial clinic notes (oral surgeon, ENT, Orthodontist)</li> </ul>
<b>Mandibular Advancement Devices for Treatment of Obstructive Sleep Apnea</b>	Medical Necessity review is not required for this service.

The MCG Manuals are proprietary and cannot be published and/or distributed. However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Sleep-disordered breathing includes a spectrum of disorders ranging from primary snoring to obstructive sleep apnea (OSA). Obstructive sleep apnea syndrome (OSAS) is defined as an apnea-hypopnea index of more than five events per hour, and often also has mental or physical effects such as excessive daytime sleepiness. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries and increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone.

Patients with primary snoring have an apnea-hypopnea index of fewer than five events per hour and no complaints of daytime sleepiness. Snoring is believed to be caused by loss of tissue integrity of the soft palate. Because tissues lack support, they stretch and collapse as muscles relax during sleep. This results in a narrowed airway

and causes the soft palate to vibrate, causing snoring sounds. Primary snoring can be socially disruptive but is not harmful to the health of the patient.

There has been increasing recognition of a continuum of sleep disordered breathing disorders, ranging from simple snoring to obstructive sleep apnea (OSA). OSA refers to recurrent episodes of breathing cessation during sleep due to mechanical blockage of the airway. The diagnosis of OSA requires a minimum of 30 episodes of apnea, each lasting at least 10 seconds, during 6-7 hours of sleep. OSA patients are generally obese and the cardinal symptom is excessive daytime sleepiness. Upper airway resistance syndrome (UARS), a term first used in 1993, is a form of sleep-disordered breathing that is also associated with daytime sleepiness. Patients do not meet diagnostic criteria for OSA, and are generally non-obese. Recent investigations suggest that UARS may have different pathophysiology than OSA, for example UARS patients may have increased airway collapsibility and craniofacial abnormalities. Common polysomnographic findings for UARS include apnea-hypopnea index (AHI) <5, minimum oxygen saturation >92%, increase in alpha rhythm and a relative increase in delta sleep (Bao & Guilleminault).

Continuous Positive Airway Pressure (CPAP) is widely used as first-line therapy for UARS, although there is a lack of high-grade evidence supporting its effectiveness. CPAP is also often used as a tool to diagnose UARS by seeing whether patients respond to a trial of CPAP treatment. Other treatment alternatives include oral appliances, septoplasty and radiofrequency reduction of enlarged nasal inferior turbinates. Classic surgical procedures used for OSA are considered by many clinicians to be too aggressive for treatment of UARS (Bao & Guilleminault).

Other methods of treating snoring and OSA include weight loss, nasal continuous positive airway pressure (CPAP), laser-assisted uvula palatoplasty (LAUP), uvulopalatopharyngoplasty (UPPP) and radiofrequency tissue ablation. Disadvantages of the surgical procedures are that they can be painful and are often associated with side effects. Radiofrequency ablation generally requires multiple treatment sessions.

A **CPAP** is defined as a device that provides constant air pressure to keep the airway open and allows patients to breathe unassisted. It is prescribed for patients with obstructive sleep apnea. The immediate clinical effectiveness of CPAP for patients with obstructive sleep apnea is well documented.

There are currently more than 35 different oral appliances on the market for OSA and/or snoring. The most widely used type of oral device is **mandibular advancement devices (MAD)** which act to keep the pharyngeal airspaces open by moving the mandible forward by advancing or downwardly rotating the mandible (Schoem, 2000).

**Hypoglossal nerve stimulation** is a new treatment for obstructive sleep apnea (OSA). It addresses the issue of tongue prolapse into the pharynx which causes airway blockage. Tongue prolapse may be due to decreased neuromuscular activity in the genioglossus muscle, the principal tongue protrusor muscle. Electrical stimulation of the hypoglossus muscle may result in activation of the genioglossus muscle, increasing tongue protrusion and opening the pharynx (Eisele, 1997).

A review article published in 1999 (Loube) mentioned that there is a multicenter clinical trial underway on the feasibility of a hypoglossal nerve stimulator (Inspire system; Medtronic), but that the trial has been slowed due to technical issues. The most recent entry on hypoglossal nerve stimulation on the Medtronic Web site was in 1997.

A **new nasal expiratory positive airway pressure device** (Provent® Sleep Apnea Therapy, Ventus Medical Inc.) has recently been approved by the FDA for the treatment of OSA. The Provent® Sleep Apnea Therapy device is a disposable, nightly-use device that consists of a one-way valve surrounded by a ring of soft foam. The device is placed just inside the nostrils and is held in place with adhesive. It works by limiting the airflow out of the nose during expiration, which increases pressure in the upper airway to keep it open for subsequent inspiration. During inspiration, the patient breaths freely through the nose and/or mouth (Kaiser 2010).

The **Pillar Palatal Implant System** (Restore Medical; St Paul, MN) is a treatment option for snoring and obstructive sleep apnea (OSA). Three implants made of braided polyester filaments are placed in the soft palate to help stiffen the soft palate and increase structural integrity. The implant system also includes a disposable delivery tool that is used for positioning and placement of the implant. Pillar implants are inserted during a single office visit under local anesthesia.

## Medical Technology Assessment Committee (MTAC)

### Positive Airway Pressure Device (CPAP)

#### BACKGROUND

The criteria set previously used by Group Health (from 1/1/92 through 3/96) were a direct adoption of the Medicare criteria. Changes in testing equipment have made it possible to test with greater specificity in a shorter testing period. In addition, many tests are now done using a split study, which uses half the test time for actual testing, and the other to titrate the most beneficial CPAP fit to affect the apnea previously documented. Since most of the Group Health coverage contracts include a benefit for coverage of CPAP devices at 50-80% level, the existing criteria were reviewed and modified to allow for shorter testing periods and use of the in-home testing. Throughout 1996 and 1997 with experience in managing sleep anomaly cases, a new patient population has been identified that would benefit from the use of CPAP: the Upper Airway Resistance Syndrome (UARS). Dr. Jim DeMaine requested in April 1998 that the criteria be expanded to allow use of CPAP in such cases. Although there is no clinical evidence of benefit for such treatment, there is significant expert opinion and practice that would support such a change in the criteria. In addition, Kaiser Permanente Northwest has decided to cover CPAP for UARS as long as the patient has durable medical equipment coverage (DME). While the Group Health plan criteria were modified in May 1998 to allow inclusion of UARS patients, this is not true for the private Medicare patients seen by Group Health providers. It is still important to check coverage before ordering this treatment option so that the patient understands the financial obligation represented by the treatment option selected. A CPAP is defined as a device that provides constant air pressure to keep the airway open and allows patients to breathe unassisted. It is prescribed for patients with obstructive sleep apnea. The immediate clinical effectiveness of CPAP for patients with obstructive sleep apnea is well documented. REFERENCES Fairbanks, David N.F., Fairbanks, David W.: Obstructive Sleep Apnea: Therapeutic Alternatives. American Journal of Otolaryngology. 13: 265-270, 1992. Effective treatment of Obstructive Sleep Apnea is contingent on the establishment of a correct diagnosis and the identification of pathophysiologic conditions affecting the upper airway. CPAP is a forceful stream of air delivered to the collapsible oropharyngeal airway acting as a splint to keep the airway open. Almost all OSA patients can benefit from this treatment except those with obstructed nasal airways. Short-term compliance is 90%. Long-term compliance (2-4 yr.) is 50 - 80%. Over 300 devices are patented as "anti-snore" remedies: chin strap, whip-lash type collar, psychological conditioning devices, custom made orthodontic devices, and the tongue retaining device are examples of a few. Most of these have not been proven efficacious for sleep apnea. Surgical treatments include nasal surgery (often disappointing as a solitary treatment for severe OSA), uvulopalatopharyngoplasty, UPPP (Highly effective, 80-90%, for simple snoring in young patients, but if bulky tongue, receding chin, nasal airway obstruction, or pronounced obesity exists it is less effective a single therapy), mandibulo-maxillary advancement phase 1 and 2 (97% when combined with UPPP and nasal surgery), tongue surgery (limited studies but results are promising), and tracheostomies (most successful treatment but has been almost entirely replaced by CPAP). Watson, Robert K., Thompson, A. Siobhan: Treatment Outcome of Sleep Apnea. CONN Med. 56: 125-129, 1992. 101 patients. Interviewed over 12-24 month period. CPAP most often treatment used with results of improved daytime alertness (84%). Patients with moderate OSA often had surgery which led to 85% improved daytime sleepiness, and patients with mild OSA were treated with sleep position change and weight loss with 64 - 66% improved daytime alertness. Kryger, Meir: Management of Obstructive Sleep Apnea. Clinics in Chest Medicine 13: 481-492, September 1992 Diagnosis with increased risk of death (chronic respiratory failure or obtundation) the patient should be hospitalized and monitored in ICU. Do Dx Sleep Study ASAP. O2 treatment may result in severe CO2 retention. If severe OSA Dx -- treat with urgent CPAP therapy. Mechanical ventilation recommended for patients with hypercapnea that are difficult to arouse or obtunded. BiPAP is used when all night treatment with CPAP is found to be ineffective. ATS Board of Directors: Indications and Standards for Use of Nasal Continuous Positive Airway Pressure (CPAP) in Sleep Apnea Syndromes. American Journal of Respiratory Critical Care Medicine 150: 1738-1745, 1994 Indications for CPAP: Effective in the treatment of patients with clinically important obstructive sleep apnea/hyponea syndrome. Treatment is indicated when there is documented sleep-related apnea/hyponea and evidence of clinical impairment. CPAP may be effective in the treatment of patients with clinically significant Cheyne Stokes respiration or central apnea with clinical impairment. Limited data to substantiate the later. CPAP is not routinely indicated in individuals with simple snoring that is not associated with pauses in respiration or with clinical impairment. CPAP is a safe, effective for therapy with rare contraindications. Relative contraindications include patients with bullous lung disease and recurrent sinus or ear infections. There are no absolute contraindications. Greater than 5-10 episodes of apnea or hyponea per hour is

considered beyond the board limits of normal. Strollo, Patrick J. and Rogers, Robert M.: Obstructive Sleep Apnea. The New England Journal of Medicine 334: 99-104, 1996 Affects 2-4% of middle age adults. Positive airway pressure, delivered through mask, is the initial treatment of choice in clinically important sleep apnea. The following are conditions associated with the varieties of Sleep Apnea: Obstructive Sleep Apnea: Cessation of airflow for greater than or equal to 10 seconds despite continued ventilatory effort. 5 or more episodes per hour Usually associated with a decrease of greater than or equal to 4% in oxyhemoglobin saturation. Obstructive sleep hypopnea: Decrease of 30-50% in airflow for greater than or equal to 10 seconds 15 or more episodes per hour of sleep May be associated with a decrease of greater than or equal to 4% in oxyhemoglobin saturation. Upper-airway resistance: No significant decrease in airflow (snoring is usual) 15 or more episodes of arousal per hour of sleep No significant decrease in oxyhemoglobin saturation Features Common to all three: Arousal associated with increasing ventilatory effort (as measured by esophageal balloon) Excessive daytime sleepiness Sleep 1996 Nov; 19(9 Suppl):S101-S110, Management of simple snoring, upper airway resistance syndrome, and moderate sleep apnea syndrome. Levy P, Pepin JL, Mayer P, Wuyam B, Veale D; Sleep and Respiration Unit, Grenoble University hospital, France. The spectrum of respiratory sleep disorders has been extended in the last years to include conditions that are less well defined than severe obstructive sleep apnea (OSA). Moderate OSA< snoring, and upper airway resistance syndrome (UARS) represent three clinical questions. Therefore, the therapeutic approach remains unclear. We have tried to define these entities and to review the respective indications and efficacy of pharmacological treatment, weight loss, sleep posture, oral appliances, upper airway surgery, and finally, continuous positive airway pressure (CPAP). From these data, we also aim to define strategies of treatment for moderate OSA, snoring, and UARS. However, these conditions are likely to be particularly appropriate for randomized trials comparing different modalities of treatment that may be the only way to validate these treatment strategies. Sleep 1993 Aug; 16(5):403-408, Significance and treatment of nonapneic snoring. Strollo PJ Jr, Sanders MH, Wilford Hall Medical Center, Lackland Air Force Base, Texas. Snoring has been associated with an increased risk of vascular morbidity and mortality and with the complaint of excessive daytime sleepiness. Much of this risk may be attributable to concomitant sleep apnea or hypopnea. Recent work suggests that in certain individuals, snoring without apnea or hypopnea can lead to sleep disruption. This appears to be due to augmented ventilatory effort in response to an increased "internal" resistive load that results in repetitive arousals from sleep. This condition has been termed the upper airway resistance syndrome (UARS). Identification of load-related arousals in patients with the UARS may require the addition of esophageal pressure monitoring to the diagnostic polysomnogram. Nasal continuous positive airway pressure (CPAP) effectively eliminates snoring, hypopnea and apnea and, therefore, may be useful in treating this form of sleep-disordered breathing. The diagnostic criteria and indications, if any, for chronic treatment of these nonapneic snorers with nasal CPAP as well as long-term compliance remain to be determined.

### **Sleep Apnea: Hypoglossal Nerve Stimulation**

#### **BACKGROUND**

Hypoglossal nerve stimulation is a new treatment for obstructive sleep apnea (OSA). It addresses the issue of tongue prolapse into the pharynx which causes airway blockage. Tongue prolapse may be due to decreased neuromuscular activity in the genioglossus muscle, the principal tongue protruder muscle. Electrical stimulation of the hypoglossus muscle may result in activation of the genioglossus muscle, increasing tongue protrusion and opening the pharynx (Eisele, 1997). A review article published in 1999 (Loube) mentioned that there is a multicenter clinical trial underway on the feasibility of a hypoglossal nerve stimulator (Inspire system; Medtronic), but that the trial has been slowed due to technical issues. The most recent entry on hypoglossal nerve stimulation on the Medtronic web site was in 1997.

#### **08/08/2001: MTAC REVIEW**

##### **Sleep Apnea: Hypoglossal Nerve Stimulation**

**Evidence Conclusion:** There is insufficient evidence on which to base conclusions about the effect of hypoglossal nerve stimulation on health outcomes associated with obstructive sleep apnea.

**Articles:** The search yielded 113 articles. Most of the articles were on uvulopalatopharyngoplasty or glossectomy. There was one empirical article on hypoglossal nerve stimulation. This was a small case series which included only 5 patients with sleep apnea (also included were 15 patients that were undergoing a surgical procedure involving the neck). Because of the small number of sleep apnea patients and a dearth of clinical outcomes, this study was not reviewed.

The use of hypoglossal nerve stimulation in the treatment of sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Nasal Expiratory Positive Airway Pressure for Obstructive Sleep Apnea**

#### **BACKGROUND**

Obstructive sleep apnea (OSA) is a relatively common disorder that is characterized by recurrent episodes of complete (apnea) or partial (hypopnea) upper airway obstruction during sleep, with recurrent arousals and sleep fragmentation. Patients with OSA often experience daytime sleepiness, fatigue, or poor concentration, and have signs of sleep disturbance such as snoring and restlessness. If untreated OSA is associated with an increased risk of hypertension, cardiovascular complications, diabetes, and motor vehicle accidents (Balk 2012). A new nasal expiratory positive airway pressure device (Provent® Sleep Apnea Therapy, Ventus Medical Inc.) has recently been approved by the FDA for the treatment of OSA. The Provent® Sleep Apnea Therapy device is a disposable, nightly-use device that consists of a one-way valve surrounded by a ring of soft foam. The device is placed just inside the nostrils and is held in place with adhesive. It works by limiting the airflow out of the nose during expiration, which increases pressure in the upper airway to keep it open for subsequent inspiration. During inspiration, the patient breaths freely through the nose and/or mouth (Kaiser 2010).

**10/16/2012: MTAC REVIEW**

**Nasal Expiratory Positive Airway Pressure for Obstructive Sleep Apnea**

**Evidence Conclusion:** In 2010, Kaiser reviewed the safety and efficacy of a nasal EPAP device. Based on data from two case-series, Kaiser concluded that there was insufficient evidence to determine whether the device is a medically appropriate treatment for obstructive sleep apnea (Kaiser 2010).

A recent randomized controlled trial (RCT) evaluated the safety and efficacy of a nasal EPAP device compared to a sham device in 250 subjects with newly diagnosed or previously untreated obstructive sleep apnea. Polysomnography was performed on 2 non-consecutive nights (random order: device-on, device-off) at week1 and after 3 months of treatment. Results from this study suggest that after 3 months patients using the EPAP device had significantly greater improvements in Apnea Hypoxia Index (AHI) compared to the sham group. Adherence to treatment was determined by self-report and was approximately 88% in the EPAP group and 92% in the sham group. The most common device related adverse events were: nasal congestion, nasal discomfort, dry mouth, exhalation difficulty, and discomfort with the device. There were no serious device related adverse events. This study had several limitations: power was not assessed, the intent to treat analysis did not include all randomized patients, results are not generalizable to previously treated patients, and the study was funded by the manufacturer (Berry 2011).

<b>AHI results at week 1 and month 3 (Berry 011)</b>					
	EPAP		Sham		P-value*
	Device-off	Device-on	Device-off	Device-on	
Median (25 <sup>th</sup> to 75 <sup>th</sup> quartiles)					
Week 1	13.8 (5.3 to 22.6)	5.0† (1.7 to 11.6)	11.1 (4.8 to 21.8)	11.6 (4.0 to 21.0)	<0.001
Month 3	14.4 (5.5 to 21.4)	5.6† (2.1 to 12.5)	10.2 (3.4 to 19.3)	8.3 (4.2 to 20.6)	<0.001

\*P-value (EPAP vs. Sham).

†P<0.001 EPAP device-on vs. EPAP device off.

**Conclusion:** Results from a RCT that compared the safety and efficacy of a nasal EPAP device compared to a sham device found that after 3 months of use patients using the EPAP device had significantly greater improvements in Apnea Hypoxia Index (AHI) compared to the sham group. This trial had several limitations. Additionally, the safety and efficacy of this device compared to CPAP is unknown.

**Articles:** The literature search revealed 6 studies (1 randomized controlled trial and 5 observational studies) that evaluated the safety and effectiveness of the EPAP device. Studies were excluded if they had severe methodological limitations, less than 25 subjects, or less than 30 days of follow-up. The following studies were selected for review: Berry RB, Kryger MH, Massie CA. A novel nasal expiratory airway pressure (EPAP) device for the treatment of obstructive sleep apnea: a randomized controlled trial. *Sleep*. 2011;34:497-485. See [Evidence Table](#). Kaiser Permanente. Provent Nasal Resistance Device for obstructive sleep apnea. September 2010. [http://pkc.kp.org/national/cpg/intc/topics/03\\_07\\_112.html](http://pkc.kp.org/national/cpg/intc/topics/03_07_112.html).

The use of nasal expiratory positive airway pressure for obstructive sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

**Pillar Implants for Obstructive Sleep Apnea and Snoring**

**BACKGROUND**

Sleep-disordered breathing includes a spectrum of disorders ranging from primary snoring to obstructive sleep apnea (OSA). Obstructive sleep apnea syndrome (OSAS) is defined as an apnea-hypopnea index of more than five events per hour, and often also has mental or physical effects such as excessive daytime sleepiness. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries and

increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone. Patients with primary snoring have an apnea-hypopnea index of fewer than five events per hour and no complaints of daytime sleepiness. Snoring is believed to be caused by loss of tissue integrity of the soft palate. Because tissues lack support, they stretch and collapse as muscles relax during sleep. This results in a narrowed airway and causes the soft palate to vibrate, causing snoring sounds. Primary snoring can be socially disruptive but is not harmful to the health of the patient. The Pillar Palatal Implant System (Restore Medical; St Paul, MN) is a treatment option for snoring and obstructive sleep apnea (OSA). Three implants made of braided polyester filaments are placed in the soft palate to help stiffen the soft palate and increase structural integrity. The implant system also includes a disposable delivery tool that is used for positioning and placement of the implant. Pillar implants are inserted during a single office visit under local anesthesia. Other methods of treating snoring and OSA include weight loss, nasal continuous positive airway pressure (CPAP), laser-assisted uvula palatoplasty (LAUP), uvulopalatopharyngoplasty (UPPP) and radiofrequency tissue ablation. Disadvantages of the surgical procedures are that they can be painful and are often associated with side effects. Radiofrequency ablation generally requires multiple treatment sessions. The Restore Medical Web site claims that pillar implants are cleared by the FDA for treatment of snoring and OSA. The review request noted that approval could not be confirmed on the FDA Web site.

## **12/05/2005: MTAC REVIEW**

### **Pillar Implants for Obstructive Sleep Apnea and Snoring**

**Evidence Conclusion:** *Obstructive sleep apnea:* There is no published evidence on the effect of pillar implants on health outcomes for patients with obstructive sleep apnea. *Snoring:* The only published studies on the effectiveness of pillar implants for treating primary snoring were case series. The two studies with the largest sample sizes and longest follow-up periods were reviewed. The authors of the larger study (Kuhnel et al., 2005, n=106) did not clearly list their outcome variables and may have selectively reported positive outcomes. They reported a significant decrease in daytime sleepiness and a reduction in the snoring index after treatment. The smaller study (Maurer et al., 2005, n=40) reported a significant reduction in bed-partner-reported snoring and self-reported daytime sleepiness a year after treatment. There was no significant change when recordings of snoring were evaluated—recordings were available for only half of the patients. No serious adverse effects were reported in either study. The efficacy of the intervention compared to an alternative treatment or no treatment can be evaluated.

**Articles:** *Obstructive sleep apnea:* No empirical studies were identified. The Kaiser review stated “there were no studies published in the Medline literature reporting use of palatal implant in patients with obstructive sleep apnea.” *Snoring:* No randomized controlled trials or non-randomized comparative studies were identified. There were several case series. The two largest case series, which also had the longest follow-up, were critically appraised. The articles were by a similar team of German researchers, but there does not appear to be overlap in the patients included in the two studies. The two articles critically appraised are: Kuhnel TS, Hein G, Hohenhorst W, Maurer JT. Soft palate implants: a new option for treating habitual snoring. *Eur Arch Otorhinolaryngol* 2005; 262: 277-280. See [Evidence Table](#). Maurer JT, Hein G, Verse T. Long-term results of palatal implants for primary snoring. *Otolaryngology-Head and Neck Surgery* 2005; 133: 573-578. See [Evidence Table](#).

The use of Pillar implants in the treatment of obstructive sleep apnea and snoring does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Oral pressure therapy (OPT) for the Treatment of Obstructive Sleep Apnea**

#### **BACKGROUND**

Obstructive sleep apnea (OSA) is a common medical condition that affects approximately 2-4% of middle-age men and women in the United States. It is characterized by recurrent episodes of partial or complete collapse or obstruction of the upper airways during sleep. This leads to repeated momentary cessation of breathing (apnea) or significant reductions in breathing amplitude (hypopnea) resulting in significant hypoxemia and hypercapnia. The apnea /hypopnea index (AHI) describes the total number of apnea/hypopnea episodes per hour of sleep which is usually <5 in normal individuals. AHI scores of 5-15, 15-30, and >30 categorize patients with sleep apnea as mild, moderate, and severe, respectively. OSA is often associated with loud snoring, increasing respiratory effort, intermittent arterial oxygen desaturation, observed apnea, and disrupted sleep. Other symptoms include excessive daytime sleepiness, sleep attacks, and non-restorative sleep. OSA is a serious disorder that may significantly increase morbidity and mortality. Its potential health consequences include hypertension, arrhythmia, cerebrovascular disease, neuropsychiatric problems. It may also be associated with motor vehicle accidents, as well as social and work related problems (Farid-Moayer 2013, van Zeller 2013, Badran 2014, Jordan 2014, Ward 2014). Conservative treatments for OSA include weight loss, modification of the patient's sleep position, medications to relieve nasal obstruction, as well as avoidance of evening alcohol, sleep medications, and sedatives. For those who fail these measures, night-time continuous positive airway pressure (CPAP) via nasal or face mask is the recommended standard and effective treatment for OSA. This positive airway ventilation

stabilizes the whole upper airway reduces the AHI, normalizes the oxyhemoglobin saturation, and reduces the cortical arousals associated with the apnea /hypopnea events. However, CPAP is not well tolerated by patients, is contraindicated in claustrophobic patients, and may be associated by a number of side effects. It was reported that up to 30% of OSA patients refuse CPAP treatment, and only 50% of those who accept it can tolerate its long-term use. When adherence is defined as more than 4 hours nightly use, 46-83% of patients have reported to be non-adherent (Sawyer 2011, Zeller 2013, Jordan 2014). Alternative therapies for cases who cannot tolerate or do not respond to CPAP therapy, include the use of oral and nasal appliances, surgical procedures, laser treatment, or tracheotomy when all other treatments fail. Despite the range therapeutic options available for managing OSA, there is no treatment that is both completely effective and fully tolerated by all patient (Farid-Moayer 2013, Colrain 2013). Oral pressure therapy (OPT) is a new concept for relieving airway obstruction to treat OSA. It is a novel noninvasive treatment modality that applies vacuum in the mouth to stabilize upper airway tissue in patients with OSA. The commercially available OPT system is composed of three components: an oral interface, a bedside console containing a pump, and tubing set. The oral interface is a mouthpiece that incorporates a lip seal and a connector. The pump applies continuous negative pressure to the oral interface and consists of a vacuum pump, a controller, and pressure measurement component. The tubing set connects the pump to the oral interface. The negative pressure in the oral cavity is intended to create a pressure gradient to draw the soft palate anteriorly into contact with the tongue to improve the airway flow during sleep. The patient breathes normally through the nose while sleeping, thus nasal patency to allow closed-mouth breathing is required for the use of that device (Colrain 2013, Farid-Moayer 2013). The Attune Sleep Apnea System and the Winx Sleep Therapy System (that has an additional data management software application) were approved by US Food and Drug Administration in 2012 for home use in the treatment of obstructive sleep apnea (OSA) in adults.

#### **06/16/2014: MTAC REVIEW**

##### **Oral pressure therapy (OPT) for the Treatment of Obstructive Sleep Apnea**

**Evidence Conclusion:** The published studies on the oral pressure therapy for obstructive sleep apnea were conducted by the same group of investigators who had financial ties to ApniCure the manufacturer of the device, which also funded the studies. These were only observational studies where the patients acted as their own controls. The first (Farid-Moayer et al, 2013) was a feasibility study conducted among 71 patients from a single center, and the second (ATLAST study, Colrain et al, 2013) was a larger multicenter study initially, but included only a limited number of patients in the final analysis. The authors of ATLAST described the study as a prospective, randomized, crossover study. However, as they indicated, randomization was for the “first-night order of control versus treatment”. The study did not have a control group, and OPT therapy was not compared to CPAP therapy, sham therapy, or any other treatment for OSA. The control subjects were those who underwent their baseline PSG before OPT while the treatment group had their PSG in the first treatment night. After the first night PSG, all participants received OPT for 28 days. The study included highly selected and motivated individuals with OSA, and only 14% of those who signed the consent were included in the analysis cohort. PSG was only performed at 2 nights at baseline and after 28 days of therapy. This does not allow for excluding the effect of the night to night variations in PSG or evaluating the long-term efficacy safety, or tolerability of the OPT. Conclusion: There is insufficient published evidence to date to determine the safety, efficacy, long term effect, tolerability and compliance with the oral pressure therapy for the treatment of obstructive sleep apnea.

**Articles:** The literature search for studies on oral pressure therapy for the treatment of obstructive sleep study revealed two publications for a feasibility study, and a larger observational study. All were conducted by the same group of authors. The two published feasibility studies were conducted by the same group of investigators in the same center, with similar inclusion/exclusion criteria and patient characteristics, which makes it hard to determine if there is patient overlap between the studies. The authors indicate that in one study the mouthpiece was individually customized to the subjects, while it was only selected from 10 available fits in the other. The first feasibility study and the multicenter study were critically appraised. Colrain IM, Black J, Siegel LC, Bogan RK, A multicenter evaluation of oral pressure therapy for the treatment of obstructive sleep apnea. *Sleep Med.* 2013;14:830-837. [See Evidence Table](#). Farid-Moayer M, Siegel LC, Black J. A feasibility evaluation of oral pressure therapy for the treatment of obstructive sleep apnea. *Ther Adv Respir Dis.* 2013;7:3-12. [See Evidence Table](#).

The use of Oral pressure therapy (OPT) for the treatment of obstructive sleep apnea does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **Mandibular Advancement Devices for Treatment of Obstructive Sleep Apnea**

##### **BACKGROUND**

There has been increasing recognition of a continuum of sleep disordered breathing disorders, ranging from simple snoring to obstructive sleep apnea (OSA). OSA refers to recurrent episodes of breathing cessation during sleep due to mechanical blockage of the airway. The diagnosis of OSA requires a minimum of 30 episodes of apnea, each lasting at least 10 seconds, during 6-7 hours of sleep. OSA patients are generally obese and the

cardinal symptom is excessive daytime sleepiness. Upper airway resistance syndrome (UARS), a term first used in 1993, is a form of sleep-disordered breathing that is also associated with daytime sleepiness. Patients do not meet diagnostic criteria for OSA, and are generally non-obese. Recent investigations suggest that UARS may have different pathophysiology than OSA, for example UARS patients may have increased airway collapsibility and craniofacial abnormalities. Common polysomnographic findings for UARS include Apnea-hypopnea index (AHI) <5, minimum oxygen saturation >92%, increase in alpha rhythm and a relative increase in delta sleep (Bao & Guilleminault). Continuous Positive Airway Pressure (CPAP) is widely used as first-line therapy for UARS although there is a lack of high-grade evidence supporting its effectiveness. CPAP is also often used as a tool to diagnose UARS by seeing whether patients respond to a trial of CPAP treatment. Other treatment alternatives include oral appliances, septoplasty and radiofrequency reduction of enlarged nasal inferior turbinates. Classic surgical procedures used for OSA are considered by many clinicians to be too aggressive for treatment of UARS (Bao & Guilleminault). There are currently more than 35 different oral appliances on the market for OSA and/or snoring. The most widely used type of oral device is mandibular advancement devices (MAD) which act to keep the pharyngeal airspaces open by moving the mandible forward by advancing or downwardly rotating the mandible (Schoem, 2000).

### **12/13/2000: MTAC REVIEW**

#### **Mandibular Advancement Devices for Treatment of Obstructive Sleep Apnea**

**Evidence Conclusion:** There is insufficient evidence to permit conclusions about the effect of oral appliances on health outcomes. Since there are over 35 OAs, each needs to be considered separately. Only one commercially available oral appliance (Herbst device, Bloch RCT) was evaluated in the recent studies. The Bloch RCT was subject to threats to validity including small sample size, absence of a placebo controlled-group, no washout period between treatments, short intervention period (one week per treatment) and inappropriate p-value cut-off (i.e. did not adjust for multiple comparisons). The other new RCT, Wilhelmsson, used a custom-made oral appliance rather than a commercially available device. There were no long-term data on the effectiveness of any oral device. There were also no long-term data from RCTs on potential adverse effects associated with long-term use of oral devices. A cross-sectional study (Clark) suggests that there may be a high prevalence of adverse effects; this study was not able to measure the severity of complications.

**Articles:** Since the articles reviewed for the previous MTAC evaluation, there were two new RCTs (one was a cross-over trial), one cross-sectional study examining long-term use of an oral appliance and one case series. The randomized cross-over study compared two types of oral appliances and a no-treatment control group. The other RCT compared an oral appliance with uvulopalatopharyngoplasty (UPPP). *Evidence tables were created for two RCTs and the cross-sectional study:* Bloch KE, Jinnong AI, Zhang N, Kaplan V, Stohckli PW, Russi EW. A randomized, controlled crossover trial of two oral appliances for sleep apnea treatment. *Am J Respir Crit Care Med* 2000; 162: 246-51. See [Evidence Table](#). Clark GT, Sohn JW, Hong, CN. Treating obstructive sleep apnea and snoring: Assessment of an anterior mandibular positioning device. *JADA* 2000;131: 765-771. See [Evidence Table](#). Wilhelmsson B, Tegelberg A, Walker-Engstrom ML, Ringqvist M, Andersson L, Krekmanov L, Ringqvist I. A prospective randomized study of a dental appliance compared with uvulopalatopharyngoplasty in the treatment of obstructive sleep apnea. See [Evidence Table](#).

The use of the Herbst, and Monbloc mandibular advancement devices for the treatment of obstructive sleep apnea meet the *Group Health Medical Technology Assessment Criteria*.

### **06/06/2005: MTAC REVIEW**

#### **Mandibular Advancement Devices for Treatment of Obstructive Sleep Apnea**

**Evidence Conclusion:** There was only one empirical study evaluating the safety and efficacy of MAD for UARS, a case series with 32 patients (Yoshida, 2002). The investigators created an oral device for patients diagnosed with UARS. They assessed clinical variables using polysomnography at baseline, and 14-60 days after first use of the device. The investigators found statistically significant improvement in most of the polysomnography outcomes at follow-up, including a significant reduction in daytime sleepiness according to the Epworth sleepiness scale. The study is limited by the small size and case series design—patients were not blinded and there was no comparison or control group. Improvement could have been due to the natural history of the condition or to a placebo effect. In addition, the performance of the devices may differ from other custom-made or commercially available mandibular advancement devices.

**Articles:** Only one empirical study was identified. This was a case series with 32 patients and was critically appraised: Yoshida K. Oral device therapy for the upper airway resistance syndrome patient. *J Prosthet Dent* 2002; 87: 427-30. See [Evidence Table](#).

The use of the Herbst, and Monbloc mandibular advancement devices for the treatment of upper airway resistance syndrome does not meet the *Group Health Medical Technology Assessment Criteria*.

## Maxillomandibular Advancement Surgery for Sleep Apnea

### BACKGROUND

Sleep apnea is characterized by repeated apnea or hypopnea during sleep. Apnea, which is the cessation of airflow for ten or more seconds, could be central or obstructive. If respiratory efforts persist despite cessation of airflow, the apnea is obstructive. Obstructive sleep apnea syndrome (OSAS) is defined by the presence of at least a minimum number of apneas or hypopneas per hour, and the presence of mental or physical effects or both. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries, and increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone. Methods of treating OSA include weight loss, nasal continuous positive airway pressure (CPAP), surgical or laser resection of the uvula, tonsils or soft palate, and tracheostomy when all other treatments fail. Surgical treatment approach varies and the results are affected by age, cause of obstruction, and severity of disease. The best method to of treatment remains controversial. Maxillomandibular advancement (MMA) pulls forward the anterior pharyngeal tissues attached to the maxilla, mandible, and hyoid to increase the posterior airway space. It is a currently accepted treatment for OSAS; however, its indication is unsettled and is often limited to the severe cases where other surgeries have failed.

### 08/09/2001: MTAC REVIEW

#### Maxillomandibular Advancement Surgery

**Evidence Conclusion:** Maxillomandibular advancement (MMA) may be successful, and safe for treating selected patients with OSA. However these series do not provide sufficient evidence to determine the efficacy of MMA in the treatment of obstructive sleep apnea. Case series offer the lowest grade of evidence and have several internal threats to their validity.

**Articles:** The search yielded 113 articles. Most of the articles were on uvulopalatopharyngoplasty or glossectomy. Three articles were found on maxillomandibular advancement (MMA). All three were case series, two small (n=19 and n=21), and a bigger series (n=50). *Critical appraisal was made for the following articles:* Hochban W, Brandenburg. et al. Surgical Treatment of Obstructive Sleep Apnea by Maxillomandibular Advancement. *Sleep* 1994; 17 (7): 624-629 [See Evidence Table](#). Nimkarn Y, Miles PG, Waite PD. ## Background

Stress urinary incontinence (SUI) is defined as leakage of urine during activities that cause increased abdominal pressure such as exercise or coughing in the absence of a detrusor contraction. It is the most common form of urinary incontinence in women and is estimated to affect about 6.5 million women in the United States. Current understanding is that urinary continence during stress events requires both intact supportive structures (i.e. endopelvic fascia) and functioning neurological control of the muscles of the pelvic floor and urethra (Agarwala & Liu, 2002).

Treatments for stress urinary incontinence include conservative therapies such as strengthening the pelvic floor muscles with Kegel exercises and devices such as electrical stimulation devices and pessaries. There are also medications such as estrogen and various surgical treatments.

## Medical Technology Assessment Committee (MTAC)

### *Biofeedback for the Treatment of Urinary Incontinence*

#### **BACKGROUND**

Urinary incontinence (UI), defined as the involuntary loss of urine, is a common problem affecting many women of all ages, but is more prevalent in the elderly. It is estimated that UI affects 30-60% of middle aged and older women in the community, and up to 80% of nursing home residents (Herderschee 2011, Markland 2011, Goode 2010). The main types of UI are stress incontinence (SUI), urge (or urgency) incontinence (UUI), and mixed stress and urgency incontinence (MUI). Stress urinary incontinence is the most common type and occurs in about half of incontinent women. The next most common is the mixed urinary incontinence (around 30%) followed by the urge or urgency urinary incontinence. Mixed and urge incontinence predominate in older women, while stress incontinence mainly occurs in young and middle-age women (Lipp 2011). SUI is the involuntary leakage of urine with activities that increase intra-abdominal pressure such as coughing, sneezing, lifting, or sport activities. SUI occurs as a result of a combination of intrinsic urethral sphincter muscle weakness and an anatomic defect in the urethral support, leading to insufficient closure pressure in the urethra during physical effort. The etiology of SUI is multifactorial and includes pregnancy, vaginal delivery, pelvic surgery, neurologic causes, active lifestyle, and various comorbidities. UUI is the involuntary leakage of urine accompanied by or immediately preceded by a sensation of urgency, or the sudden compelling desire to pass urine which is difficult to defer. This can be caused by an involuntary bladder contraction that overcomes the sphincter mechanism; or poor bladder compliance due to loss of the viscoelastic features of the bladder. UUI is part of the spectrum of overactive bladder. MUI is the symptom complex of involuntary leakage associate with both urgency and effort and exertion (Lipp 2011, Deng 2011, Markland 2011). Urinary incontinence is not a life-threatening condition, but has a profound negative impact on the quality of life. Symptoms of UI interfere with the performance of everyday household and social activities, and may lead to anxiety, frustration, social isolation, and depression. It is reported that UI is associated with a 30% increase in functional decline, a 2-fold increase in the risk of falls, and nursing home placement (Goode 2010, Markland 2011, Mladenovic 2011). Treatment options for urinary incontinence can be divided into conservative

measures, pharmacotherapy, and surgical interventions. Conservative treatment is usually the first-line therapy for many patients and is useful for both stress and urge incontinence. Behavioral treatments have been well studied and proved to be effective in reducing leakage by 50-80%, with 10-30% of the patients achieving continence. These interventions improve incontinence by teaching skills and helping patients change their behavior. Behavioral programs comprise multiple individualized components which may include bladder control strategies, self-monitoring (bladder diary), scheduled or prompted voiding, delayed voiding, urge suppression strategies, moderate weight loss, fluid management, caffeine reduction, pelvic floor muscle training, and /or other lifestyle changes. Behavioral treatment is most useful when the person is motivated, wants to be actively involved in therapy, can follow directions, and when there is a readily identifiable and measurable response (Markland 2011, Lipp 2011). Pelvic floor muscle training (PFMT) and exercise, also known as Kegel exercise is considered a cornerstone in behavioral treatment. PFMT is a program of repeated voluntary pelvic floor muscle contractions taught and supervised by a health care professional. These work by increasing the strength and tone of the pelvic floor muscles, which in turn increases the urethral closure force and prevents stress incontinence during an abrupt increase in intra-abdominal pressure. It is also useful for urge incontinence as the detrusor contractions can be reflexively or voluntarily inhibited by tightening the pelvic floor. The success of PFMT depends on the patient's ability to perform the exercise correctly and the motivation to actually practice it regularly. In clinical practice, PFMT is often combined by some type of feedback or biofeedback to help the woman learn how to contract the muscle, to improve the effectiveness of the contraction through modulating the performance of the learned contraction, and to encourage further exercising (Herderschee 2011, Goode 2010, Deng 2011). Feedback is defined as the return of part of the output of a system to the input in a way that affects its performance. It thus provides information on what was done, rather than what to do, i.e. the bodily sensation felt by the woman performing the contraction gives inherent feedback about the movement. Augmented feedback is a feedback with supplementary information provided e.g. verbal feedback from a clinician palpating or observing the contraction. Biofeedback (BF) is a form of augmented feedback that uses monitoring devices to display information about the operation of a bodily function that is not normally consciously controlled, to help the patient learn to control the function consciously. When performed in conjunction with Kegel exercises for the treatment of UI, specialized pressure transducers or sensors are inserted in the vagina or rectum, or placed on the perineum, and biofeedback instruments are used to reinforce correct techniques through visual and auditory cues. BF typically gives the user an auditory or visual record of the contraction or both. This can potentially be helpful and motivating women who find it difficult to identify and isolate their pelvic floor muscles. BF devices vary considerably; many of the devices used in the studies consist of air or water filled balloons that are inserted into the rectum or vagina to measure pressure. Other devices measure electrical activity (electromyography) via surface metal electrodes on vaginal or anal probes. Some devices can only be used in clinical setting because they require a health professional to set up and use the equipment, and others are very simple and portable and are designed for home use (Herderschee 2011). A typical program of biofeedback consists of 10 to 20 training sessions; 30 minutes each. Training sessions are typically performed in a quiet environment, and under the supervision of a physiotherapist or specialized nurse. Patients are instructed to use mental techniques to contract the pelvic muscles and feedback is provided for a successful contraction. This feedback may be signals such as lights, verbal praise, or other auditory or visual stimuli. The Food and Drug Administration have cleared a variety of biofeedback devices for marketing. It defines a biofeedback device as "an instrument that provides a visual or auditory signal corresponding to the status of one or more of a patient's physiological parameters) so that the patient can control voluntarily these physiological parameters."

#### **04/14/1999: MTAC REVIEW**

##### **Biofeedback for the Treatment of Urinary Incontinence**

**Evidence Conclusion:** The published scientific evidence on biofeedback consists of small-randomized trials with typically one-month follow-up. These studies reported that adding biofeedback to a trial of pelvic floor muscle exercises did not produce any incremental benefit. It was noted that there were 3 randomized controlled trials that provided good evidence that biofeedback produces no incremental improvement in urinary incontinence compared to pelvic muscle exercise alone. It was also noted that biofeedback was currently a covered service at Group Health Northwest and that this policy may undergo re-evaluation as a result of evaluating the evidence.

**Articles:** Berghmans, LCM et al, Neurology and Urodynamics, 1996;15:37-52. See [Evidence Table](#). Burns, PA et al, J. Gerontology, 1993;48 M167-M174 See [Evidence Table](#). Burton, JR, et al, J Am Geriatr Soc. 1988; 36:693-698 See [Evidence Table](#). Burgio, KL, et al. Am J Obstet Gynecol, 1986;154:58-64 See [Evidence Table](#).

Biofeedback for the treatment of stress or urge urinary incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **10/09/2002: MTAC REVIEW**

##### **Biofeedback for the Treatment of Urinary Incontinence**

**Evidence Conclusion:** The new evidence on the benefit of biofeedback compared to pelvic floor muscle exercise alone consists of one RCT and one meta-analysis, both with threatened validity. Even with their methodological limitations, neither found a significant benefit of adding biofeedback to PFM exercises. There was also an additional RCT that compared PFM exercise with biofeedback to drug treatment (Burgio) and found a greater reduction in incontinent episodes with PFM exercise. Although the Burgio study had reasonably valid methods, it did not include a group receiving PFM exercises without biofeedback, so the additive benefit of using a biofeedback device with an exercise program cannot be determined. The new evidence on biofeedback for the treatment of urinary incontinence is consistent with earlier evidence that biofeedback does not substantially add to the effectiveness of pelvic floor muscle exercise.

**Articles:** The search yielded 73 articles, many of which were review articles or opinion pieces. There was one meta-analysis of RCTs and two RCTs. One of the RCTs was published prior to 1999, but was not included in the previous review. The two RCTs and the meta-analysis were critically appraised: Weatherall M. Biofeedback or pelvic floor muscle exercises for female genuine stress incontinence: A meta-analysis of trials identified in a systematic review. *BJU Internat* 1999; 83: 1015-1016. (Some methodological information taken from: Berghmans LCM, Hendriks HJM, Bo K. Conservative treatment of stress urinary incontinence in women: a systematic review of randomized controlled trials. *Br J Urol* 1998; 82: 181-191. See [Evidence Table](#). Lacock J, Brown J, Cusack C et al. Pelvic floor reeducation for stress incontinence: comparing three methods. *Br J Commun Nurs* 2001; 6: 230-237. See [Evidence Table](#). The use of biofeedback in the treatment of urinary incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 10/17/2011: MTAC REVIEW

##### **Biofeedback for the Treatment of Urinary Incontinence**

**Evidence Conclusion:** Herderschee and colleagues' (2011) meta-analysis included 24 randomized or quasi randomized trials that compared the use of PFMT program with a form of feedback or biofeedback in women with urinary incontinence. The results of the meta-analysis indicate that women who received biofeedback were significantly more likely to report that their urinary incontinence was improved or cured compared to those who received PFMT alone. The meta-analysis had valid methodology; however, the trials included were small, some were quasi randomized, and all, but one small study, had moderate or high risk of bias. In addition, there were many variations in the regimens of biofeedback added to PFMT and women in the biofeedback or feedback group had more contact with the health providers. The overall results of the meta-analysis show that women in the biofeedback groups had statistically significant higher satisfaction and perception of improvement in symptoms compared to those in the PFMT only groups. However, the number of leak episodes indicates that the addition of biofeedback to PFMT leads to approximately one less leak every eight days. The limitations in the trials included in the analysis make it hard to determine whether the improvement was due to the intervention, bias, more contact with health providers, or other confounding factors.

**Articles:** The search revealed one recent Cochrane review of trials on feedback and biofeedback for augmenting pelvic floor muscle training in women with urinary incontinence. A number of RCTs that were included in the meta-analysis were also identified. Only the Cochrane's meta-analysis was selected for critical appraisal. Herderschee R, Hay-Smith EJ, Herbison GP, et al. Feedback or biofeedback to augment pelvic floor muscle training for urinary incontinence in women. *Cochrane Database Syst Rev*. 2011;(7):CD009252. See [Evidence Table](#).

The use of biofeedback in the treatment of urinary incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **Collagen Injections for Stress Urinary Incontinence**

##### **BACKGROUND**

Stress incontinence is one of the two common types of urinary incontinence. The primary symptom is an involuntary loss of urine during physical exertion associated with increased intra-abdominal pressure, such as with coughing, laughing or sneezing. Treatments for stress incontinence include exercises to strengthen the external urethral sphincter, mechanical devices (pessaries) to support the urinary sphincter muscles, medications such as estrogen and phenylpropanolamine (PPA) and surgery. Injection of periurethral bulking agents for stress incontinence was first described by Murless in 1938 who used a sclerosing agent, sodium morrhuate. Injectable materials are usually used for patients with incontinence due to intrinsic sphincter deficiency (ISD). Currently, the most commonly used bulking agent is collagen. Collagen, however, is biodegradable, and therefore any benefit it may provide is short-lived. According to researchers, the ideal injectable substance has not yet been developed but it would be durable yet nonimmunogenic, noncarcinogenic, nonmigratory and produce minimal inflammatory responses (Lightner; Pannek). Collagen used for treating urinary incontinence is a bovine-derived collagen gel manufactured by the Bard Company and injected sub or periurethrally via percutaneous injection. Its mechanism

of action is to increase tissue bulk in the area of the urethra until the urethra becomes closed. Multiple injections of up to 30 ml. may be injected in a single patient and up to 5 subsequent collagen treatments may be required to produce clinical improvement. A collagen implant, which is injected into the submucosal tissue of the urethra and/or the bladder neck and into the adjacent tissues of the urethra, is a prosthetic device used in the treatment of stress urinary incontinence resulting from intrinsic sphincter deficiency (ISD). ISD is a cause of stress urinary incontinence in which the urethral sphincter is unable to contract and generate sufficient resistance in the bladder, especially during stress maneuvers. Duraspere is an injectable bulking agent that is composed of pyrolytic carbon-coated beads suspended in a water based carrier gel. In September 1999 the FDA approved Durasphere. A transurethral or periurethral method of injection can be used. A potential advantage of Durasphere over collagen is that the particle size is relatively large (251 to 300 $\mu$ ) and particle migration is not believed to occur. Durasphere is also believed to not cause allergic reactions. However, recent studies have refuted that assumption.

#### **1999: MTAC REVIEW**

##### **Collagen Injections for Stress Urinary Incontinence**

**Evidence Review:** The published scientific evidence on collagen injection consists mostly of small case series with 1-2 year follow up. Several case series with good follow up in a population of women with stress incontinence reported short term benefit in 25-80% of patients which declines to 25-30% over the course of 3 years. Reported complication rates ranged from 10 to 20%. One study reports that 9% of women and 25% of men eventually required surgical intervention for their incontinence. The wide range of reported outcomes makes interpretation of the effect of collagen injection difficult. Evidence tables of the relevant published studies are presented below.

**Articles:** Swami, S et al. Collagen for female genuine stress incontinence after a minimum two year follow-up. 1997, *British Journal of Urology*, 80, 757-761 See [Evidence Table](#). Stothers, L et al. Complications of periurethral collagen for stress urinary incontinence. 1998, *J. Urol.* 159, 806-807 See [Evidence Table](#).

Collagen Injection for urinary incontinence did not pass the *Group Health Medical Technology Assessment Criteria*.

#### **2002: MTAC REVIEW**

##### **Collagen Injections for Stress Urinary Incontinence**

**Evidence Review:** The best evidence was an RCT that compared injections with Durasphere to collagen injections among women with stress urinary incontinence due to intrinsic sphincter deficiency (Lightner). The authors did not find a significant difference in effectiveness between the two treatments. In both groups, about 66% of women in the analysis had an improvement of >1 continence grade on the Stamey scale after 12 months of follow-up. There was no placebo comparison and it may be that neither collagen nor Duraspere performs better than placebo. MTAC evaluated collagen injections in 1999 and found that there was insufficient evidence of effectiveness. The validity of the Lightner study was also threatened by the high dropout rate. Only 65% of patients completed the 12-month follow-up and there was no intention to treat analysis. The other article reviewed (Pannek) was a small case series that identified two cases of particle migration three months after Duraspere injections. Additional research is needed to verify the extent of particle migration and determine any possible harms associated with this migration.

**Articles:** The search yielded 9 articles. There were two empirical articles, one RCT and one case series (n=20). Both articles were reviewed. A case series of this size (n=20) would not normally be reviewed, but this article was included because it dealt with the safety of the technology. *The following articles were critically appraised.* Lightner D, Calvosa C, Andersen R, Klimberg I, Brito CG, Snyder J. et al. A new injectable bulking agent for treatment of stress urinary incontinence: Results of a multicenter, randomized, controlled double-blind study of Durasphere. *Urology* 2001;58:12-15. See [Evidence Table](#). Pannek J, Brands FH, Senge T. Particle migration after transurethral injection of carbon coated beads for stress urinary incontinence. *J Urol* 2001;166:1350-1353. See [Evidence Table](#).

Durasphere Injection for urinary incontinence did not pass the *Group Health Medical Technology Assessment Criteria*.

#### **Extracorporeal Magnetic Innervation for Urinary Incontinence**

##### **BACKGROUND**

Extra-corporeal magnetic innervation therapy (approved by the FDA in June 1998) is a technology designed to treat stress urinary incontinence. Extra-corporeal magnetic innervation therapy is a technology that has been developed to provide conservative therapy for stress urinary incontinence by creating a magnetic field and the induction of electrical activity to de-polarize the nerves and exercise the muscles of the pelvic floor. The technology provides a potential alternative to surgical treatment for incontinence. It provides an additional option to conservative therapies such as fluid restriction, medical management, timed voiding, Kegel exercises, biofeedback and electrical stimulation. Its promoters state that this technology will prove more attractive to patients than electrical stimulation because patches or probes, skin contact or gel, and undressing for treatment are not

necessary. Patients are positioned in a special chair provided with a cushion containing a magnetic field generator which is powered and controlled by an external power unit. The output of the power unit consists of pulses of current at 275 microseconds in duration and which can be adjusted in amplitude by the clinician. Treatment involves approximately ten minutes of intermittent low frequency stimulation (5 Hz) followed by a rest interval of 1-5 minutes and then ten minutes of intermittent high frequency stimulation (50 Hz). Treatments are given twice a week for six weeks. The FDA has approved this as Class II device requiring a physician's prescription and administration.

#### **02/06/2000: MTAC REVIEW**

##### **Extracorporeal Magnetic Innervation for Urinary Incontinence**

**Evidence Conclusion:** Although extracorporeal magnetic innervation therapy has FDA approval, there is insufficient scientific evidence to permit conclusions regarding the effects of this technology on health outcomes. This study is a cohort study without a control group and therefore lacks the validity of a randomized control trial. Validity of the before and after results are threatened by the drop-out or lack of follow-up of 14 patients in the original group. Validity is also threatened by the likelihood of co-interventions such as advice regarding voiding and fluid management. The possibility of a placebo effect is real.

Observation bias is likely in this study (e.g., the investigators received payment from the manufacturer).

**Articles:** Four articles were located using Medline (OVID). Articles were sorted on the basis of study type. One case series of seven male patients was rejected because the population was limited to males with spinal cord injury. A second study was eliminated because the 12 patients underwent saline infusion into the bladder followed by magnetic stimulation of S3. A third study was excluded because it reviewed literature dealing with urethral pressure in anesthetized dogs. Gallaway NT, El-Galley RE, Sand PK et al. Extracorporeal magnetic innervation therapy for stress urinary incontinence. *Urology*. 53 (6): 1108-11, 1999 June. See [Evidence Table](#).

The use of extracorporeal magnetic innervation for the treatment of stress urinary incontinence has been approved by the FDA and therefore meets *Group Health Medical Technology Assessment Criteria*.

#### **Intravaginal Electrical Stimulation for Urinary Incontinence**

##### **BACKGROUND**

Urinary incontinence (UI), the accidental release of urine, affects up to 30 million women in the United States. Most symptoms of UI will fall into two different categories. The first, stress incontinence, is characterized by the involuntary loss of urine occurring after exerting some force on the bladder through physical activities such as coughing, sneezing, laughing, exercising or lifting. Urge incontinence, on the other hand, causes urine leakage due to bladder spasms or untimely contractions. Symptoms of both stress and urge incontinence may be experienced at the same time and is most often referred to as mixed incontinence. While some causes of UI can be attributed to medications or urinary tract infection and may improve after treating the cause, in most cases of urinary incontinence, the cause is difficult to target. In any case, urinary incontinence is embarrassing and uncomfortable and can severely disrupt the quality of life. Pelvic floor muscle training (PFMT) is considered first line treatment for UI and is aimed to target the pelvic musculature. It is a noninvasive education and exercise program that involves repeated voluntary contraction of the pelvic floor musculature building strength, endurance and coordination. Biofeedback is often included in PFMT in an effort to promote adherence and efficiency through the contraction and timing of the correct muscles. Biofeedback is also used to assess improvement over time (Berghmans, Hendriks et al. 1998; Domoulin and Hay-Smith 2010). In the same way, intravaginal electrical stimulation (IVES) also targets the pelvic musculature by sending a mild electric current intended to trigger muscle contraction and, consequently, a strengthening effect similar to that of PFMT. It has also been hypothesized that the electrical stimulation encourages growth of nerve cells that cause the muscles to contract (Schreiner, Santos et al. 2013). In any case, the technology is designed to be used at-home for acute and on-going treatment. With a variety of devices on the market, the technology, in its simplest form, consists of a unit with built in surface electrodes that can be temporarily inserted into the vagina. Most of the devices also come with a hand-held controller allowing the regulation of current and duration. Several IVES devices have been approved by the U.S. Food and Drug Administration (FDA) as class II devices under the non-implanted electrical continence device classification.

#### **04/21/2014: MTAC REVIEW**

##### **Intravaginal Electrical Stimulation for Urinary Incontinence**

**Evidence Conclusion:** In 1996, Smith randomized 18 women with genuine stress urinary incontinence to either PFMT or IVES. After at least 16 weeks of treatment, 44% of the patients in the PFMT group showed objective improvement with one patient reported as cured, three with improvement and the remaining five with no significant improvement. In the IVES group, however, there was 66% improvement with two cured patients, four with improvement and three failures. Smith concludes that the device is safe, however, there was no discussion or reports of either how safety was measured or if data on adverse events were routinely collected. In addition, Smith

concludes that IVES is at least as effective as PFMT, however, the total number of patients in the group was small and not statistically significant (Smith 1996). [\[Evidence Table 1\]](#) In an attempt to assess the effectiveness of physiotherapeutic treatment modalities in women with proven urge urinary incontinence Berghmans and colleagues randomized 68 patients to one of four treatment arms. With one control group of patients receiving no treatment, the remainder of the groups received IVES, PFMT or both. The primary outcome measure, the DAI, is a combined parameter that quantifies bladder over activity using a score between 0 and 1 where '0' represents no activity and '1' represents severe over activity. Ultimately, the investigators concluded that IVES was the only effective treatment for urge urinary incontinence, with a 0.28 difference in DAI score between pre- and post-treatment, but this conclusion is prone to bias as the intended sample size was 80 and only 68 patients were included in the ITT analysis (Berghmans, van Waalwijk van Doorn et al. 2002). [\[Evidence Table 2\]](#). IVES treatment was compared to PFMT in a trial including 35 women aged 65 or older. The control group was given verbal instruction on how to perform Kegel exercises while the IVES group received maximal IVES for 30 minutes three times a week. With several objective and subjective outcomes being measured the authors make several conclusions regarding treatment with IVES of one of which claims high physical and emotional cost for the treated individuals. It is unclear how they came to this conclusion as there is no mention of any kind of QoL questionnaires nor was there systematic collection of adverse effects. In terms of the effectiveness of the IVES device, the authors report no significant improvement in objective outcomes and deem it unreasonable to advise elderly women to undertake this treatment (Spruijt, Vierhout et al. 2003). [\[Evidence Table 3\]](#). Limitations of the reviewed evidence include small study populations which limit the ability to rule out the role of chance as an explanation of findings and short follow-up times, which limit conclusions regarding the durability of any treatment effects. Data on adverse events and outcomes were not systematically collected in any of the selected studies. Any benefit observed in the urge and stress urinary incontinence studies do not appear to be superior to less invasive treatments such as PMFT. In general, the studies are significantly heterogeneous in their methodology and follow up and suffer from variation in stimulation parameters. Ultimately, there is no clear demonstration that IVES results in improved health outcomes in patients in the long run.

Conclusion: There is insufficient evidence to support the treatment of mixed urinary incontinence with IVES. There is insufficient evidence to support the treatment of stress urinary incontinence with IVES. There is insufficient evidence to support the treatment of urge urinary incontinence with IVES. There is insufficient evidence to support the safety of IVES in females with urinary incontinence.

**Articles:** The search initially revealed over 700 publications related to urinary incontinence. Articles were screened for comparison studies investigating intravaginal electrical stimulation (IVES) treatment for incontinent females after which the literature was narrowed down to 21 randomized controlled trials (RCTs) summarized in tables 1, 2 and 3. The studies varied in the treatment of urinary incontinence ranging from stress urinary incontinence, to urge and mixed urinary incontinence and none were powered to determine equivalence. In addition, IVES treatment was compared to several different treatment options including various nonpharmacologic, pharmacologic and surgical. Studies that compared IVES to PFMT were selected for critical appraisal. The following studies were selected for review: Smith, JJ. Intravaginal stimulation randomized trial. *The Journal of Urology*. 1996;155:127-130 [Evidence Table 1](#). Berghmans B, van Waalwijk van Doorn E, Nieman F, et al. Efficacy of physical therapeutic modalities in women with proven bladder overactivity. *European Urology*. 2002;41:581-587 [Evidence Table 2](#). Spruijt J, Vierhout M, Verstraeten R, et al. Vaginal electrical stimulation of the pelvic floor: a randomized feasibility study in urinary incontinent elderly women. *Acta Obstet Gynecol Scand*. 2003;82:1043-1048 [Evidence Table 3](#).

The use of IVES does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Radiofrequency Bladder Neck Suspension / Transurethral Radiofrequency Energy Tissue Remodeling for Treatment of Stress Urinary Incontinence (TRETTSUI)**

#### **BACKGROUND**

Urinary incontinence is a common symptom that affects women of all ages. Stress urinary incontinence is one of the most common types of urinary incontinence and is defined as the involuntary leakage of urine on exertion, sneezing, or coughing. Risk factors for stress urinary incontinence include obesity, pregnancy, and childbirth (Deng 2011, Rogers 2008). Treatment options for stress urinary incontinence include conservative measures, pharmacotherapy, and surgical interventions. Conservation treatments such as weight loss, pelvic floor muscles exercise (also known as Kegel exercises), as well as other behavioral and lifestyle modifications are the first-lines of treatment for stress urinary incontinence. Duloxetine, a combined serotonin and norepinephrine reuptake inhibitor, has shown some efficacy for the treatment of stress urinary incontinence; however, it failed to obtain FDA approval due to concerns for liver toxicity and suicidal events. Currently, there are no FDA approved drug therapies for stress urinary incontinence. Surgical therapy is indicated for patients who have not responded to conservative treatment options. Surgical interventions include retropubic colposuspension (Burch suspension), midurethral or bladder neck slings, injection of urethral bulking agents, and tension-free vaginal tape (Deng 2011, Rogers 2008). Transurethral radiofrequency micro-remodeling has been proposed as a minimally invasive treatment for stress incontinence among women who fail conservative therapies. In this procedure, controlled, low-

level radiofrequency energy results in localized collagen denaturation. This leads to reduced regional dynamic tissue compliance without creating stricture or reducing luminal caliber (Appell 2008, Elser 2009). Another radiofrequency treatment for stress urinary incontinence is transvaginal radiofrequency bladder neck suspension. This approach differs from the transurethral procedure in two ways. First, the transvaginal procedure is a surgical procedure whereas the transurethral procedure is a non-surgical procedure that does not require an incision. Second, higher levels of radiofrequency energy are used in the transvaginal procedure. These higher levels of energy result in higher temperatures which causes tissue necrosis instead of collagen denaturation to reduce involuntary urinary leakage (Appell 2008).

#### **08/13/2003: MTAC REVIEW**

##### **Radiofrequency Bladder Neck Suspension / Transurethral Radiofrequency Energy Tissue Remodeling for Treatment of Stress Urinary Incontinence (TRETTSUI)**

**Evidence Conclusion:** The best available evidence on TRETTSUI is in case series reports, the weakest study design due to the potential for selection and observation bias and lack of a control or comparison group. The case series articles on the SURx laparoscopic and transvaginal systems suggest a substantial decrease in incontinence episodes 12 months after the procedure compared to baseline. In addition to type of study design, these studies are limited by the strong financial links between the authors and the SURx company, which could bias the design, analysis and/or reporting of results.

**Articles:** The Medline search yielded 4 articles. There were no randomized or non-randomized controlled trials. There was one case series on the SURx Transvaginal system that was critically appraised. In addition, there were two publications using the SURx Laparoscopic system that reported on the same series of patients. These two articles were critically appraised in the same evidence table. No published studies on the Novasys product were identified. SURx Transvaginal study: Dmochowski RR, Avon M, Ross J et al. Transvaginal radiofrequency treatment of the endopelvic fascia: A prospective evaluation for the treatment of genuine stress urinary incontinence. *J Urol* 2003; 169: 1028-1032. See [Evidence Table](#). SURx Laparoscopic study: Fulmer BR, Sakamoto K, Turk TM et al. Acute and long-term outcomes of radiofrequency bladder neck suspension. *J Urol* 2002; 167: 141-145. Ross JW, Galen DI, Abbott K. et al. A prospective multisite study of radiofrequency bipolar energy for treatment of genuine stress incontinence. *J Am Assoc Gynecol Laparosc* 2002; 9: 493-499. See [Evidence Table](#).

The use of Transurethral Radiofrequency Energy Tissue Remodeling in the treatment of Stress Urinary Incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **06/20/2011: MTAC REVIEW**

##### **Radiofrequency Bladder Neck Suspension / Transurethral Radiofrequency Energy Tissue Remodeling for Treatment of Stress Urinary Incontinence (TRETTSUI)**

**Evidence Conclusion:** A randomized controlled trial that included 173 women evaluated the safety and efficacy of transurethral radiofrequency micro-remodeling for the treatment of female stress urinary incontinence compared to sham treatment. There were two primary outcomes for this study – quality of life and leak pressure point (LPP). An improvement in quality of life was defined as a 10 point or greater increase on the Incontinence Quality of Life (I-QOL) score. After 12 months of follow-up, 48% of subjects in the intervention group and 44% in the control group experienced an improvement in quality of life (P=0.07). However, in patients with moderate to severe stress urinary incontinence (I-QOL score of 0 to 60 points), 74% of subjects in the intervention group compared to 50% in the control group experienced an improvement in quality of life (P=0.03). There was no significant difference in the percent of subjects with mild stress urinary incontinence (I-QOL score of 61 to 90 points) who experienced an improvement in quality of life (intervention=22% vs. control=35%, P=0.02). Women in the intervention group experienced an increase in LPP at 12 months ( $13.2 \pm 39.2$  cmH<sub>2</sub>O), while women in the control group experienced a decrease in LPP ( $-2.0 \pm 33.8$  cmH<sub>2</sub>O) (P=0.02). There was no significant difference in adverse events between the two treatment groups. The most commonly reported adverse events were wet overactive bladder and dysuria (Appell 2006). This trial had several methodological limitations: an intent-to-treat analysis was not performed; it is not clear if the investigators were blinded; power was not assessed; and it is not stated if the subgroup analyses were planned. An interim analysis from a prospective case-series that included 139 women with stress urinary incontinence who had failed conservative treatments and had not undergone surgery or bulking agent treatment also evaluated the safety and long-term efficacy of transurethral radiofrequency micro-remodeling for the treatment of female stress urinary incontinence. After 18 months, patients experienced significant reductions in the median number of leaks per day ( $-0.43$ , range  $-34.3$  to  $18.9$ , P=0.006) and per week ( $-3.0$  range  $-240.0$  to  $132.0$ , P=0.006) compared to baseline. Additionally, 46.7% of patients had at least 50% fewer leaks (P<0.0001) compared to baseline. With regard to quality of life, 65 patients (47.8%) experienced at least a 10 point improvement in I-QOL score. During the first three days post-treatment, the most common adverse events were dysuria (N=7, 5.2%), urinary retention (N=6, 4.4%), post-procedure pain (N=4, 2.9%), and urinary tract infection (N=4, 2.9%). At 12 months, one patient reported an increase in leakage, which was probably treatment related.

Between 12 and 18 months one patient experienced a myocardial infarction, which was determined to be unrelated to the treatment (Elser 2009). Results from this study should be interpreted with caution as this study is a case-series and therefore more prone to bias. Additionally, 73 subjects (53%) discontinued the study for various reasons. **Conclusion:** Transurethral radiofrequency micro-remodeling: Results from a randomized controlled trial with several methodological limitations suggest that transurethral radiofrequency micro-remodeling may be safe and effective for the treatment of female stress urinary incontinence. More studies are needed to address the durability of the effect and whether women who undergo transurethral radiofrequency micro-remodeling can subsequently undergo other procedures such as retropubic colposuspension (Burch suspension) or tension-free vaginal tape without undo complications. Transvaginal radiofrequency bladder neck suspension: There is insufficient information to determine the safety and efficacy of transvaginal radiofrequency bladder neck suspension for the treatment of female stress urinary incontinence.

**Articles:** *Assessment objective* To determine the safety and efficacy of transurethral radiofrequency micro-remodeling for the treatment of stress urinary incontinence. To determine the safety and efficacy of transvaginal radiofrequency bladder neck suspension for the treatment of stress urinary incontinence. Only one randomized controlled trial was identified that evaluated the safety and efficacy of transurethral radiofrequency micro-remodeling for the treatment of stress urinary incontinence. It was selected for review. Since the 2003 MTAC review, two retrospective cohort studies were identified that evaluated transvaginal radiofrequency bladder neck suspension for the treatment of stress urinary incontinence. As both of these studies included less than 25 participants, neither of them were selected for review (Buchsbaum 2007, Ismail 2008). The following study was critically appraised: Appell RA, Juma S, Wells WG, et al. Transurethral radiofrequency energy collagen micro-remodeling for the treatment of female stress urinary incontinence. *Neurourol Urodyn* 2006; 25: 331-336. See [Evidence Table](#).

The use of Transurethral Radiofrequency Energy Tissue Remodeling in the treatment of Stress Urinary Incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of transvaginal radiofrequency bladder neck suspension in the treatment of Stress Urinary Incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

### **SPARC® Sling for Treatment of Urinary Incontinence**

#### **BACKGROUND**

Stress urinary incontinence (SUI) is defined as leakage of urine during activities that cause increased abdominal pressure such as exercise or coughing in the absence of a detrusor contraction. It is the most common form of urinary incontinence in women and is estimated to affect about 6.5 million women in the United States. Current understanding is that urinary continence during stress events requires both intact supportive structures (i.e. endopelvic fascia) and functioning neurological control of the muscles of the pelvic floor and urethra (Agarwala & Liu, 2002). Treatments for stress urinary incontinence include conservative therapies such as strengthening the pelvic floor muscles with Kegel exercises and devices such as electrical stimulation devices and pessaries. There are also medications such as estrogen and various surgical treatments. Surgical procedures for stress incontinence attempt to provide support to the bladder neck and/or urethra to limit the movement of these structures. Sling procedures are a surgical option for treating common stress urinary incontinence secondary to intrinsic sphincteric deficiency and urethral hypermobility. The sling procedure involves using abdominal fasci, cadaveric fasci or polypropylene mesh as sling material. The piece of muscle fiber or synthetic material is attached under the urethra and bladder neck and secured to the abdominal wall and pelvic bone. When the patient's abdominal fasci is used, an abdominal incision is required. Synthetic slings are generally inserted through a vaginal approach. Newer sling procedures include SPARC and tension-free vaginal tape (TVT). Both procedures place the sling under the urethra without tension that is intended to minimize disruption of normal urethral mobility. In addition, both use a sling made of loosely woven polypropylene mesh, require a relatively short operating time and can be performed under local anesthesia with sedation (Staskin & Plzak, 2002). The SPARC system differs from TVT in the way in which the sling is placed under the urethra. TVT passes the sling anchoring trocars from below, using a rigid catheter guide. In contrast, SPARC uses small diameter needles that are passed from above through two small suprapubic incisions". In addition, unlike TVT, the SPARC mesh has a knotted "tensioning suture" that allows adjustment of the sling (Staskin & Plzak, 2002).

#### **08/13/2003: MTAC REVIEW**

#### **SPARC® Sling for Treatment of Urinary Incontinence**

**Evidence Conclusion:** There is insufficient evidence to determine the effectiveness of the SPARC sling for the treatment of stress urinary incontinence in women. The single published empirical study reports only on 4 patients who experienced vaginal erosion after the SPARC procedure.

**Articles:** The search yielded 27 articles. Most of these were on related procedures such as tension-free vaginal tape. There was one empirical article on SPARC. This was a case series that presented data on 4 patients who

experienced vaginal erosion of the mesh after the sling procedure. Due to the small sample size and the lack of data on the patients in the series who did not experience vaginal erosion, this study was not critically appraised.

The use of SPARC Sling in the treatment of urinary incontinence does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Urgent PC Neuromodulation System for Overactive Bladder; Percutaneous Tibial Nerve Stimulation (PTNS) BACKGROUND**

Overactive bladder (OAB) is defined by the International Continence Society as the presence of urinary urgency with or without urge incontinence that is usually accompanied by frequency and nocturia, in the absence of urinary tract infection or other obvious pathology. Urgency, the hallmark of OAB, is defined as the sudden compelling desire to urinate, a sensation that is difficult to defer. Urinary frequency is defined as voiding 8 or more times in a 24-hour period. Nocturia is defined as the need to wake up one or more times per night to void. The National Overactive Bladder Evaluation (NOBLE) epidemiologic study estimated that 16.9% of adult women in the US had OAB syndrome; 9.3% with incontinence, and 7.6% without incontinence (Abrams 2002, Stewart 2003, Martinson 2013). OAB is not a disease but a symptom complex that is generally not life-threatening, but has a significant impact on the quality of life, sleep, work productivity, social relationships, mental health, sexual and physical activity. Treatment options for overactive bladder can be divided into 1. Conservative measures as behavioral interventions and pharmacotherapy, and 2. More invasive procedures. Most treatments may improve patient symptoms but are unlikely to eliminate all symptoms. A successful treatment requires a participant who is motivated and well informed about the variable and chronic course of the condition. The first line treatment of OAB is typically behavioral interventions, which consist of bladder training, bladder control, pelvic floor muscle exercises, fluid management, and weight loss. Behavioral interventions may not eliminate all symptoms but lead to significant reductions of symptoms and improve the quality of life of most patients. Pharmacological therapy may be used in combination with behavioral intervention or as a second line treatment. Antimuscarinic drugs or anticholinergics lead to significant improvement in the patient symptoms but are commonly associated with side effects as dry mouth, blurred vision, urinary retention and infection, dyspepsia, and impaired cognitive function. Patients who fail behavioral and pharmacological therapy, who do not tolerate its side effects, or are not candidates for conservative therapy and still have bothersome symptoms, may be offered alternative invasive measures. These include invasive surgical procedures e.g. bladder denervation, detrusor myomectomy, urinary diversion, bladder augmentation, neobladder construction, and others. Surgical procedures have variable cure rates and adverse events. Other less invasive options include detrusor injection with botulinum toxin (BTX), and pelvic neuromodulation therapy (Ridout 2010, Peters 2009, 2010, 2012, Gormley 2012). Pelvic neuromodulation utilizes electrical stimulation to target specific nerves in the sacral plexus that control the pelvic floor and bladder functions. Neuromodulation is either invasive using implantable sacral nerve stimulation (SNS), or minimally or noninvasive using a removable device such as transvaginal or transanal electrostimulation, magnetic stimulation, or percutaneous tibial nerve stimulation (PTNS). The specific mechanism of action is unknown, but it is thought that neuromodulation may have a direct effect on the bladder or a central effect on the micturition centers in the brain. Neuromodulation of the sacral nerve, also known as pacemaker for the bladder, uses mild electrical pulse to activate or inhibit neural reflexes by continuously stimulating the sacral nerves that innervate the pelvic floor and lower urinary tract. A unilateral lead is implanted in the vicinity of S3 nerve root and attached to a small pacemaker placed within a subdermal pocket in the buttock region. SNS therapy was found to be effective for refractory OAB, but is invasive and associated with adverse events related to the implant procedure, the presence of the implant, or due to undesirable stimulation. In addition, SNS requires reoperation to replace the implantable generator due to the limited longevity of the neurostimulator. The SNS technology continues to evolve (Peters 2009, 2010, 2012, Al-Shaiji 2011, Mossdoeff-Steinhauser 2013). PTNS, also known as Stoller afferent nerve stimulation (SANS), developed by Stoller in the late 1990s, is a form of peripheral neuromodulation. It is a minimally invasive, office-based procedure that involves percutaneous insertion of a fine (34-gauge) needle at the level of the posterior tibial nerve, slightly above the medial malleolus of the ankle (the insertion point for the needle corresponds with an acupuncture point used for a variety of urinary disorders). The needle is connected to a low voltage (6V) stimulator device with 0-10mA at a fixed frequency of 20Hz. The amplitude is increased until the toes are seen to fan or the big toe to flex. The current is set at the highest tolerated level and the stimulation is continued for 30 minutes. Neuromodulation to the pelvic floor is delivered through the S2-S4 junction of the sacral nerve plexus through the posterior tibial nerve. During the initial therapy, treatment is delivered for 30 minutes and repeated weekly for 12 weeks. OAB is a chronic disease and patients who respond to PTNS may need to receive long-term therapy in order to sustain the benefit of PTNS therapy (Peters 2009, Shaiji 2011, Burton 2012, Martinson 2013, Mossdoeff-Steinhauser 2013).

PTNS was approved by the FDA in 2000 as an office-based therapy for OAB.

## **10/01/2007: MTAC REVIEW**

## **Urgent PC Neuromodulation System for Overactive Bladder; Percutaneous Tibial Nerve Stimulation (PTNS)**

**Evidence Conclusion:** There is insufficient evidence to determine the safety and efficacy of percutaneous tibial nerve stimulation (PTNS) for treating urinary urgency, urinary frequency and urge incontinence. No published randomized or non-randomized controlled trials were identified. This is particularly problematic because there is known to be a high placebo effect in studies evaluating treatments for urinary incontinence. Only case series were available. A team based in the Netherlands published several case series that used either the Urgent PC Neuromodulation System (Uroplasty) or a precursor of this device. The studies were conducted before FDA approval. Results of the case series on the Urgent PC were similar. Vandoninck et al. (2003), for example, reported a substantial reduction in incontinence episodes and voiding frequency at the end of treatment among patients for whom data were available. Two other case series were evaluated. Both of these utilized the PerQ Sans (UroSurge), a device similar to the Urgent PC. It is not known whether the PerQ Sans is currently commercially available in the U.S. The Ruiz (2004) and Govier (2001) case series found significant improvement in urinary incontinence symptoms. One study was conducted in the United States; two of the five authors in the U.S. study reported financial relationships with the device manufacturer. Other limitations of the case series include missing data and lack of long-term follow-up.

**Articles:** The ideal study is a randomized controlled trial comparing PTNS to a placebo and/or alternative established intervention. No randomized controlled trials or non-randomized comparison studies were identified. The search yielded only case series. Sample sizes ranged from 11 to 132, most were in the range of 35 to 55 patients. Seven out of the 10 case series identified were conducted by the same research group in the Netherlands. The articles differed on the indications for treatment (urge incontinence, overactive bladder syndrome, etc.) and the outcomes reported. The largest case series from the Netherlands team, and two other case series (one conducted in Spain, the other in the U.S.) were critically appraised. The remaining case series was excluded because they did not report clinical outcomes. A news release from Uroplasty in July, 2006 stated that the company is initiating a randomized controlled trial comparing Urgent PC to anticholinergic medication for patients with symptoms of urge incontinence and urgency and frequency. The announcement did not report the expected date of study completion. *The studies critically appraised in evidence tables are:*

Vandoninck V, van Balken MR, Agro EF et al. Percutaneous tibial nerve stimulation in the treatment of overactive bladder: Urodynamic data. *Neurol Urodynam* 2003; 22: 227-232. See [Evidence Table](#). Ruiz BC, Outeirino P, Martinez PC et al. Peripheral afferent nerve stimulation for treatment of urinary tract irritative symptoms. *Eur Urol* 2004; 45: 65-67. See [Evidence Table](#). Govier FE, Litwiller S, Nitti V et al. Percutaneous afferent neuromodulation for the refractory overactive bladder: Results of a multicenter study. *J Urol* 2001; 165: 1193-1198. See [Evidence Table](#).

The use of Percutaneous Tibial Nerve Stimulation in the treatment of overactive bladder does not meet the *Group Health Medical Technology Assessment Criteria*.

### **04/15/2013: MTAC REVIEW**

## **Urgent PC Neuromodulation System for Overactive Bladder; Percutaneous Tibial Nerve Stimulation (PTNS)**

**Evidence Conclusion:** The larger published randomized controlled trials on the use of PTNS for overactive bladder syndrome were mainly supported by the manufacturer of the PTNS system, and conducted by the same group of researchers who had financial interest and/or other relationships with the manufacture. PTNS was compared either to sham therapy or to antimuscarinic drugs. No comparisons were made versus behavioral therapy or other methods of neuromodulation as sacral nerve stimulation. There were variations between published studies in the inclusion criteria, gender, severity and duration of symptoms, previous treatments, treatment protocol, number of sessions per week during therapy, and treatment intervals during maintenance therapy. Outcome measures were mainly subjective and based on reported patient diaries. No well-conducted trials with long term follow-up and objective urodynamic outcomes were identified. Definition of response or treatment success varied between studies. Burton et al (2012), meta-analysis of randomized and prospective trials showed that the success rate varied from 37-82%. Two of the published RCTs (ORBIT and SUMiT) were followed by reports on mid-term follow-up (12 months for ORBIT and up to 36 months for SUMiT), but only the responders to PTNS (60-70% of those receiving the PTNS therapy) were included in the follow-up studies. Studies showed that OAB symptoms worsen after discontinuation of treatment, and that maintenance therapy, is needed to avoid recurrence of symptoms.

### **Comparison of PTNS vs. Sham therapy**

Peters and colleagues (2010) compared the efficacy of PTNS to sham therapy in 220 adult men and women with OAB (SUMiT trial, evidence table 1). The results showed a statistically significant improvement in bladder symptoms in the PTNS group compared to sham therapy group, with some non-serious adverse events. However, only just over half the patients ( 54.5%) who received the PTNS therapy showed moderate or marked response to

the therapy, almost two third of the patients still had urinary urge incontinence after 12 weeks of PTNS, and more than half still complained of urinary urgency and frequency.

*13 weeks results of the two arms of the SUmIT trial*

	PTNS n=110		Sham n=110		P value
	N	%	N	%	
<b>Global response assessment (GRA) improvement</b>					
Overall bladder symptoms*	60	54.5	23	20.9	<0.001
Urinary urgency	44	42.7	24	22.9	0.003
Urinary frequency	49	47.6	23	21.9	<0.001
Urinary urge incontinence	39	37.9	23	22.1	0.02

In another sham-controlled, but small and single-blinded trial, Finazzi-Agro and colleagues (2010) randomized 35 women with OAB who did not respond to antimuscarinic therapy to receive PTNS or a sham therapy for 12 sessions. The sessions were performed for 30 minutes three times weekly. Patients with a 50% or greater reduction in urge incontinence episodes were considered responders. The primary outcome was the percent of responders in the two groups. The results of the trial showed that 12/17 (71%) of the patients randomized to PTNS reported a 50% or greater reduction in incontinence episodes compared to none of those in the sham therapy. Improvement in the number of incontinence episodes, number of voids, voided volume, and incontinence quality of life score were statistically significant in the PTNS group but not in the sham therapy group. The results were as follows:

*Baseline values and outcomes after 12 sessions of therapy in the two groups*

Outcomes	PTNS N=18	Placebo N=17	P value
Responders, number (%)	12/17 (71%)	0/15 (0%)	<0.001
incontinence episodes/3days; mean (range)			
Before therapy	4.1 (3.3-5.2)	4.2 (3.2-5.2)	
After therapy	1.8 (1.2-2.2)	3.8 (3.0-4.5)	
P value	<0.001	0.394	
Micturitions /day, mean (range)			
Before therapy	13.6 (11.7-15.5)	14.7 (11.9-17.4)	
After therapy	9.5 (8.4-10.7)	13.9 (11.3-16.5)	
P value	<0.001	0.960	
Volume voided in ml mean, (range)			
Before therapy	150.5 (126.8-174.3)	146.0 (121.0-171.1)	
After therapy	186.5 (160.9-212.0)	150.4 (125.8-175.1)	
P value	<0.001	0.879	
QoL score, mean ( range)			
Before therapy	69.6 (65.8-73.3)	69.5 (65.5-73.5)	
After therapy	81.3 (73.4-89.2)	70.6 (62.2-79.1)	
P value	0.025	0.619	

According to the definition used in this Finazzi-Agro and colleagues' trial, no patient in the sham group was considered a responder. In contrast, the results of the SUmIT trial showed that ~ 20% of the patients responded to sham therapy. This discrepancy in results may be due to the difference between the two trials in the definition of response used, or to variations in inclusion criteria (the SUmIT trial included men and women with OAB, while Finazzi-Agro and colleagues' study included only women with detrusor overactivity incontinence). In a meta-analysis, Burton and colleagues (evidence table 3) performed a subgroup analysis for four RCTs (total n=289) that compared PTNS to sham therapy and showed that patients who received PTNS were seven times more likely to have a successful treatment versus sham therapy (risk ratio 7.02; 95% CI 1.69-29.17). A Cochrane review (Rai et al, 2012) compared anticholinergic drugs versus non-drug active therapies for non-neurogenic overactive bladder syndrome in adults. Among the comparisons made was one between anticholinergic drugs versus external electrostimulation. This included only the OrBIT trial reviewed for this report.

Comparison of PTNS vs. active therapy with extended-release tolterodine

In the OrBIT trial (evidence table 2), Peters and colleagues compared the effectiveness of PTNS to extended-release tolterodine (Detrol LA) in reducing OAB symptoms. The trial included 100 adults with OAB symptoms, at least 8 voids/24 hours, and with or without a history of anticholinergic drug use. The primary outcome of the trial was the reduction in frequency of urinary voids /24 hours. The study was randomized and controlled, but it was not blinded and the outcomes were subjective, which does not allow ruling out the placebo effect of PTNS. The patients in the two arms were observed differently during follow-up (visits were made in person for the PTNS

group and by phone for the Detrol La group). The duration of follow- was only 12 weeks, the dropout rate were >15%, and analysis was not based on ITT. The study was supported by the manufacturer, and the authors had financial interest with the industry. The results of the OrBIT trial showed a significantly higher improvement in the Global Response Assessment rate with PTNS compared to Detrol LA when self-reported, but not when assessed by the investigator. There was no significant difference in the OAB symptom improvement between the two treatment groups.

Outcomes after 12 weeks of therapy in the two study groups (OrBIT trial)

	PTNS N=50	Detrol LA N=50	P value
<b>Global response assessment (GRA)*</b>	N=44	N=43

Mean reduction in voids/24 hours	2.4 ± 4.0	2.5 ± 3.9	0.44††

\* 79.5% versus 54.8% when self-assessed, p=0.01

Phase 2 of the OrBIT trial (MacDiarmid, 2010) only followed-up responders to the PTNS therapy (n=33). The maintenance therapy received by those 33 patients was not defined, but the authors indicated that the treatment intervals were selected by the subjects and sound clinical judgment. Only 25 patients (50% of the subjects randomized to PTNS; 75% of responders) had complete data at 12 month. Phase 2 did not compare outcomes of PTNS to pharmacologic therapy, and its duration was insufficient to determine the long-term outcomes of the therapy. Side effects of PTNS No serious adverse events were reported in any of the studies. The reported mild or moderate side effects included swelling, worsening of incontinence, headache, hematuria, inability to tolerate stimulation, leg cramps, foot/toe pain, and vasovagal response to needle placement. Maintenance therapy The two studies that reported on intermediate-term outcomes (12 months for OrBIT and up to 36 months for the SUmiT extension study (STEP), only included the responders to PTNS, a number of which dropped out during follow-up. There was no standardized protocol for maintenance therapy. Regimens varied between weekly and monthly intervals based on the patient's selection and clinician's judgment of symptom control. STEP study (Peters 2012, 2013), an extension of the SUmiT trial to determine the sustained effect of the therapy over 24 and 36 months, included 50 of the 60 patients who responded to PTNS therapy (out of 110 randomized to PTNS in SUmiT). The participants received PTNS therapy over 3 months in a tapering fashion (2 treatments at a 14-day interval, followed by 2 treatments at 21 day interval, then once at a 28 day interval). After the three months, treatments were tailored according to the patients' OAB symptoms. Patients completed OAB symptoms and QoL questionnaire every 3 months and 3-day voiding diaries were completed every 6 months. 24 months results of STEP Patients received an average of 1.3 treatments/month. 35/60 (58% of responders to PTNS in SUmiT, 32% of those initially randomized to PTNS therapy) completed follow-up. 28/35 (80%) of those who completed follow-up (46.6% of responders to PTNS in SUmiT) reported moderate or marked improvement for overall bladder symptoms. 36 months results of STEP Patients received an average of 1.1 treatments/month. 29/60 (48% of the responders to PTNS in SUmiT, 26% of those initially randomized to PTNS therapy) completed 36 months of follow-up. 28/29 (96.6%) of those who completed follow-up (46.6% of responders to PTNS in SUmiT) reported moderate or marked improvement for overall bladder symptoms. Conclusion: There is evidence from 2 sham-controlled trials that PTNS therapy has more than a placebo short-term effect in improving OAB symptoms. The results of the OrBIT trial showed that PTNS was not superior to pharmacotherapy with Detrol LA in reducing OAB symptoms. The results of the SUmiT trial and its extension study (STEP) indicate that just over half (54.5%) of patients treated with PTNS experienced short-term moderate or marked improvement with the therapy. The published studies did not analyze the results of PTNS therapy separately for men and women. Data on long-term outcomes were observational. There is evidence that responders to PTNS therapy need to continue using PTNS therapy in order to sustain the improvement in OAB symptoms. Not all responders at 12 weeks will sustain their response with maintenance therapy. No serious adverse events related to PTNS therapy were reported. The trials were supported by the manufacturer, and the principal authors had financial interests and/or other relationships with the manufacturer.

Articles: The literature search for studies published after the 2007 MTAC review of PTNS for the treatment of overactive bladder in adults revealed four randomized controlled trials, two of which were conducted by the same group of authors (SUmiT and OrBIT trials) and two had additional publications with extended follow-up data (2 and

3 years follow-up of SUMiT were published as STEP trial). The search also identified two systematic reviews (one with a meta-analysis) of studies on the effect of PTNS for overactive bladder, and an updated Cochrane review that compared anticholinergic drug vs. non-drug active therapies for OAB in adults. The two larger trials and the meta-analysis on the effectiveness of PTNS for OAB were selected for critical appraisal: Burton C, Sajja A, Latthe PM. Effectiveness of percutaneous posterior tibial nerve stimulation for overactive bladder: a systematic review and meta-analysis. *Neurourol Urodyn*. 2012;31:1206-1216. See [Evidence Table](#). ## Clinical Review Criteria

### Tumor Treating Fields Therapy

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	<a href="#">Tumor Treatment Fields Therapy (L34823)</a>
Local Coverage Article	None

##### For Non-Medicare Members

- I. Tumor-treating fields (TTF) to treat primary (not recurrent) supratentorial glioblastoma multiforme (GBM) may be considered medically necessary when **ALL of the following** are met:
  - A. Patient is 18 years of age or older; and
  - B. Karnofsky Performance Status\* is 70% or higher; and
  - C. Documentation of histologically-confirmed primary glioblastoma multiforme; and
  - D. Patient has completed standard concomitant chemoradiation with temozolomide(TMZ); and
  - E. Disease did not progress through chemo radiation (possible "pseudo progression" does not exclude patients from receiving TTF) and
  - F. TTF will be administered concurrently with TMZ, unless TMZ has been ineffective, not tolerated, or is contraindicated and
  - G. TTF must be started no later than 60 days from the end of chemo radiation
- II. For continued treatment of TTF, member must meet **ALL of the following**:
  - A. Has no signs of disease progression and
  - B. Concurrent use of TMZ continues

**All authorizations are for 90 days. Re-authorizations require updated clinical notes and imaging.**

\*Karnofsky Performance Status Scale

Condition	Value (%)	level of Functional Capacity
Able to carry on normal activity and to work; no special care needed	100%	No complaints; no evidence of disease
	90%	Able to carry on normal activity; minor signs or symptoms of disease
	80%	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed	70%	Cares for self; unable to carry on normal activity or to do active work
	60%	Requires occasional assistance but is able to care for most personal needs
	50%	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; diseases may be progressing rapidly	40%	Disabled; requires special care and assistance
	30%	Severely disabled; hospital admission

	indicated although death not imminent
20%	Very sick; hospital admission necessary; active supportive treatment necessary
10%	Moribund; fatal processes progressing rapidly
0%	Dead

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Glioblastoma (GBM), an incurable disease, has the highest incidence rate (3.19/100,000 population) amongst the central nervous system (CNS) tumors with an average survival of 15 months (Thakkar et al., 2014). Numerous genetic and environmental risk factors have been investigated but none is associated with a large population of GBM (Wrensch, Minn, Chew, Bondy, & Berger, 2002). The median age of diagnosis is 64 years and GBM is frequently found in the supratentorial region (Adams et al., 2013). GBM is an aggressive malignancy with poor prognosis and low survival. The first year relative survival rate is 35% and this estimate decreases over time (Ostrom et al., 2013) making the long term survival very harsh. Standard treatment consists of resection with combination of radiation and chemotherapy. These therapies, whether combined or utilized alone, do not significantly decrease mortality and do not lack adverse effects. Because GBM infiltrates the brain, it is prone to recurrence. Management of recurrence became challenging and therefore indispensable for better clinical outcomes. Different therapeutic options have been investigated but tumor treating fields (TTFields), a novel treatment, seems comparable to standard chemotherapy including Temozolomide and is less toxic (Roger Stupp et al., 2012).

TTFields, developed by NovoCure Ltd, is a medical device for the treatment of recurrent GBM. It is a portable, non-invasive, battery-operated and wearable device that disrupts the division of cancer cells and proliferation in the supratentorial region by delivering low-intensity and intermediate frequency (200 kHz) alternating electric fields via transducer arrays applied to the scalp by means of hypoallergenic ceramic disks, which are placed on the scalp using Hydrogel (Axelgaard Manufacturing Co, Ltd, Fallbrook, CA) as a conductor; It is believed that TTFields inhibits cytokinesis and microtubule assemble, and therefore inhibiting growth and causing death of cancer cells (Butowski, Wong, Mehta, & Wilson, 2013). The NovoTTF-100A received premarket approval from the Food and Drug Administration (FDA) on April 10, 2011 for treatment in adult patients with confirmed GBM, following confirmed recurrence in an upper region of the brain after receiving chemotherapy. The device is intended to be used independently and as an alternative to standard medical therapy after surgical and radiation options have been exhausted (FDA 2011).

The review of the safety and effectiveness of TTFields Therapy for the treatment of recurrent GBM in adults has been reviewed previously. However, it is being reviewed based on a request from the Clinical Review Unit with a focus on the combination of TTFields plus Temozolomide as maintenance therapy on newly diagnosed GBM. It is also being reviewed for coverage decision support.

## Medical Technology Assessment Committee (MTAC)

### Tumor Treatment Fields Therapy

#### 08/19/2013: MTAC REVIEW

**Evidence Conclusion:** The randomized phase III trial sought to compare the overall survival of subjects treated with the NovoTTF-100A alone to subjects treated with the best standard of care (BSC) chemotherapy available for recurrent GBM (Stupp, Wong et al. 2012). In the clinical study, 237 subjects with previously diagnosed GBM who experienced recurrence of their tumor or their condition worsened despite conventional therapy (surgery and chemo-radiotherapy followed by chemotherapy) were randomly assigned to receive either NovoTTF-100A stand-alone treatment or the BSC chemotherapy (as determined by the local physician). The primary endpoint for the study was overall survival, as assessed by the log-rank test in the intent-to-treat population. In addition, the study examined the safety and tolerability of NovoTTF-100A treatment based on the incidence and severity of adverse events and toxicities. Secondary endpoints measured in the study included the progression free survival rate at 6 months, time to progression, one year survival rate, quality of life and radiological response rate. The ITT population includes all subjects who were randomized to the trial. At a median follow up of 39 months 93% of patients had died. The analysis was performed by the treatment group to which the subject was randomized. The study results showed that overall survival with the NovoTTF-100A System was no superior to that seen with active best standard of care chemotherapy. There was a slightly higher incidence of neurological adverse events in the NovoTTF-100A treated group (43.1%) compared to the best standard of care control group (36.3%). Mild to moderate skin irritation beneath the device electrodes was seen in 16% of NovoTTF-100A-treated subjects.

NovoTFF-100A treated subjects experienced a lower frequency of the classic adverse events as seen with chemotherapy (such as gastrointestinal, hematological and infectious adverse events) with the best standard of care. Quality of life surveys indicated an improved quality of life in the NovoTFF-100A recurrent GBM subjects compared to the best standard of care recurrent GBM subjects. The trial was generally well designed and conducted with recruitment from 28 different clinics, randomization and minimal loss to follow up. Limitations identified by the authors include the somewhat heterogeneous patient population with patients included after progression of one or several lines of prior chemotherapy. The authors also observed that the study could have benefited from a placebo or treatment-free control arm. Some limitations that are not highlighted by the authors include the decreasing number of subjects remaining after 12 months which may limit the ability to reliably estimate the long term survival outcomes. Furthermore, it is important to note that the primary investigator, as well as a number of other authors had financial and professional ties with the manufacturer of the device Novocure Ltd., Rye Beach, New Hampshire. Although the study failed to show that the NovoTFF-100A treatment is superior to chemotherapy with respect to overall survival the NovoTFF-100A treatment exhibits minimal toxicity, has clinically comparable primary and secondary effectiveness and better quality of life compared to the chemotherapies used in the control arm of the study.

**Articles:** A literature search was conducted revealing a small pilot trial and one larger pivotal study. The pilot study was an open-label prospective single arm study to assess the safety and effectiveness of TTFields for the treatment of GBM. The pivotal study was prospective, open label, best standard of care randomized control trial to compare the overall survival of subjects treated with NovoTFF-100A alone to subjects treated with the best standard of care chemotherapy available for recurrent GBM. In addition, the search revealed a case study illustrating one patient's success with TTFields therapy and one expert opinion article discussing the concept, evidence and future of TTFields. The clinical study that formed the FDA's basis for determining that the NovoTFF-100A System is safe and effective for its intended use was selected for review: Stupp R, Wong ET, Kanner AA, Steinberg D, Engelhard H, et al. NovoTFF-100A versus physician's choice chemotherapy in recurrent glioblastoma: A randomized phase III trial of a novel treatment modality. *European Journal of Cancer*. 2012;48, 2192-2202. See [Evidence Table](#).

The use of TT Fields Therapy does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Tumor Treating Fields plus Temozolomide as maintenance therapy for Glioblastoma Multiforme (GBM)**

#### **03/21/2016: MTAC REVIEW**

**Evidence Conclusion:** The previous review on TTFields, completed in 2013, aimed to determine the safety and efficacy of TTFields therapy compared to standard medical therapy, for the treatment of recurrent GBM for adult patients. The study evaluating NovoTFF-100A versus Physician Choice Chemotherapy in recurrent glioblastoma (Roger Stupp et al., 2012) was reviewed and no improvement in overall survival was identified. The author of the review concluded that there was insufficient evidence to determine the safety and effectiveness of TTFields Therapy. Stupp, R., S. Taillibert, et al. (2015). "Maintenance Therapy With Tumor-treating Fields plus Temozolomide vs Temozolomide Alone for Glioblastoma: A Randomized Clinical Trial." See [Evidence Table 1](#). This randomized phase 3 trial, open label, parallel design, multicenter, (R. Stupp et al., 2015) intended to assess the efficacy and safety of TTFields in combination with temozolomide for treatment of patients with GBM after initial treatment with chemoradiation. After patients were diagnosed, they were initially treated with chemoradiation comprised of Temozolomide and concomitant radiation. Brain MRI was required 2 weeks prior to starting the maintenance treatment (to exclude progression cases). After completion of the initial treatment, patients were randomized at a ratio of 2 to 1 to receive TTFields + Temozolomide (n=466) or Temozolomide alone (n=229). TTFields was initiated within 4-7 weeks from the last dose of concomitant chemoradiotherapy. While Temozolomide was given on a basis of 150-200 mg/m<sup>2</sup>/d for 5 days every 28 days for 6-12 cycles, TTFields was delivered continuously (>18 hours/day) via 4 transducer arrays placed on the shaved scalp and connected to a portable medical device. The primary outcome was progression-free survival (PFS) in the intent-to-treat population (significance level of 0.01) and the secondary outcome was the overall survival (OS) in the per-protocol population (significance level of 0.006). Safety and tolerability were also evaluated. A total of 695 patients were recruited but the trial was terminated after the interim analysis showed a benefit in Progression Free Survival. This interim analysis was conducted after the first 315 randomized patients reached a minimum of 18-month follow-up. Thus, data from 315 patients with 210 patients in the intervention group and 105 patients in the control group were analyzed. Baseline characteristics were nearly similar across the groups with median age of 57 years. The findings were based on the interim analysis. Patients who were treated with TTFields plus Temozolomide had longer PFS [7.1 months (CI, 5.9 – 8.2)] than those who were treated with Temozolomide alone [4 months (95%CI, 3.3 – 5.2)]. Likewise, patients who were treated with TTFields plus Temozolomide had longer OS [20.5 months (16.7 - 25)] than those who were treated with Temozolomide alone [15.6 months (CI, 13.3 – 19.1)]. In addition, no major increases in toxic effects were associated with the intervention. The most common adverse events were thrombocytopenia, mild to moderate skin irritation, and general disorders. In conclusion, the combination of TTFields plus Temozolomide prolonged PFS as well as OS compared to Temozolomide alone for the

maintenance treatment of patients with GBM. However, this is an interim analysis with less than 50% of participation with exclusion of patients with early progression decreasing the quality of the evidence. MTAC will re-review the technology once full data are analyzed. Conclusion: The interim analysis with less than 50% participation suggests that TTF plus Temozolomide may prolong progression-free survival and overall survival versus Temozolomide alone. Nevertheless, the study failed to include patients with severe prognosis, therefore results should be interpreted with cautious. Other pitfalls remain in the open-label nature of the RCT leading to placebo effects and variation in the delivery of chemotherapy and radiochemotherapy.

**Articles:** A literature search was conducted revealing 13 articles (Please refer to appendix B) of which one meets inclusion criteria (studies involving histologically confirmed GBM, standard concomitant chemoradiation with Temozolomide, age >18 years with ≥ 70% on Karnofsky Performance Status (KPS) score and good renal and bone marrow function, received TTFields plus Temozolomide as maintenance therapy). The study on “Maintenance Therapy with tumor-treating fields plus temozolomide vs Temozolomide alone for Glioblastoma: A randomized clinical trial” will be critically appraised.

The use of Tumor Treating Fields (TTFields) plus Temozolomide as maintenance therapy for Glioblastoma multiforme (GBM) does meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies (and/or) provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Carpal tunnel syndrome (CTS) is a neuromuscular clinical condition caused by compression or irritation of the median nerve where it passes under the transverse carpal ligament in the wrist. Thickening of tendon sheaths or encroachment by other structures lead to a sustained rise in pressure within the canal. The pressure is further increased by flexion or extension of the wrist. The incidence of CTS in the United States has been estimated at 1-3 cases per 1,000 subjects per year, with a prevalence of 50 cases per 1,000 per year. CTS is more common in individuals 45-65 years of age and among females. The etiology of the syndrome is not well known and continues to be debated. It is believed that it may have a hereditary component and that physical occupational activity such as repeated and forceful movement of the hand and wrist or the use of handheld powered vibratory tools can predispose to the condition. Other predisposing causes included rheumatoid arthritis, pregnancy, obesity, and hypothyroidism (Nathan 2005, Verdugo 2008, Bickel 2010, Palmer 2011, Page 2013).

The most common symptoms of carpal tunnel syndrome are pain, tingling, and numbness within the median nerve distribution of the hand (thumb, index and middle, and radial half of the ring finger). Pain may radiate to the arm and is often worse at night and when gripping an object for a long duration of time. In advanced stages, thenar muscle weakness can occur. Based on symptoms alone, the British Society for Surgery of the Hand has classified carpal tunnel syndrome into mild, moderate and severe. In mild carpal tunnel syndrome there is intermittent paresthesia which may be nocturnal or associated with certain hand positions or conditions such as pregnancy or hypothyroidism. In moderate carpal tunnel syndrome there is constant paresthesia which interferes with activities of daily living and wakes the patients from sleep. It is associated with reversible numbness and/or pain. Severe cases have constant numbness or pain associated with weakness and/or wasting of the thenar muscles, but with small risk of damage to the nerve (McCartan 2012, Page 2013).

Carpal tunnel syndrome may be treated by surgical or non-surgical approaches. Non-surgical treatments are usually offered to patients with intermittent symptoms of mild to moderate CTS. These include the use of wrist splints, local steroid injections, oral steroid therapy, activity modification, ergonomic modification, or therapeutic ultrasound. The more severe or refractory cases may require surgical decompression of the median nerve. Surgery involves complete division of the flexor retinaculum to release the median nerve and can be performed through a number of different techniques as the standard open carpal tunnel release, the mini-open release, and the endoscopic carpal

tunnel decompression. Each technique has its advantages and drawbacks (McCartan 2012, Figaro 2012, Page 2013).

The standard open carpal tunnel release (O-CTR), the oldest and most commonly used technique, involves releasing the flexor retinaculum under direct vision to ensure a complete release. The procedure is safe and simple, but is associated with painful and sensitive scars, decrease in grip strength, and long healing time. A less aggressive mini-open release (mini-OCTR) involves division of the retinaculum with limited access through a 1-1.5 cm incision at the distal wrist crease and the use of specially developed instruments. Carpal tunnel release can also be performed endoscopically (E-CTR) using single or double portal techniques to visualize the under surface of the flexor retinaculum and guide the surgeon's knife. The mini-open or endoscopic techniques cause less tissue trauma, have a smaller scar, less postoperative pain, faster recovery, and conserves the grip strength. However, these techniques with their limited approaches are associated with decreased visualization of the median nerve and its terminal branches (thenar muscular branch and palmar branch, vascular structures, and anatomic variations, all of which may increase the risk of neurovascular injury during the procedure. In addition, these techniques may carry the risk of incomplete release of the flexor retinaculum as a result of poor visualization, leading to persistent symptoms. (McCartan 2012, Nakamichi 2010, de la Fuente 2012).

Mini-open carpal tunnel release (Mini-OCTR) and percutaneous carpal tunnel release using ultrasonographic guidance are recently developed surgical techniques that allow combining the advantages of both the O-CTR and mini-OCTR i.e. the direct visualization of all the key anatomic structures including the variants together with the small incision. The size of the incision with percutaneous carpal tunnel release is 0.4-0.6 cm compared to 1-2 cm for the mini, and >4cm for the classic carpal tunnel release. These newly developed techniques may potentially lead to the same neurological and functional outcomes as O-CTR but with less scar sensitivity and pain, and better grip strength. The sonographically guided percutaneous needle technique is office-based and performed under local anesthetic. However, not all patients are legible for the procedure, and the results of hand surgeries performed under ultrasonography depend on the surgeons experience with ultrasound, which is known to be examiner dependent, and involves a learning curve and interobserver variation in interpretation. In addition, there are many unanswered questions as regards the contraindications to the percutaneous procedure, the release extent at the deepest layer portions, best approach, best location, and best advancing direction of the instrument (Nakamichi 2010, de la Fuente 2012, McShane 2012, Rojo –Manuante 2013).

## Medical Technology Assessment Committee (MTAC)

### Ultrasound Guided Percutaneous Needle Release of Carpal Tunnel

#### 08/19/2013: MTAC REVIEW

**Evidence Conclusion:** There is a lack of published literature on ultrasound-guided percutaneous release of the carpal tunnel for individuals with carpal tunnel syndrome. The larger of two published studies to date, was a small non-randomized observational study that compared the outcomes of percutaneous carpal tunnel release vs. mini-open surgical release performed under ultrasonographic guidance. The technique was not compared to the standard open surgery, and the patients were not randomized to the procedures but were assigned to one versus the other according to the orthopedist's discretion based primarily on the safe zone that varied between the study participants and also on the patient's preference. In conclusion, there is insufficient published evidence to determine the efficacy and safety ultrasound-guided percutaneous release of the carpal tunnel for individuals with carpal tunnel syndrome.

**Articles:** The published literature on ultrasound-guided percutaneous release of the carpal tunnel is very limited. The search revealed only one nonrandomized study that compared the technique with mini-OCTR both performed under ultrasonographic guidance, and a very small retrospective case series with 17 patients. The following study was selected for critical appraisal: Nakamichi K, Tachibana S, Yamamoto S, et al. Percutaneous carpal tunnel release compared with mini-open release using ultrasonographic guidance for both techniques. *J Hand Surg Am.* 2010;35:437-445. [See Evidence Table](#)

Ultrasound Guided Percutaneous Needle Release of Carpal Tunnel did not pass the *Group Health Medical Technology Assessment Criteria*.

#### Criteria

##### For Medicare Members

No documents found. CPT codes have no restrictions.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Preeclampsia is a major cause of maternal and perinatal morbidity and mortality. Among pregnant women, cardiac output may be associated with increased risk of preeclampsia. Ultracom is a continuous-wave Doppler computer that measures cardiac output. Using UltraCom, at-risk women can be identified and treatment to reduce maternal and neonatal adverse outcomes can be initiated.

#### Medical Technology Assessment Committee (MTAC)

##### UltraCom Scan

##### 2/14/2001: MTAC REVIEW

**Evidence Conclusion:** This review addresses three questions:

1. Does Ultracom accurately measure cardiac output?
2. Is high cardiac associated with preeclampsia?
3. Does treatment of women with high cardiac output reduce the risk of preeclampsia?

*Question 1:* There were two small studies evaluating the validity of the UltraCom test. Both studies found a high correlation between the results of UltraCom testing and thermodilution. However, the sizes of the samples (n=11 and n=12) are insufficient to show that the UltraCom test can accurately measure cardiac output compared to the best available alternative test. (Easterling 1987, 1990 Am J Perinatol)

*Question 2:* There was one prospective cohort study that suggests an association between cardiac output and preeclampsia. However, this study did not control for confounding, particularly weight. The association between cardiac output and preeclampsia could be due to the weight differences between the two groups of pregnant women rather than cardiac output differences. (Easterling 1990)

*Question 3:* There was one small randomized controlled trial that found that women with high cardiac output who were treated with atenolol had a lower rate of preeclampsia than women with high cardiac output who were given placebo. Nulliparous women treated with atenolol also had babies that weighed significantly less than women treated with placebo. (Easterling, 1999). This single study provides insufficient evidence to draw conclusions about the effect of screening with UltraCom and subsequent treatment with atenolol on maternal and neonatal health outcomes. There is no evidence on the effectiveness of any other type of treatment.

All of the available studies on the use of UltraCom with pregnant women were done by a single group of researchers. Generally, replication by various groups of researchers in different settings provides stronger effectiveness data. Moreover, these researchers are based at University Hospital, University of Washington, which is marketing the UltraCom test for pregnant diabetic women; we cannot exclude the possibility of a conflict of interest that might bias the research methodology.

**Articles:** The Medline search only identified articles that were on related topics (Doppler technique, uterine artery Doppler ultrasound) but not on empirical studies evaluating UltraCom in pregnant women. Dr. Ruth Krauss listed the citation for one article. References in that article yielded 3 other relevant articles. Evidence tables were

created for these four articles. Easterling TR, Brateng D, Schmucker B, Brown Z, Millard SP. Prevention of preeclampsia: A randomized trial of atenolol in hyperdynamic patients before onset of hypertension. *Obstet Gynecol* 1999; 93: 725-33. See [Evidence Table](#). Easterling TR, Benedetti TJ, Schmucker BC, Millard SP. Maternal hemodynamics in normal and preeclamptic pregnancies: A longitudinal study. *Obstet Gynecol* 1990; 76: 1061-9. See [Evidence Table](#). Easterling TR, Watts DH, Schmucker BC, Benedetti TJ. Measurement of cardiac output during pregnancy: Validation of Doppler technique and clinical observations in preeclampsia. *Obstet Gynecol* 1987; 69: 845-50. See [Evidence Table](#). Easterling TR, Carlson KL, Schmucker BC, Brateng DA, Benedetti TJ. Measurement of cardiac output in pregnancy by Doppler technique. *Am J Perinatol* 1990; 7: 220-222. See [Evidence Table](#).

The use of UltraCom Scan in the screening and treatment of hypertension in pregnancy does not meet the *Group Health Medical Technology Assessment Criteria*.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Heart failure (HF) is a major and growing health problem worldwide and is the leading cause of hospitalization in the Western world. In the United States more than 5 million patients suffer from HF, and more than one million are admitted annually to hospitals for acute decompensated heart failure (ADHF). The great majority of patients present with dyspnea and edema from the volume overload and pulmonary congestion driven by sodium and water retention, and many are discharged without clinical evidence of adequate decongestion. The prognosis of patients with ADHF is poor with an approximately 4% in-hospital mortality rate. 25% are readmitted within 30 days, and up to 23% die within 6 months. 25-33% of patients with ADHF develop acute cardiorenal syndrome which is defined as worsening renal function (often defined as an increase in creatinine  $\geq 0.3$  mg/dL from baseline). This results from a number of contributing factors and is usually associated with poor outcome (Chiong 2010, Giglioli 2011, Bart 2012, Felker 2012).

Standard therapy for decompensated HF consists predominantly of intravenous (IV) loop diuretics and vasodilators. Loop diuretics induce rapid diuresis that reduces lung congestion and edema. Intravenous administration of an effective dose of furosemide (a loop diuretic) typically results in a diuretic effect within 30 minutes and peaks at one hour. Heart failure patients require a higher dose to achieve this same effect. It was reported that in ADHF, renal responsiveness to loop diuretics may be decreased, and that patients with New York Heart Association (NYHA) class II or III HF have one third to one fourth the natriuretic response as compared with normal subjects. This response decreases further as the severity of HF increases, and higher doses are required. The effectiveness of the diuretics also declines with repeated exposure, and resistance to the therapy may develop as heart failure progresses. In some patients fluid overload persists despite the higher doses. Investigators described two types of diuretic resistance; short-term resistance, which is a decrease in response to the first administration, and long-term resistance that develops after long-term administration of loop diuretics. Approximately 25%-30% of HF patients develop diuretic resistance which is usually associated with worsened outcomes and higher risk of death. In some cases, the intravenous administration of diuretics to patients with ADHF may directly contribute to worsening of renal function, and its continued use for treating persistent congestion after the onset of worsening renal function, may lead to additional kidney injury. Despite the concerns about these potential harms associated with higher doses of diuretic therapy and the lack of proven survival benefit, diuretics remain the standard therapy for removing the excess extracellular fluid in patients with heart failure. Other therapeutic alternatives include inotropic therapy, IV nitroglycerine and natriuretic peptides. When

these pharmacological approaches fail, or are unsuitable, the alternative means for fluid removal are dialysis, phlebotomy, or ultrafiltration (Costanzo 2005, 2007, Chiong 2012, Bart 2012, Felker 2009, 2012)

The concept of extracorporeal removal of fluid with ultrafiltration has been used for decades to treat refractory edema. The pump-driven extracorporeal ultrafiltration (UF) was described in the 1970s, and was used for patients with heart failure in the mid-1980s. Ultrafiltration is accomplished by mechanically drawing blood from the patient either through peripheral or central venous access. Plasma is then filtered by means of the negative hydrostatic pressure generated by a second pump, and re-infused back into the patient. The ultrafiltrate is composed of water with electrolytes in the same concentration as in the serum without the cells or proteins which are too large to pass through the filter pores. Unlike dialysis, ultrafiltration operates by convection in eliminating iso-osmolar extracellular fluid resulting in a decrease in ventricular filling pressure without significant changes in the renal function, creatinine, or urea concentration. It is reported that ultrafiltration can improve cardiac hemodynamics by reducing both right and left sided filling pressure, increasing the stroke volume and cardiac output. Researchers also found that it restores diuretic responsiveness and improves natriuresis without changes in the heart rate, systolic blood pressure, intravascular volume, or electrolytes. A potential advantage of UF over loop diuretics is that the ultrafiltrate is isotonic, whereas the urinary output with loop diuretics is hypotonic, thus UF removes more sodium (and less potassium) than diuretics for an equivalent volume loss. Ultrafiltration is not a substitute for dialysis, and will not lead to removal of accumulated toxins or potassium in hyperkalemic patients (Bourge 2005, Boyle 2005, Costanzo 2005).

Earlier, ultrafiltration required physician placement of a double-lumen central venous catheter and monitoring by a dialysis technician. Recently a simpler, smaller, and portable ultrafiltration device was introduced (System 100, CHF Solutions, Minneapolis, Minnesota). The device is less invasive, and does not require intensive care unit monitoring or central intravenous access. It allows a technician to place the blood withdrawal and infusion catheters in peripheral veins, usually the brachial-cephalic system, with subsequent monitoring by a clinical nurse. The device removes water and non-protein-bound small and medium molecular weight solutes through a semipermeable membrane when hydrostatic pressure generated by blood pressure or external blood pump exceeds oncotic pressure. The fluid removal rate can range from 100 to 500 ml/hour and is set by the treating physician. UF requires systemic anticoagulation with the possibility of excess bleeding. Other potential complications include air embolism, and overly aggressive volume removal (Bourge 2005, Bart 2012).

The ACC/AHA clinical practice guidelines do not recommend the use of UF as a class I therapeutic option but as a class II recommendation (level B evidence) for the relief of fluid overload in patients with refractory congestion not responding to medical therapy.

CHF Solutions received marketing clearance from the FDA for System 100 in June 2002 and for central venous access with the system in December 2003. System 100 is indicated for temporary (up to 8 hours) ultrafiltration treatment of patients with fluid overload. In 2005, System 100 was renamed Aquadex FlexFlow™ and launched with several new features (according to the manufacturer).

## Medical Technology Assessment Committee (MTAC)

### *Ultrafiltration in the Treatment of Congestive Heart Failure*

**08/07/2006: MTAC REVIEW**

**Evidence Conclusion:** The RAPID-CHF trial (Bart 2005) was a randomized, controlled, non-blinded trial that compared usual care vs. usual care plus ultrafiltration (UF) in 40 patients admitted to hospital with acute decompensated heart failure and fluid overload. Patients randomized to the usual care group received the conventional heart failure therapy. Those in the UF group received an 8 hour UF treatment with a maximum fluid removal rate of 500 cc/hour. Diuretics were administered after the 8 hours of UF, and additional courses of UF were allowed after 24 hours. The results of the trial show that the weight loss (primary endpoint of the trial) was not significantly different between the two study groups. The average volume removal of fluid was significantly higher in the UF group at 24 and 48 hours. Patients in the two treatment groups experienced improvement in their symptoms during the treatment period. The improvement observed was significantly greater in the UF group compared to the usual care group at 48 hours but not at 24 hours. The significant difference may be due to the greater fluid removal or due to chance as the trial was small, un-blinded, and the outcome measure was subjective. Costanzo et al (2005) reported their experience with early initiation of UF in 20 selected HF patients admitted to hospital with manifest signs and symptoms of fluid overload. The patients underwent UF which was continued until the acute decompensation heart failure symptoms were resolved. The removal of fluid was aggressive (8,654 + 4,205 ml) and resulted in a mean decrease of 6 kg of weight at discharge, and improvement in the clinical signs of symptoms of fluid overload that seem to have lasted for the 90 days of follow-up. This was only an observational case series with no comparison or control group and subject to selection and observation bias. The results of the UNLOAD (or UltrafiltrationN versus IV diuretics for patients hospitalized for Acute

Decompensated congestive heart failure) trial was presented at the 2006 ACC conference in Atlanta, but have not been published in a peer reviewed journal to date. The trial randomized 200 patients from 28 centers to receive the standard intravenous diuretic drug therapy or IV diuretics plus ultrafiltration to treat fluid overload. The study was not blinded, the primary outcomes were weight loss and dyspnea score at 48 hours, and the patients were followed up for 90 days. The unpublished results of the trial indicate that both treatments were associated with significant improvement in the dyspnea score at 48 hours, but with no significant difference between the two treatment groups. Patients in the UF group had significantly greater net fluid and weight loss at 48 hours, and a lower incidence of hypokalemia. The results also show that the hospital readmission rate, during the 3 months of follow-up, was significantly lower in the UF group, vs. the IV diuretic group. All three studies were funded or supported by the manufacturer of the device CHF Solutions, Brooklyn Park, Minnesota, which may introduce bias. In conclusion, there is insufficient evidence to date to determine the efficacy and long-term safety of ultrafiltration versus standard care in acute decompensated heart failure, or to determine who would benefit most from the intervention.

**Articles:** The search yielded around 280 articles most of which were review articles, opinion pieces, or dealt with the technical aspects of the procedures. There was one RCT, and several small case series, many of which dated back in the 1980s and 1990s. The RCT and the relevant case series using the new UF device (System 100, CHF Solutions, Minneapolis, Minnesota) were selected for critical appraisal: Bart BA, Boyle A, Bank AJ, et al. Ultrafiltration versus usual care for hospitalized patients with heart failure. The Relief for Acutely fluid-overloaded Patients with Decompensated Congestive Heart Failure (RAPID-CHF) trial. *J Am Coll Cardiol* 2005;46:2043-2046. See [Evidence Table](#). MR, Saltzberg M, O'sollivan J, et al. Early ultrafiltration in patients with decompensated heart failure and diuretic resistance. *J Am Coll Cardiol* 2005;46:2047-2051. See [Evidence Table](#).

The use of ultrafiltration in the treatment of congestive heart failure does not meet the *Group Health Medical Technology Assessment Criteria*.

#### 06/17/2013: MTAC REVIEW

##### Ultrafiltration in the Treatment of Congestive Heart Failure

**Evidence Conclusion:** All published trials on the use of ultrafiltration in patients with acute decompensated heart failure with or without renal dysfunction compared UF with IV diuretic based therapy. No published RCT, to date, examined the efficacy and safety of ultrafiltration in patients with ADHF who were refractory to diuretics. This latter indication of ultrafiltration was only evaluated in a one retrospective study with no control group. [Ultrafiltration as a first line therapy](#) The UNLOAD (ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure) trial compared ultrafiltration to diuretic therapy in patients hospitalized for acute decompensated heart failure. The trial examined UF as a first-line early therapy not as a rescue therapy (i.e. patients did not have to fail an initial diuretic therapy to be included in the trial). 200 patients were randomized to receive early UF (within 24 hours of hospitalization) or intravenous diuretic drug therapy. The co-primary outcomes were weight loss and patient self-assessed dyspnea score at 48 hours. The results show that both the UF and IV diuretic therapies were associated with significant improvement in the dyspnea score at 48 hours, with no statistically significant difference between the two treatment groups. Patients in the UF group had significantly greater fluid and weight loss at 48 hours, and a lower incidence of hypokalemia. This however, did not have an impact on the length of the index hospital stay. The rates of rehospitalization and unscheduled visits during the 90 days of follow-up were significantly lower in the UF group, vs. the IV diuretic group. The results also show a higher rise in serum creatinine levels in the UF group vs. the IV diuretic group (twice as many patients in the UF arm experienced an increase in sCr level >0.3 ml/dL during the first 24 hours of therapy) but the difference did not reach a statistically significant level. The authors considered the lack of significant difference between the two groups for this as well as other outcomes, as similar effects when the trial was not designed as equivalent study, and the lack of significant differences could results from insufficient statistical power. The study was a multicenter RCT but had several limitations many of which were acknowledged by the authors. The trial had a relatively small size and short follow-up duration, excluded patients with hypotension or hemodynamic instability, and used suboptimal dose and mode of administration of loop diuretics. The dose of the diuretic, duration, and rate of UF were all based on the discretion of the attending physician who was not blinded to the randomization groups and could be a source of bias. In addition, the authors did not present any data on low-salt diet compliance, or criteria for hospitalization. The study was supported by CHF Solution Inc., and the primary author as well as a number of other authors had financial ties to the manufacturer of the device CHF Solutions, Brooklyn Park, Minnesota. The Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF, sponsored by the NHLBI) investigated the role of UF as a treatment for patients with persistent congestion and worsening of kidney function (increase in serum creatinine  $\geq 0.3$  mg/dL within 12 weeks before or 10 days after index admission). 188 patients were randomized to undergo ultrafiltration (fluid removal at a rate of 200 ml/hour using Aquadex System 100; CHF Solutions), or to receive stepped pharmacological therapy involving increasing the doses of loop diuretics (with or without metolazone), vasodilators and inotropes (based on an algorithm that aimed at achieving urine output of 3-5 liters/ day). The assigned treatment was continued in the two groups until signs and symptoms of congestion were

improved as possible. The primary endpoint was bivariate (simultaneous) change in serum creatinine level and body weight in 96 hours after randomization. The trial was not blinded and the patients were followed-up for 60 days. Recruitment for the trial was stopped early before reaching the planned size of 200 subjects based on the advice of the data and safety monitoring board due to lack of benefit and excess adverse events with ultrafiltration. The results of CARRESS-HF show that stepped pharmacological therapy was superior to UF when the primary end point was assessed at 96 hours after randomization. There was a statistically significant reduction the serum creatinine (sCr) in the pharmacologic therapy group compared to the UF group. There was no significant difference between the groups in weight loss at 96 hours. At the 60 days of follow-up, there were no statistically significant differences in weight loss, or rate of hospitalization due to heart failure. There was a nonsignificant increase in the all-cause readmission rate in the UF group. UF, was also associated with a significantly higher rate of serious adverse events including kidney failure, bleeding complications, and catheter-related complications. The sixty day mortality was 17% for the UF group and 13% for the pharmacological therapy group with no significant difference between the groups, however, as indicated earlier, a lack of significant difference does not indicate equivalence due to the study design. These results should be interpreted with caution and cannot be generalized to patients with ADHF with better renal function than those included in the trial.

**Other published trials** Two other very small published RCTs (ULTRADISCO (Giglioli et al 2011), and Hanna and colleagues' trial (2012) also compared ultrafiltration versus intravenous diuretics in patients hospitalized for ADHF. The trials had intermediate outcomes (hemodynamic variables in the ULTRADISCO trials, and time for pulmonary wedge pressure to be maintained at >18 mmHg for ≥4 consecutive hours in Hanna and colleagues' study). Their overall results showed greater fluid loss with UF vs. diuretic therapy with no significant difference between the groups in the serum creatinine levels. Ultrafiltration as a rescue therapy for patients with ADHF who are refractory to IV diuretic therapy

The literature search did not identify any published RCT to date, that examined the efficacy and safety of ultrafiltration in patients with ADHF who were refractory to diuretics. In a retrospective observational study with no comparison group, Patarroyo and colleagues (2012) analyzed data from hospital records for adult patients with ADHF admitted to one heart failure intensive care unit in Cleveland Ohio ((2004-2009) and who required slow continuous ultrafiltration therapy (SCUF). The study population was a highly selected group of 63 adult patients with advanced HF, worsening renal function, and congestion refractory to hemodynamically guided intensive medical therapy. Their median age was 58 years, mean LV ejection fraction 26 ±15%, baseline serum creatinine (sCr) 1.9 ± 0.8 mg/dL and hemodynamics consistent with cardiogenic shock. SCUF was initiated after a mean of 8 days from admission, was performed at a rate of 200ml/hr. and for a mean duration of 8 days. At the initiation of SCUF therapy the sCr level was 2.2 ± 0.9 mg/dL. The mean duration of the UF therapy was 3+2 days, and the primary endpoint of the study was all-cause mortality and the secondary endpoint included number of readmissions for ADHF and dialysis-dependent status at time of discharge. The results of the analysis showed that after 48 hours of SCUF the overall cohort lost weight significantly compared to baseline (mean 4.4 kg). This was associated with significant improvement in hemodynamic variables but with no improvements in sCr levels or blood urea. 37 patients (59%) required conversion to continuous hemodialysis during their hospital stay and 9 (14%) were dependent on hemodialysis at hospital discharge. 34/37 (93%) of these patients were readmitted to the hospital within 60 days form discharge. 19/63 patients (30%) died during the index hospitalization, and 4 were discharged to terminal care in hospice. The overall 1-year all-cause mortality was 70% and 2 of the surviving patients underwent heart transplantation. The results of the study should be interpreted with caution due to the study design and its inclusion of severely ill patients. Conclusion: There is insufficient evidence to support the use of ultrafiltration as a first-line treatment in hospitalized ADHF with volume overload. There is insufficient evidence to determine the safety and efficacy of ultrafiltration in patients with ADHF who are refractory to diuretic therapy. Results from UNLOAD trial, suggest, but do not provide good evidence, that ultrafiltration may provide better correction of volume overload than IV diuretics (given at the dose used in the trial) in patients hospitalized ADHF who are not resistant to diuretic therapy. The trial had its limitations and does not provide any evidence on the safest and most effective rates of fluid removal, duration of treatment, or the conditions for termination of ultrafiltration. There is evidence from the CARRESS-HF that IV loop diuretic-based therapy adding distal-acting diuretics, IV vasodilator and inotropic agents as needed is superior to ultrafiltration in patients with acute decompensated heart failure and worsening renal function. CARESS-HF results show increased incidence of worsening kidney function in the ultrafiltration group versus the stepped pharmacologic therapy group.

A large ongoing trial (AVOID-HF) (NCT01474200) involving 810 patients in 40 US centers is examining the effect of UF vs. intravenous diuretics in reducing hospitalization in patients with ADHF before worsening renal function.

**Articles:** UNLOAD trial (Costanzo et al 2007, evidence table 1) [See Evidence Table](#). CARRESS-HF (Bart yet al 2012, evidence table 2) [See Evidence Table](#)

The use of ultrafiltration in the treatment of congestive heart failure does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### UniSpacer Knee System

- McKeever Hemiarthroplasty Prosthesis
- MacIntosh Hemiarthroplasty Prosthesis
- Shabaro Tibial Plateau Prosthesis

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

This device is not called out by Medicare as separate from knee arthroplasty.

#### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

The UniSpacer is a small, kidney shaped insert made of cobalt chrome that is intended to correct the knee alignment, decrease pain and improve joint stability for patients with early stages of osteoarthritis. It is a device that fits between the natural bone structures of the knee and stays in place without the aid of bone cement or screws. Not everyone is a candidate for the UniSpacer. It is suitable for patients with isolated, moderate degeneration of the medial compartment, patellofemoral compartment, or lateral condyle, and not suitable for patients with subchondral bone loss, significant patellofemoral disease, or significant lateral compartment disease. The anterior and posterior cruciate ligaments must be intact.

According to the manufacturer, the operation is conducted under general or regional anesthesia and takes about one hour to complete. After surgery patients need physical therapy for 6-8 weeks and may need to wear braces 1-2 weeks or more. Recovery may take as long as one year.

The UniSpacer has been approved by FDA on 1/4/2001 as a Class II device.

### Medical Technology Assessment Committee (MTAC)

#### UniSpacer Knee System

#### 12/11/2002: MTAC REVIEW

**Evidence Conclusion:** Due to lack of scientific data, there is no evidence to determine the role of the UniSpacer Knee System in the treatment of osteoarthritis.

**Articles:** The search did not yield any articles on the UniSpacer knee system or its equivalents.

The use of UniSpacer Knee System in the treatment of osteoarthritis of the knee does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Myoelectric Upper Limb Prosthesis

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	None
Local Coverage Article	None
GH Medical Policy	Due to the absence of a NCD, LCD, or other coverage guidance, GHC has chosen to use their own Medical Policy - Myoelectric Upper Limb Prosthesis

##### For Non-Medicare Members

1. Myoelectric upper limb prosthetic components may be medically necessary when **ALL of the following** criteria are met:
  - A. The patient has an amputation or missing limb at the wrist or above (forearm, elbow, etc.); AND
  - B. Standard body-powered prosthetic devices cannot be used or are insufficient to meet the functional needs of the individual in performing activities of daily living. The inadequacies of a standard device must be documented in detail by a physical or occupational or physiatrist therapist who is not employed by the vendor or prosthetist; AND
  - C. The remaining musculature of the arm(s) contains the minimum microvolt threshold to allow operation of a myoelectric prosthetic device, as demonstrated by functional testing using a physical or computer model prosthesis; AND
  - D. The patient has demonstrated sufficient neurological and cognitive function to operate the prosthesis effectively; AND
  - E. The patient is free of comorbidities that could interfere with function of the prosthesis (neuromuscular disease, etc.); AND
  - F. Functional evaluation by a qualified professional (e.g., prosthetist) indicates that with training, use of a myoelectric prosthesis is likely to meet the functional needs of the individual (e.g., gripping, releasing, holding, and coordinating movement of the prosthesis) when performing activities of daily living. This evaluation should consider the patient's needs for control, durability (maintenance), function (speed, work capability), and usability. **Both of the following** criteria must be met:
    - i. The device is necessary for the patient to perform instrumental activities of daily (see B above)
    - ii. The device is not primarily for the purpose of allowing the patient to perform vocational, leisure or recreational activities.
  - G. Patient must be at least 1 year old.

Prosthesis with individually powered digits, including but not limited to partial hand prosthesis, is considered investigational.

Repair and/or replacement of an external prosthetic device, including an upper limb myoelectric prosthetic device, is covered as follows:

- Repair is covered only when anatomical change or reasonable wear and tear renders the item nonfunctional and the repair will make the equipment usable.

- Replacement is covered only when anatomical change or reasonable wear and tear renders the item nonfunctional and non-repairable.

Repair or replacement of an external prosthetic device, including an upper limb myoelectric prosthetic device, made unusable or nonfunctioning because of individual misuse, abuse or neglect is not covered

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

External prosthetic appliances, often referred to as prosthetic devices or prostheses, are devices used to replace the functions of missing body parts. A passive prosthesis is a type of device that must be moved manually, typically by the opposite arm. The standard prosthetic appliance for replacement of an upper extremity, either below or above the elbow, is a body-powered prosthesis with a terminal hook device. This type of prosthetic device is the most durable and requires gross body movement and sufficient strength for adequate use. It is attached to the user's body through a system of harnesses. The patient controls the hand, forearm and elbow by movement of the harness system. Gross body motion is required to pull the harness and thereby move the prosthesis. Usage of a body-powered prosthesis requires adequate space for compensation of movement; the user must be able to place his/her body in front of the object to be manipulated. This type of device allows voluntary closing or opening of the hand, but not both.

The myoelectric device functions by means of electrical impulses. It is a prosthetic device used as an alternative to a passive or conventional body-powered device which enables a patient to adjust the force of his/her grip and both open and closes the hand voluntarily. Myoelectric devices may be recommended for amputees who are unable to use body-powered devices or who require improved grip function/motion for performance of daily activities. Adults or children with above- or below-the-elbow amputations may use the device effectively, although for children there is some controversy regarding use because due to normal growth patterns the prosthesis may require multiple socket replacements over time.

Unlike body-powered prosthetic devices, myoelectric devices move the prosthetic limbs with small, electric, motorized controls, which allow more precise movement. Small electrodes are installed in the socket of the prosthesis. The electrodes sense electrical activity of the muscles, called electromyographic (EMG) signals. When amplified, the EMG signal stimulates the motors in the device to perform a function. The signal is very weak (i.e., 5–200 microvolts); an individual must be able to produce a strong enough EMG signal for the device to record and amplify; that is, the person must possess a minimum microvolt threshold in the remaining musculature of the arm. The user must also be able to isolate muscle contraction, so that if one muscle is contracted (e.g., flexion), the opposing muscle is relaxed (e.g., extension). Contraction of both muscles (co-contraction) would result in signals turning the motor on and off at the same time, causing the device not to function and eliminating its myoelectric capability.

Myoelectric devices operate on rechargeable batteries and require no external cables or harnesses. The myoelectric prosthetic device does not require gross body movements or added space for compensation of movement to provide adequate functional movement; it can be operated in any user position that allows muscle contraction. Instead of a suspension harness, the devices use one of two suspension techniques: skeletal/soft tissue lock or suction.

Proponents suggest that myoelectric devices have many advantages over conventional ones. When designing prostheses to replace a hand, manufacturers attempt to replicate the grip function, the hand's major function. Other functions that are often replicated are pinch force, wrist rotation and elbow function. Investigators assert that a myoelectric device offers greater grip capabilities and more improved rotational function than conventional devices. Furthermore, because no control cable or harness is associated with the myoelectric device, cosmetic skin can be applied to the device to enhance cosmetic appearance. More recent control systems incorporate programmable microprocessors allowing various ranges of adjustment, performance of multiple functions and sequential operation of elbow, wrist and hand motions. In some cases, a combination of myoelectric and body-powered technology (i.e., hybrid prosthesis) is used to enhance the amputee's overall functionality, depending on the level and location of amputation. Patients with amputations above the transhumeral level may elect a body-powered device to control shoulder and elbow movement and a myoelectric device to control hand and wrist motion, allowing control of two joints at once. There are also devices that are similar to the normal wrist, enabling the terminal device to be rotated, thus allowing more natural movement or placement. More recently, hand devices have become available with five individual powered digits and separately powered prosthetic digits are available

for individuals who have lost a part of the hand or finger.

## Medical Technology Assessment Committee(MTAC)

### Controlled Upper Limb Prosthesis

08/11/2004: MTAC REVIEW

**Evidence Conclusion:** There is minimal published data on the microprocessor- controlled upper limb prosthesis. These data do not provide evidence on the benefit of using these more sophisticated prostheses in improving health outcomes of the amputees, their impact on their physical and social activities, or to suggest which patients will benefit more with using them.

**Articles:** The search yielded 35 articles. The majority dealt with the technical aspects and mechanisms of action of the prostheses. The search did not reveal any randomized controlled trials. Only one case series (N=18) that investigated the satisfaction level of young users of myoelectric prosthesis was identified. This was a small case series, and did not involve a microprocessor.

Controlled upper limb prosthesis in the treatment of members with missing or amputated upper limb does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Uvulopalatopharyngoplasty (UPPP)

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

The LCD is retired.

##### For Non-Medicare Members

Group Health has elected to use the Uvulopalatopharyngoplasty (GHC-0245) MCG\* for medical necessity determinations.

**MCG\* are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 12 months of clinical notes from requesting provider and/or specialist (pulmonary, ENT)
- Most recent sleep study results

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Sleep-disordered breathing includes a spectrum of disorders ranging from primary snoring to obstructive sleep apnea (OSA). Obstructive Sleep Apnea Syndrome (OSAS) is defined as an apnea-hypopnea index of more than five events per hour, and often also have mental or physical effects such as excessive daytime sleepiness. Potential health consequences of OSAS are cardiovascular diseases, neuropsychiatric problems, injuries and increased mortality. Obstructive sleep apnea results from a combination of a structurally small upper airway and a loss of upper airway muscle tone.

Methods of treating OSA include weight loss, nasal continuous positive airway pressure (CPAP), surgical or laser resection of the uvula, tonsils or soft palate, or tracheostomy when all other treatments fail. Surgical treatment approach varies, and the results are affected by age, cause of obstruction, and severity of the disease. The best method of treatment remains controversial.

Uvulopalatopharyngoplasty (UPPP) is a surgical procedure used to treat sleep apnea or snoring. It removes excess tissue in the throat in an attempt to widen the airway. The soft tissue removed may include the uvula, tonsils, adenoids, tongue or roof of the mouth. It takes 2 to 3 weeks to recover from the surgery.

#### Medical Technology Assessment Committee (MTAC)

1997 Literature Search

**Articles:** Based on the literature below there is limited evidence of the value of LAUP or UPPP in the treatment of OSAS (Obstructive Sleep Apnea Syndrome). While there is strong evidence supporting the value of CPAP in the treatment of OSAS, compliance in the use of the CPAP device remains a problem. Anand-V-K, Ferguson-P-W, Schoen-I-S, Obstructive sleep apnea: comparison of continuous positive airway pressure and surgical treatment, Otolaryngology-Head-Neck Surgery. Sept: 105(3) 382-90. Retrospective review, 400 cases of patients diagnosed with OSA (Obstructive Sleep Apnea). A comparative analysis with polysomnography revealed superior cures with CPAP, although long term compliance remains problematic. Conclusion was use of CPAP as initial therapy in patients with no clinically apparent causes for obstruction: nasal polyps, deviated nasal septum, or obstructive tonsillar hypertrophy. Mickelson, SA., Laser-Assisted Uvulopalatoplasty for Obstructive Sleep Apnea, Laryngoscope: 106(I Pt 1): 10-3, 1996 Jan. Study Size 34, Consecutive prospective patients; Improved RDI by at

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

least 50% in 53.8% of the study group. Snoring was reduced by 92.3%. Conclusion: Results suggest that LAUP MAY be efficacious in management of OSAS. Vaidya AM, Petruzzelli GJ., McGee D., Gopalsami C., Identifying obstructive sleep apnea in patients presenting for laser-assisted uvulopalatoplasty, Laryngoscope: 106(4): 431-7 1996 Apr. 850 patients with snoring evaluated. While body mass index, falling asleep while driving, snoring every night, and stopping breathing during sleep were found to correlate strongly with increasing RDI (Respiratory Disease Index), it was strongly recommended that a referral for PSG (polysomnography Study) be initiated if there is any suspicion of OSAS. Walker RP, Grigg-Damberger MM, Gopalsami C, Totten MC., Laser-assisted uvulopalatoplasty for snoring and obstructive sleep apnea: results in 170 patients, Laryngoscope. 105(9 Pt 1): 938-43, 1995 Sept July 1993 - December 1994, 541 consecutive patients referred for treatment of snoring. 274 had LAUP treatments. As of January 1995 LAUP treatment courses were completed for 170 patients. 105 had diagnosis of snoring and 65 had diagnosis of OSAS based on preoperative polysomnography. Of the 65 OSAS patients 16 cases achieved success as measured on post-op polysomnography. Conclusion: LAUP may be a viable surgical option for patients with snoring and mild sleep apnea. Schechtman KB, Sher AE., Piccirillo JF., Methodological and statistical problems in sleep apnea research: the literature on Uvulopalatopharyngoplasty. Sleep 18(8): 659-66 1995 Oct. A comprehensive review of the literature on surgical treatment of sleep apnea found 37 appropriate papers (total n = 992) on UPPP. Problems identified: 1) There were no randomized studies and few (n=4) with control groups. 2) Median sample size was only 21.5; thus statistical power was low and clinically important associations were routinely classified as "not statistically significant". 3) Only one paper presented the confidence bounds that might distinguish between statistical and clinical significance. 4) Because of short follow-up times and infrequent repeat follow-ups, little is known about whether UPPP results deteriorate in time. 5) In at least 15 papers, bias caused by retrospective designs and nonrandom loss to follow-up raised questions about generalizability of results. 6) Few papers associated polysomnography data with patient-based quality of life measures. 7) Missing data and inconsistent definitions were common. 8) Baseline measures were often biased because the same assessment was inappropriately but routinely used for both screening and baseline. LU SJ, Chang SY., Shiao GM., Comparison between short-term and long-term post-operative evaluation of sleep apnea after Uvulopalatopharyngoplasty. Journal of Laryngology & Otology. 109(4): 308-12 1995 Apr. Sample 15 OSAS patients who had UPPP with pre-operative, initial post-operative and long-term post-operative polysomnography studies (more than 5 years after surgery). The subjective improvement after operation is not adequately correlated to the PSG results. Suggestion that long-term follow-up for patients after UPPP is necessary. Watson, Robert K., Thompson, A. Siobhan: Treatment Outcome of Sleep Apnea. CONN Med. 56: 125-129, 1992. 101 patients. Interviewed over 12-24 month period. CPAP most often treatment used with results of improved daytime alertness (84%). Patients with moderate OSA often had surgery which led to 85% improved daytime sleepiness, and patients with mild OSA were treated with sleep position change and weight loss with 64 - 66% improved daytime alertness.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Benign prostatic hyperplasia (BPH) is most common among men between 50 to 60 years old. BPH growth is associated with aging and varies from person to person. The doubling time of BPH growth is 4.5 years and 10 years between the ages of 31- 50 and 51 to 70 respectively [1]. Although the exact etiology is not well known, BPH is characterized by an augmentation of epithelial and stroma cells in the periurethral region of the prostate [1] resulting in a compression of the wall of the urethra and a decrease of the urine flow. Men with BPH present with low urinary tract symptoms (LUTS), including urinary frequency, urgency, intermittency, hesitancy, nocturia, straining, incomplete emptying, or weak urinary stream [2]. These conditions compromise erectile function and result in low quality of life (QOL) and depression. BPH are generally evaluated by using one of the following scores: the American Urological Association Symptom Index (AUASI) and the International Prostate Symptoms Score (IPSS). AUASI is a self-administered questionnaire with symptoms scores ranging from 0 to 35 with higher scores (>20) equivalent to severe symptoms. The IPSS includes AUASI and QOL questions [1].

Various management options are available for BPH symptoms. These include watchful waiting, surgery, radiation, and medication such as  $\alpha$ -1 blockers, 5- $\alpha$ - reductase inhibitors, antimuscarinics, beta-3 adrenoreceptor agonists or phosphodiesterase-5 inhibitors (PDE5i). Surgery, which is recommended in case of complications or if medical management fails, consists of transurethral resection of the prostate (TURP) and has been associated with various adverse events affecting erectile function and QOL [1]. However, Prostatic Urethral Lift (PUL or UroLift), a novel therapeutic approach is believed to conserve erectile function.

The Prostatic Urethral Lift (UroLift) is a minimally invasive procedure that provides anterolateral mechanical traction of the lateral lobes of the prostate, reducing obstruction and opening the urethral lumen. The procedure is carried out transurethrally under local or general anesthesia [3]. The system is composed of a UroLift Delivery Device and a UroLift Permanent Implant. The UroLift Delivery Device is positioned through the obstructed urethra to access and compress one lateral lobe of the prostate toward the capsule. The implant, made with nitinol, stainless steel urethral end piece and polyethylene terephthalate suture (PET), is attached in the urethra and the other end anchored to the outer part of the prostatic capsule, retracting the prostatic lobe and liberating the urethral lumen. The procedure is performed endoscopically with minimal incision or thermal injury of the prostate. Multiple implants can be introduced

during each procedure [3].

The Prostatic Urethral Lift was approved by the Food and Drug Administration (FDA) in 2013 and is indicated for the treatment of symptoms due to urinary outflow obstruction secondary to benign prostatic hyperplasia (BPH) in men age 50 and above. The technology has not been reviewed previously by MTAC. It is being reviewed for the first time based on a request from the Clinical review Unit for coverage decision.

## Medical Technology Assessment Committee (MTAC)

### ***Prostatic Urethral Lift (PUL or UroLift) for the treatment of benign prostatic hyperplasia (BPH)***

#### **03/21/2016: MTAC REVIEW**

**Evidence Conclusion: Conclusion from INTC review** - "Urolift may be viable alternative to TURP for patients with LUTS secondary to BPH. Short-term data from low to moderate quality, industry-funded studies conclude that Urolift is effective and safe. The overall quality of the evidence is low to moderate. However, due to concerns regarding risk of bias in these studies, a definitive conclusion regarding the long-term safety and effectiveness of UroLift cannot be made from existing evidence. Additional, high quality studies with longer follow-up are needed to confirm preliminary findings".

**Articles:** Since the search did not identify new studies, and because INTC evidence review is recent, their review can be adopted. In addition, the search did not find studies comparing PUL to medical management. [See Summary of RCTs.](#)

The use of Prostatic Urethral Lift (PUL or UroLift) for the treatment of benign prostatic hyperplasia (BPH) does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### UroVysion FISH Test

- Assay Tests for the Diagnosis of Bladder Cancer

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

[Palmetto GBA - Bladder Tumor Marker FISH Coding and Coding Guidelines](#)

CPT codes – 88120 88121

#### For Non-Medicare Members

UroVysion FISH test is covered for members with a suspected new diagnosis of bladder cancer or known prior history of bladder cancer, who have an atypical cytology in spite of normal cystoscopy and upper tract imaging.

A negative test will preclude further evaluation and a positive test either increases the frequency of surveillance or prompts urothelial biopsy.

The FISH test is not covered when used for all other indications, such as, screening for bladder cancer or for the evaluation of hematuria. The tests below are not covered for any indication:

- BTA Stat test
- NMP22 test
- Aura-Tek FDP test

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

In 2012, cancer of the urinary bladder accounted for 73,510 new cases and 14,880 deaths in the USA, making it the sixth most common and tenth most lethal malignancy in the country (Siegel, Naishadham et al. 2012). Most patients present with superficial low-grade transitional cell carcinoma which is readily resectable and, in some cases, requires additional chemotherapy or immunotherapy (Rouprêt, Babjuk et al. 2013). Although these tumors have a high recurrence, they usually do not invade the bladder wall or metastasize. One third of incident bladder cancers, however, progress into invasive cancer presenting as solid, nonpapillary tumors with a high propensity for metastasis requiring radical therapy. The five year survival rate for these tumors is only 30-50% (Arentsen, de la Rosette et al. 2006). Thus, patients with a history of bladder cancer are routinely monitored for recurrence

At present, the diagnosis of both primary and recurrent bladder tumors relies upon both cystoscopy and cytology, of which, neither is completely accurate (Mian, Lodde et al. 2003). Cystoscopy is an efficient method, however, it is invasive, causes patient discomfort, may be associated with a risk of urethral and bladder neck stricture and might not detect flat tumors or carcinoma in situ (false negative rate of 30%) (Daniltchenko, Riedl et al. 2005; Denzinger, Burger et al. 2007). Cytology, often used as an adjunct to cystoscopy, has a poor sensitivity for low grade tumors and frequently the results are inconclusive for malignancy (Nabi, Greene et al. 2004). In addition, patients with atypical cytology pose a challenging problem due to uncertainty about the presence of cancer. Options for management of this predicament include observation with the possibility of missing a diagnosis or biopsying every patient.

Due to the limitations of cytology, molecular-based detection techniques represent potentially attractive strategies for noninvasive detection of aggressive bladder cancer using urine as the specimen source. Among these is the UroVysion™ Kit, a multi-target, multicolor FISH assay designed to detect aneuploidy for chromosomes 3, 7, 17 or the loss of the 9p21 locus (Sarosdy, Schellhammer et al. 2002). Better performance has been reported in detecting carcinoma in situ and high-grade tumors (Lokeshwar, Habuchi et al. 2005).

UroVysion (Abbott-Vysis, Wiesbaden, Germany) was approved by the FDA in January 2005 for the cytologic detection of cancer cells in voided urine specimens.

## Medical Technology Assessment Committee (MTAC)

### UroVysion FISH Test

#### 10/13/2004: MTAC REVIEW

**Evidence Conclusion:** The studies reviewed compared the performance of the UroVysion FISH test to the other noninvasive tests used to detect new or recurrent urinary bladder carcinoma, using voided urine specimens. Cystoscopic evaluation (or bladder resection) with histopathologic studies for the suspicious cases was used as gold standard. All studies were conducted among patients referred to cystoscopy for a history of bladder carcinoma, or urinary signs/symptoms. Sarosdy's study only included patients with a history of transitional cell carcinoma, and Halling as well as Placer included patients with either a history of urothelial carcinoma or other genitourinary symptoms and signs. The ages of the study subjects ranged from 28 to 98 years, and the majority were men. Patient characteristics and inclusion criteria provided were insufficient, exclusion criteria were not discussed, and except for one study with consecutive patients, the authors do not explain how the subjects were selected for the studies. None of the studies evaluated the test as a screening tool, and none evaluated its role in improving the management of urothelial carcinomas. Overall the studies reviewed showed that FISH test was more sensitive than urine cytology in detecting new or recurrent bladder carcinomas among the patients studied. The specificity of the two tests was similar. Compared to the gold standard of cystoscopy/histopathologic evaluation, the overall sensitivity of FISH assays ranged from 71% to 81%, and the overall specificity ranged from 66% in Sarosdy et al's study to 96% in Halling et al's study. The test appears to be more sensitive in detecting later stages, and higher grades of the disease however; the numbers of patients in the subgroups were too small.

**Articles:** The search yielded 29 articles. There were 14 studies that compared the FISH test with cytologic analysis and/or other tests. In five of these studies the urine specimens were obtained from bladder washings during cystoscopy. These studies were excluded as this review deals specifically with the noninvasive UroVysion FISH test using voided urine specimens. Nine studies on UroVysion FISH test in voided urine were identified. Sensitivity and/or specificity of the test was/were not reported in three of the studies. Four of the remaining studies that had a gold standard, and reported sensitivity and specificity were critically appraised. Selection of these studies for critical review was based on the sample size and validity of the study methodology. *The following articles were critically appraised*: Sarosdy MF, Schellhammer P, Bokinsky, et al. Clinical evaluation of a multi-target fluorescent in situ hybridization assay for the detection of bladder cancer. *J Urol* 2002;168:1950-1954. See [Evidence Table](#) Halling KC, King W, Sokolova I, et al. A comparison of cytology and fluorescence in situ hybridization for the detection of urothelial carcinoma. *J Urol* 2000;164:1768-1775. See [Evidence Table](#) Halling KC, King W, Sokolova I, et al. A comparison of BTA stat, hemoglobin dipstick, telomerase and vysis assays for the detection of urothelial carcinoma in urine. *J Urol* 2002;167:2001-2006. See [Evidence Table](#) Placer J, Espinet B, Salido M, et al. Clinical utility of a multiprobe FISH assay in voided urine specimens for the detection of bladder cancer and its recurrence, compared with urinary cytology. *Eur Urol* 2002;42:547-552. See [Evidence Table](#)

The use of UroVysion FISH test in the evaluation of new or recurrent urinary bladder carcinoma does not meet the *Group Health Medical Technology Assessment Criteria*.

### UroVysion FISH Test

#### 6/17/2013: MTAC REVIEW

**Evidence Conclusion:** The accuracy of the UroVysion FISH assay for the diagnosis of bladder cancer in patients with atypical cells has two major components, validity and precision. In this context, the validity of the UroVysion FISH assay refers to the degree to which it does what it is designed to do (i.e. detect urothelial carcinoma of the bladder) and the precision refers to its reliability or its consistency from one application to the next. In both of the selected studies, the validity of the FISH assay was measured by testing every patient who underwent cystoscopy and cytology with atypical cells within a certain time frame and then reviewing the clinical and pathological data on each patient for congruence. The end result, in both studies, was sensitivity and specificity which allows us to measure how well the test classifies people with the cancer as sick and those without cancer as healthy. In addition, two other measures, positive and negative predictive values, were determined to measure how well the test performed in the given population. Both of the selected studies employed similar methodologic techniques. The UroVysion test was performed on all patients presenting with atypical cytology, both with and without cancer history, within a certain time frame. Results were reviewed comprehensively to evaluate the clinical and pathological data on each patient. Clinical stage was assigned by the operative surgeon and all cytology results were interpreted by an experienced cytopathologist, who was blinded to clinical findings. Cytology results were considered atypical if it was not unequivocally positive or negative. The results of both studies show that the use of the UroVysion test is beneficial in patients with equivocal and negative cystoscopy. Lotan and colleagues found in patients with no cancer history the sensitivity was 77.8% and the specificity was 100% and in patients with cancer

history the sensitivity and specificity were both 100%. These findings were validated by Schlomer and colleagues results which show that in patients with cystoscopically visualized lesions UroVysion had a positive predictive value of 100% but there were false negative results. In patients with equivocal cystoscopy and a history of cancer all four high grade tumors were detected and there were no false negative findings. In patients with equivocal cystoscopy and no prior cancer the positive predictive value was 100% and there were no false negative results. In patients with negative cystoscopy the UroVysion test detected all cancers but the positive predictive value was 10% and 29% in patients with and without a history of cancer, respectively. Although these prospective studies indicate that the use of UroVysion in patients with atypical cytology is beneficial in identifying cancer in patients with atypical results they come with limitations. First and foremost, both studies are working with relatively small samples threatening the generalizability of the study. In addition to the small samples, both studies yielded and excluded uninformative UroVysion results. Furthermore, both studies employed more than one diagnostic technique which leads to potential bias. It should also be noted that the UroVysion FISH assay has been approved by the FDA as a noninvasive tool for the detection of cancer cells through voided urine. A portion of the sample collections described in the two prospective studies included specimens that were obtained via bladder washings during cystoscopy which makes comparison difficult with studies that solely used voided urinary samples.

#### For Non-Medicare Members

Group Health has elected to use the Traction, Spine (A-0345) MCG\* 20<sup>th</sup> edition for medical necessity determinations. This service is not covered per MCG guidelines.

**\*The MCG manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider &/or specialist

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Chronic lower back pain is a major health problem and cause of disability in Western countries. The cause of the persistent pain is not well understood for the majority of patients. It generally occurs without specific damage or signs that can be revealed by imaging or other neurophysiological techniques. It is believed that the pain starts as acute pain of muscle and connective tissue and persists among approximately one third of the patients (Rittweger 2002). Mechanical low back pain may have various causes including degenerative disc disease, degenerative spondylosis, disc herniation, facet arthropathy, and others. Patients with low back pain may also experience reduced lumbar flexibility, reduced flexion-relaxation and static balance. The pain is aggravated by sitting, standing and lifting, which increase axial loading on the spine. Walking may relieve some of the pain but patients experience more relief by lying down as it unloads the spine and reduces intradiscal pressure (Gose 1998).

Conservative medical care for chronic back pain includes bed rest, steroid injection, anti-inflammatory drugs, muscle relaxants, conventional physiotherapy, exercises, stretching, manipulative techniques, ultrasound treatments, electric stimulation techniques and others. These measures ease the pain for some patients but are ineffective, intolerable, or unsuitable for others. Patients not responding to conservative therapy may be offered conventional or percutaneous surgical procedures such as disc space decompression, epidural blocks, and spinal instrumentation. These interventions play an important role in treating patients with low back pain due to herniated disc and degenerative disc problems. However, surgery may not relieve all the pain, and could permanently disrupt the biomechanical and physiological function of the disc. Moreover, not all patients are candidates for surgery.

Some researchers have found that lumbar traction, if adequately applied, may alleviate many of the conditions that cause low back pain. Conventional traction involves simple mechanical stretch which when applied continuously, or by certain techniques, may lead to paravertebral muscle recruitment and increase the intradiscal pressure (Ramos 1994). This observation led to the continuous development of devices and equipment that would achieve

decompression of the lumbar discs at a force that the patients can tolerate without stimulating the reactive reflexes of the lumbar musculature (Gose 1998), i.e. without an increase in the resistance to the applied force.

Several systems for vertebral axial decompression have been introduced including the VAX-D equipment, and the Decompression Reduction Stabilization (DRS) System later developed to the Spina System then the Accu-spina Logic System. According to the manufacturer's web site, the latter system provides lumbar decompression, cervical decompression, and high tension oscillation all in one machine, which is also certified to administer IDD therapy treatments.

The VAX-D applies distraction tensions to the patient's lumbar spine in order to non-surgically decompress the spine and intervertebral discs. The patient lies prone on the VAX table that has a split design, and is restrained by holding on to adjustable handgrips with the arms extended above the head to stabilize the shoulder girdle and upper body. Patients are allowed to release the handgrips at any time during the treatment. The upper body lies over a stationary portion, and a special harness designed to apply forces to the lateral pelvic alae is fitted and tightened around the patient, and connected to a tensionometer at the caudal end of the table. The distraction-relaxation cycles are automated, and continuous feedback from the tensionometer is captured on a chart printout, which allows the operator to constantly monitor the patient. The therapy consists of an average of 20 sessions comprising 15 cycles of decompression and relaxation. The cycles are characterized by one minute of distraction and one minute of relaxation. The therapeutic range of tension is 50-95 pounds, which is reduced by 10-15 pounds when the patients are asymptomatic or the symptoms have reached a plateau. The investigators of this technology indicate it for patients with low-back pain associated with herniated discs, or degenerative disc disease, and contraindicate it for patients with cauda equine syndrome, infection, tumor severe osteoporosis, fractures, bilateral pars defect, spondylolisthesis Grade 2, and the presence of surgical hardware (Ramos 2004).

The Spina IDD System is also a non-invasive procedure that provides static intermittent and cyclic distraction forces to relieve the pressure on structures causing chronic neck or lower back pain. The system consists of a table split into two cushions, and a controller unit. The patient is anchored by means of a pelvic harness to the traction connector for the prescribed period of time. The therapy is provided in 20 treatment sessions over a period of 35 days. Each session lasts for approximately 30 minutes.

Both the VAX-D System and the Spina System were cleared by the FDA as Class II Medical devices 510 (k). The technology is being reviewed based on requests for coverage of the Internal Disc Compression Therapy.

## Medical Technology Assessment Committee (MTAC)

### *Internal Disc Decompression Therapy in the Treatment of Pain from Spinal Disc Problems*

#### **06/09/1999: MTAC REVIEW**

**Evidence Conclusion:** The published scientific evidence reporting clinical outcomes from VaxD treatment consists of a case series of 778 patients diagnosed with herniated or degenerated lumbar discs or facet syndrome. This study reports improvements in pain, mobility, activity and satisfaction following treatment. The validity of these results are uninterpretable however because no statistical analysis was reported and no information on the length and completeness of patient follow up was presented. Another small retrospective case series of 17 patients reports some changes in sensory nerve function as measured by a Current Perception Threshold neurometer following VaxD but the relationship between these changes and clinical improvement is unclear. The published evidence is not sufficient to determine if the benefits of Vax-D outweigh the harms of treatment. No studies which compare benefits and harms of Vax-D to the natural history of disc related low back pain have been published. Data from the large case series was obtained from 22 medical centers in the US. However, a lack of statistical analysis of this data does not permit conclusions to be made regarding the effect of Vax-D on back pain. The best published evidence is insufficient to demonstrate that Vax-D is effective and therefore Vax-D does not represent an efficient use of healthcare resources.

**Articles:** Gose, EA, et al, Neurological Research, 1998, 20:186-190 See [Evidence Table](#).

The use of internal disc decompression therapy in the treatment of pain from spinal disc problems does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **02/06/2006: MTAC REVIEW**

### *Internal Disc Decompression Therapy in the Treatment of Pain from Spinal Disc Problems*

**Evidence Conclusion:** The literature search did not reveal any published studies on the IDD Therapy or the Spina System. The latter received FDA Clearance, in July 2000 based on its equivalence to the vertebral axial decompression device (VAX-D). There was one randomized trial and few case series published on the VAX-D. The RCT and a large series were critically reviewed. Sherry et al randomized 44 patients, 18-65 years old, with

chronic low-back pain to receive either vertebral axial decompression (VAX-D) or transcutaneous electrical nerve stimulation (TENS) therapy. The primary outcome was the difference in proportion of successfully treated patients in the two treatment groups. Success of treatment was defined as 50% decrease in pain on the visual analogue scale and improvement in disability. The trial was small, poorly randomized, un-blinded, and had a high dropout rate. The authors did not conduct an intention to treat analysis, but calculated their results on data for patients who completed therapy and follow-up, and concluded that VAX-D therapy was associated with a significant reduction in pain and disability. They compared the therapy to TENS, which seems to have a negative effect. A recent Cochrane Systematic Review (Khadiilkar 2005) of published RCTs evaluating the effect of TENS on lower back pain, showed that the efficacy of TENS therapy was limited and inconsistent. Gose et al, reported the results of 778 patients with low back pain who had received at least 10 sessions of VAX-D therapy in 22 centers in the USA. The primary outcome was reduction in pain, improvement in mobility, ability to walk and sit, and patient satisfaction with the treatment. The study was only observational, and had no control or comparison group. Moreover, all outcomes were subjective, and apparently there was no extended follow-up after the end of treatment. Overall, the results show that the treatment was successful among 71% of cases, with treatment success defined as a reduction in pain to 0 or 1 on a 0-5 scale. In conclusion, the current literature does not provide sufficient evidence to recommend the use of the VAX-D therapy, or the Spina System for the management of chronic low back pain. Larger, multi-center randomized controlled trials are needed to determine the effectiveness and long-term net health outcomes of the therapy. The published scientific evidence reporting clinical outcomes from VaxD treatment consists of a case series of 778 patients diagnosed with herniated or degenerated lumbar discs or facet syndrome. This study reports improvements in pain, mobility, activity and satisfaction following treatment. The validity of these results are uninterpretable however because no statistical analysis was reported and no information on the length and completeness of patient follow up was presented. Another small retrospective case series of 17 patients reports some changes in sensory nerve function as measured by a Current Perception Threshold neurometer following VaxD but the relationship between these changes and clinical improvement is unclear.

**Articles:** The search yielded 20 articles several of which were not related to the devices. Four studies on the vertebral axial decompression therapy using the VAX-D device were identified. One was a RCT comparing it to TENS, and the other three were case series with patient sizes varying from 5 to 778 patients. The RCT and the largest case series were selected for critical appraisal. No articles on the Spina System were identified. *The following articles were critically appraised:* Sherry E, Kitchener P, and Smart R. A prospective randomized controlled study of VAX-D and TENS for the treatment of chronic low back pain. *Neurol Res* 2001;53:780-784. [See Evidence Table.](#) Gose EE, Naguszewski WK, and Naguszewski RK. Vertebral axis decompression therapy for pain associated with herniated or degenerated discs or facet syndrome: An outcome study. *Neurol Res* 1998;20:186-190. [See Evidence Table.](#)

The use of internal disc decompression therapy in the treatment of pain from spinal disc problems does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Vectra DA (Multiple Biomarker Disease Activity [MBDA])

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

The MolDX Team has completed the Vectra DA assessment and determined that the test meets criteria for analytical and clinical validity, and clinical utility as a reasonable and necessary Medicare benefit. [See Link here.](#)

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder that primarily involves synovial joints. It is debilitating disease that if uncontrolled, may lead to joint destruction, functional disability, and premature death. It is thus important to detect RA early, and to control the disease as soon as possible after diagnosis to delay its progression and preserve physical function.

Treatment of RA has shifted from symptom management, to reducing the disease activity and delaying its progression. Recent guidelines recommend treating RA promptly and aggressively aiming for remission as a therapeutic target (tight control or treatment-to-target strategy). Tight control may be defined as a treatment strategy tailored to the disease activity in individual patients with RA with the aim of achieving a predefined level of low disease activity, or preferably remission within a reasonable period of time. The availability of an increasing number of biologic and non-biologic effective disease-modifying anti-rheumatic drugs (DMARDs) has allowed the achievement of this treatment goal, but requires close monitoring of the disease activity, which is the cornerstone of tight control (Bakker 2007, Anderson 2012, Curtis 2012, Peabody 2013, Segurado 2014, Michaud 2015).

There are a number of composite tools available for assessing RA disease activity, six of which have been recommended by the American College of Rheumatology (ACR): Clinical Disease Activity Index (CDAI), Disease Activity Score with 28-joint counts (DAS28), Patient Activity Scale (PAS), PAS-II, Routine Assessment of Patient Index Data with 3 measures (RAPID-3), and Simplified Disease Activity Index (SDAI). These indices are based on information obtained from clinical, laboratory, and physical measures that include quantitative joint counts, patient reported outcomes, physician examination, and laboratory test including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). These composite measurements are of great importance, but are complicated, may have intra- and inter-observer variability, are unable detect subclinical synovial damage, and may be influenced by cumulative damage and other conditions unrelated to RA (Anderson 2012, Curtis 2012, Owens 2015).

More recently, researchers have been investigating biomarkers to complement the clinical assessment of RA and improve the evaluation of disease activity. No single biomarker has been found to accurately assess RA activity, and it is hypothesized that a combination of biomarkers that measure diverse pathways to RA may have the potential of providing objective information on disease activity (Curtis 2012, Hirata 2013).

Vectra DA (Crescendo Bioscience, South San Francisco, CA), is a commercially available blood test that measures the serum concentration of 12 biomarkers and combines them into an algorithm to generate a multibiomarker disease activity (MBDA) score. The biomarkers included in Vectra DA test are: VCAM-1 (vascular cell adhesion molecule-1), EGF (epidermal growth factor), VEGF-A (vascular endothelial growth factor A), IL-6 (interleukin-6), TNF-RI (tumor necrosis factor receptor, type 1), MMP-1 (matrix metalloproteinase-1 or collagenase-1), MMP-3 (matrix metalloproteinase-3 or stromelysin-1), YKL-40, SAA (serum amyloid), CRP (C-reactive protein), leptin, and resistin. The score generated by the test is believed to represent the level of RA disease activity on a scale of 1 (lowest activity)

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

to 100 (greatest activity). According to the manufacturer a score between 45 and 100 indicates high level of disease activity; 30 to 44 indicates moderate disease activity; and 1 to 29 indicates a low level of disease activity. Vectra DA test is not intended or validated to diagnose RA, but as an aid in the assessment of disease activity in adults RA patients when used in conjunction with standard clinical assessment (Curtis, 2012, Peabody 2013, Michaud 2015, Vectra.com).

## Medical Technology Assessment Committee (MTAC)

12/21/2015: MTAC REVIEW

### Vectra DA Test for Rheumatoid Arthritis

**Evidence Conclusion:** *Analytic validity* - Eastman and colleagues (2012), evaluated the analytical performance of each of the individual biomarker assays that comprise the MBDA test and the generated MBDA score. The investigators quantified the 12 serum biomarkers and found that all 12 individual assays exhibit a high level of precision with minimal cross-reactivity and interference by substances commonly seen in RA patients. The total MBDA score had good reproducibility over time with a median coefficient of variation of <2% across the score range. The same MBDA score was observed in different subjects with different biomarker profiles (Eastman 2012). *Clinical validity* - The published literature on the clinical validity of the MBDA Vectra DA test consists of observational cohort studies and posthoc analyses of randomized controlled trials performed for other reasons and among patients for whom serum samples were available to retrospectively evaluate the Vectra DA test. The studies correlated the MBDA score with other validated measures used for disease activity (mainly DAS28-CRP), radiographic joint progression, or response to therapy, and had no long-term follow-up to determine the test ability to predict clinical outcomes. Curtis and colleagues (2012), prospective cohort study (Evidence table 1): The authors used blood samples for 371 patients from 3 diverse RA cohorts in North America and Europe to validate the MBDA scores against DAS28-CRP (Disease Activity Score in 28 joints using the C-reactive protein level) as the reference measure for disease activity. The analysis of the results showed that MBDA score was positively, but moderately correlated with DAS28-CRP in both seropositive and seronegative patients (correlation coefficient  $r = 0.56$  and  $0.43$  respectively). The area under the receiver operating characteristic curve (AUROC) for discriminating low disease activity from moderate disease activity was 0.77 for seropositive patients and 0.70 for seronegative patients. The analysis also showed that changes in the MBDA scores at 6-12 weeks were significantly correlated with the corresponding changes in DAS28-CRP (Spearman's correlation coefficient  $r_s = 0.51$ ). The study did not adjust for confounding factors, and did not evaluate the ability of the test to predict long-term outcomes of RA. In addition it was partially supported by Crescendo Bioscience, the company manufacturing the laboratory test, and the authors had financial ties to the company. Bakker, et al (2012), Posthoc analysis of a completed randomized controlled trial (Evidence table 2): The investigators evaluated the performance of individual biomarkers and a MBDA (Vectra DA) test score in a subset of RA patient population enrolled in the Computer Assisted Management in Early Rheumatoid Arthritis (CAMERA) tight control study. Only patients with available serum samples were included in the study evaluating the performance MBDA test (72 patients out of the 299 enrolled in CAMERA trial). There were significant differences between the patients with available samples versus those without. Blood samples were obtained from 72 patients at baseline and from 46 patients after treatment. MBDA scores were calculated and the performance of the Vectra DA test was evaluated relative to DAS28-CRP. The analysis showed that MBDA score had a significant correlation with DAS28-CRP ( $r=0.72$ ;  $p<0.001$ ) and an area under the receiver operating characteristic curve for distinguishing remission/low from moderate/high disease activity of 0.86 ( $p<0.001$ ) using a DAS28-CRP cut-off of 2.7. The agreement of MBDA score with DAS28-CRP for classifying disease activity was fair (kappa score =0.34, 95% CI 0.19-0.49). The results also showed that MBDA score decreased from  $53\pm 18$  at baseline to  $39\pm 16$  at 6 months in response to study therapy ( $p<0.0001$ ). Neither MBDA score nor DAS28-CRP was predictive of radiographic progression. The study was based on posthoc analysis of data from a completed trial, did not adjust for confounding factors, and did not evaluate the ability of the test to predict long-term outcomes of RA. The study was supported by Crescendo Bioscience, and the authors had financial ties to the company. Hirata and colleagues (2013) evaluated MBDA score in 125 patients with RA from the Behandel Strategieën (BeSt) study. Data and serum samples were available from 179 visits (91 at baseline and 88 at year 1). The results showed that the MBDA scores was significantly correlated with DAS28-ESR (Spearman's rank correlation coefficient  $r_s=0.66$ ). It was also correlated with simplified disease activity index (SDAI), clinical disease activity index (CDAI). Changes in MBDA between baseline and year 1 were also correlated with changes in DAS28-ESR (assessed in a subgroup of 54 patients,  $r_s=0.55$ ). The study was also a posthoc analysis of patients enrolled in BeSt study, was supported by Crescendo Bioscience, Inc., and the authors had financial ties to the company. *Prediction of radiographic joint progression* - Posthoc analyses of two RCTs: SWEFOT (Hambardzumyan et al, 2015) and BeSt [Markusse et al, 2014) suggest that MBDA scores may predict radiographic damage progression in patients with RA. These analyses had their limitations including, but not limited to the use of data obtained from RCTs designed primarily to compare different RA therapies, the patients included in the trials do not represent all RA patients as those with low DAS28 were excluded, patients were not randomized to therapy based on their MBDA scores, these scores were only available at baseline, and after 1 year

(in one trial). In addition patients in SWEFOT trial switched from one drug to another during the trial, which could affect radiographic outcomes, and the treatment-to-target strategy in BeSt trial suppressed inflammation and progression of radiographic joint damage in the majority of patients. A more recently published retrospective observational study (Li, 2015) with its limitations also suggest that MBDA score may enhance the ability to predict radiographic progression in patients with RA treated with non-biologic DMARDs. In conclusion, the published studies on the relationship between MBDA and radiographic joint damage had their limitations and do not provide sufficient evidence to determine the value of MBDA in predicting progression of radiographic joint damage in patients with rheumatoid arthritis. *Clinical utility*- There are no published RCTs, to date, that compared a management strategy using the MBDA score versus another established measure of disease activity, and reported clinical outcomes such as disease progression, functional status, or quality of life. The studies that evaluated the impact of Vectra DA test on clinical-decision making used simulated cases or physician surveys, and did not report outcome data. Li and colleagues (2013), assessed the impact of MBDA, Vectra DA blood test on RA treatment decisions in 101 patients with RA. The health care providers (HCP) completed surveys before and after viewing the MBDA test result, recorded the dosage and frequency for all planned RA medications and the physician global assessment of disease activity. Frequency and types of change in treatment plan that resulted from viewing the MBDA test result were determined. The results of the study showed that, after reviewing MBDA test results treatment decisions were changed in 38 cases (38%), of which 18 involved starting, discontinuing, or switching a biologic or non-biologic DMARD. Other changes involved drug dosage, frequency or route of administration. The total frequency of use of the major classes of drug therapy changed by <5%. Treatment plans changed 63% of the time when the MBDA test result was perceived as being not consistent or somewhat consistent with the HCP assessment of disease activity. The study had its limitations including the small sample size, lack of a control group, and absence of follow-up to determine the impact on patient outcomes. Rech and colleagues (2015) analyzed the role of MBDA score in predicting disease relapse in patients with RA in sustained remission with tapered disease modifying antirheumatic drug (DMARD) therapy in RETRO trial. This was a RCT that evaluated the possibility of tapering or stopping DMARDs in patients fulfilling classification criteria for RA. The participants were randomized to 3 arms: 1. continuing DMARDs for 12 months, 2. Tapering the treatment by 50%, or 3. Reducing the dose by 50% for the first 6 months before entirely discontinuing the treatment. MBDA scores were calculated from the analysis of baseline serum samples of 94 patients participating in the RETRO trial. Retrospective analysis of data showed that baseline MBDA levels were significantly higher in patients experiencing a relapse vs. those in sustained remission. The analysis was retrospective and does not provide sufficient evidence to determine utility of MBDA in predicting the disease relapse and tapering or discontinuing the use of DMARDs accordingly. Conclusion There is insufficient evidence to determine whether MBDA is as good as or better than other established indices used to measure RA disease activity. The published studies show a moderate correlation between Vectra DA and DAS28-CRP in classifying patients into low vs. moderate to high disease. There is insufficient evidence to determine the clinical validity of Vectra DA test and its ability to predict outcomes. There is insufficient evidence to determine that Vectra DA test results have an impact on the management of patients with rheumatoid arthritis and/or improve their health outcomes.

**Articles:** The literature search revealed a study on the analytic validity of MBDA test score, four studies on the clinical validity of the MBDA Vectra Da test, and few small simulating studies or surveys on the clinical utility of the test. The following two studies on the clinical validity of MBDA test studies were selected for critical appraisal: Bakker MF, Cavet G, Jacobs JW, et al. Performance of a multi-biomarker score measuring rheumatoid arthritis disease activity in the CAMERA tight control study. *Ann Rheum Dis*. 2012 Oct; 71(10):1692-1697. See [Evidence Table 1](#). Curtis JR, van der Helm-van Mil AH, Knevel R, et al. Validation of a novel multibiomarker test to assess rheumatoid arthritis disease activity. *Arthritis Care Res (Hoboken)*. 2012 Dec; 64(12):1794-1803. See [Evidence Table 2](#).

The use of Vectra DA (Multiple Biomarker Disease Activity [MBDA]) test for monitoring disease activity in patients with rheumatoid arthritis does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Treatment of Varicose Veins

- Radiofrequency Catheter Closure
- Sclerotherapy
- Surgical Stripping
- Trivex System for Outpatient Varicose Vein Surgery
- VenaSeal Closure System
- VNUS Closure Device

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

##### Local Coverage Determination (LCD)

##### [Treatment of Varicose Veins of the Lower Extremities \(L34010\)](#)

#### For Non-Medicare Members

- I. For great saphenous vein or small saphenous vein ligation, stab phlebectomy, division, stripping, radiofrequency endovenous occlusion (VNUS procedure), Endovenous Radiofrequency Ablation Treatment (ERFA) and endovenous laser ablation of the saphenous vein (ELAS) (also known as endovenous laser treatment (EVLT) all of the following criteria must be met:
  - A. The patient is symptomatic and has one, or more, of the following:
    1. Pain or burning in the extremity
    2. Recurrent episodes of superficial phlebitis
    3. Non-healing skin ulceration
    4. Bleeding from a varicosity
    5. Stasis dermatitis
    6. Refractory dependent edema
  - B. Vein size is 4.5 mm or greater in diameter (not valve diameter at junction)
  - C. Pre-operative doppler demonstrates reflux (reflux duration of 500 milliseconds (ms) or greater in the vein to be treated).
  - D. In addition all of the following are true for ERFA and laser ablation:
    1. Absence of aneurysm in the target segment.
    2. Maximum vein diameter of 12 mm for ERFA or 20 mm for laser ablation.
    3. Absence of thrombosis or vein tortuosity, which would impair catheter advancement.
    4. The absence of significant peripheral arterial diseases.
- II. Sclerotherapy is covered for up to 6 months after a covered stab phlebectomy, endovenous ablation or a vein stripping. Sclerotherapy can be approved at these same venous sites if symptoms persist associated with persistent varicosities.

#### No evidence to support coverage for:

- A. Treatment of reticular veins, spider veins or superficial telangiectasis by any technique (considered cosmetic)
- B. Procedures with devices not FDA-approved

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Superficial venous reflux occurs when the valves that keep blood flowing out of the veins in the leg become damaged or diseased. Primary symptoms are pain, swelling and varicose veins. The basic treatment is to re-route

blood flow through other healthy veins. This can be done using several techniques: stripping the greater damaged vein, using radiofrequency energy to heat and occlude the vein, and using irritant solution to obliterate the vein.

The conventional treatment is stripping of the greater damaged vein. This procedure has favorable clinical outcomes (REF), but is associated with substantial post-operative morbidity, particularly pain and bruising. Recurrent reflux is possible with the existing treatments and the risk of recurrence increases over time.

Rather than vein stripping, radiofrequency (RF) energy to heat and occlude the damaged vein. RF energy is delivered via collapsible catheter electrodes that are introduced into the vein lumen. The operator sets the target temperature, usually 85°C. The temperature is monitored using a microprocessor-controlled bipolar generator. The procedure is performed on an outpatient basis, using either local or regional anesthesia.

Sclerotherapy is the treatment of veins that are distended, lengthened and tortuous (i.e. varicose veins) by the injection of an irritant solution to encourage obliteration of the veins by thrombosis and subsequent scarring.

The treatment of varicose veins and spider veins can be for either cosmetic purposes or for the improvement of clinical symptoms related to these conditions. In order to identify when the care will be covered a common set of clinical appropriateness criteria were developed.

### ***Radiofrequency Catheter Closure in the treatment of varicose veins***

#### BACKGROUND

Superficial venous reflux occurs when the valves that keep blood flowing out of the veins in the leg become damaged or diseased. Primary symptoms are pain, swelling and varicose veins. The basic treatment is to re-route blood flow through other healthy veins. The conventional treatment is stripping of the greater damaged vein. This procedure has favorable clinical outcomes (REF), but is associated with substantial post-operative morbidity, particularly pain and bruising. Recurrent reflux is possible with the existing treatments and the risk of recurrence increases over time. The VNUS Closure System was proposed as a minimally invasive treatment for superficial venous reflux. Rather than vein stripping, the Closure system uses radiofrequency (RF) energy to heat and occlude the damaged vein. RF energy is delivered via collapsible catheter electrodes that are introduced into the vein lumen. The operator sets the target temperature, usually 85°C. The temperature is monitored using a microprocessor-controlled bipolar generator. The procedure is performed on an outpatient basis, using either local or regional anesthesia. The VNUS Closure System received FDA approval March 1999.

#### 08/13/2003: MTAC REVIEW

#### **Radiofrequency Catheter Closure in the treatment of varicose veins**

**Evidence Conclusion:** The best, published evidence on the VNUS Closure system is a small RCT with n=33 (Rautio et al., 2002). This study found that patients had less pain and fewer sick days a mean of 50 days after the Closure procedure than patients who received the stripping operation. There was no significant difference in quality of life variables. Potential sources of bias in the Rautio RCT include lack of blinding, lack of intention to treat analysis and potential confounding. In addition, the RCT did not have long-term follow-up and did not address the issue of recurrent reflux. Also available are case series data from a multi-center registry (Merchant et al., 2002). 93% of patients had complete The use of Radiofrequency Catheter Closure in the treatment of varicose veins does not meet the Group Health Medical Technology Assessment Criteria. The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations. © Group Health Cooperative. All Rights Reserved. Occlusion after the VNUS Closure procedure. Twelve months after treatment, among the patients with data available, 94% of those with complete occlusion had varicose veins absent and 100% had reflux absent. These findings could be biased because data were missing on 20% of the patients at 12 months. Although the Rautio study suggests short-term benefit of the Closure system compared to the stripping procedure, there is insufficient evidence on long-term effectiveness.

**Articles:** The search yielded 12 articles. The best evidence was a recent case series taken from a multi-center registry and a small randomized controlled trial. The following studies were critically appraised: Rautio T, Ohinmaa A, Perala J. et al. Endovenous obliteration versus conventional stripping operation in the treatment of primary

varicose veins: A randomized controlled trial with comparison of the costs. *J Vasc Surg* 2002;35: 958-65. See [Evidence Table](#). Merchant RF, DePalma RG, Kabnick LS. Endovascular obliteration of saphenous reflux: A multicenter study. *J Vasc Surg* 2002;35: 1190-1196. See [Evidence Table](#).

The use of Radiofrequency Catheter Closure in the treatment of varicose veins does not meet the *Group Health Medical Technology Assessment Criteria*.

### **TriVex System for Outpatient Varicose Vein Surgery**

#### **BACKGROUND**

Because there are no published studies on the TriVex transilluminated powered phlebectomy for outpatient varicose vein surgery, this was documented. Transilluminated phlebectomy is a minimally invasive surgical technique for removing varicose veins. The TriVex system was introduced by Smith & Nephew in 2000. The TriVex resector and TriVex illuminator are placed under the skin through small 2mm vertical incisions on either side of the varicosity. According to Smith & Nephew, "one of the key features of the TriVex system is its ability to light the area beneath the skin. For the first time, the vein is clearly visible, allowing the surgeon to quickly and accurately remove it using a powered resector and then visually confirm its complete extraction."

#### **08/08/2001: MTAC REVIEW**

##### **TriVex System for Outpatient Varicose Vein Surgery**

**Evidence Conclusion:** There are no published studies on the TriVex System Transilluminated Powered Phlebectomy for outpatient varicose vein surgery. We were not given any unpublished data of sufficient quality to review as evidence. In conclusion, there is no evidence on which to base conclusions about the effect of this technology on health outcomes.

**Articles:** No published articles were found. Literature from the manufacturer included conference abstracts that cannot be evaluated as evidence. Conclusion: There is no evidence on which to base conclusions about the effect of this technology on health outcomes.

The use of TriVex in the treatment of Varicose Veins does not meet the *Group Health Medical Technology Assessment Criteria*.

### **VenaSeal Closure System for Varicose Veins**

#### **BACKGROUND**

Chronic venous disorders of the lower limb are estimated to affect approximately 30 million adults or 35% of screened adults in the United States [1] and manifest most frequently like varicose veins. The mechanism underlying varicose veins can be explained by a dysfunctional valve inside the veins. The valves of the superficial veins and those of the Great Saphenous Vein (GSV) transferring blood toward the heart are defective leading to venous dilation and stasis. The accumulation of blood in the vein is responsible for the swelling, pain, chronic skin changes, spontaneous hemorrhage, leg ulcers and fatigue. The progression can be expressed by a reduction of quality of life (QoL) [2].

The management of varicose veins has undergone a shift and a number of treatment options have been described; these include surgery and minimal invasive therapies. Surgery which is represented by ligation and stripping and various surgical techniques are described and involve saphenous vein inversion and removal, high ligation of the saphenous vein, ambulatory phlebectomy, trans illuminated phlebectomy, conservative venous ligation (CHIVA), and perforator ligation. Although surgery improves symptoms and leads to patient satisfaction [3-6], this is associated with hematoma, paresthesia and high recurrence rate [7]. Other treatments reside in thermal-based techniques including endovenous thermal ablation (EVTA) by radiofrequency ablation (RFA) or laser ablation. These techniques are believed to have long-term success (vein closure) rates of 78 to 84 percent [8-10] and necessitate tumescent anesthesia. In contrast, new technique such as venaseal closure system (VSCS) does not seem to require tumescent anesthesia, and has recently been approved for treatment of the incompetent GSV in the European Union, Hong Kong, and Canada [2].

The VenaSeal Closure System (VSCS) permanently treats symptomatic varicose veins of the legs by closing the affected superficial veins with a cyanoacrylate-based adhesive. The VenaSeal System is composed of a catheter, guidewire, dispenser gun, dispenser tips, and syringes. A catheter is introduced through the skin into the varicose vein and a clear liquid (adhesive) is also injected. The insertion of the catheter and the delivery of adhesive are performed under ultrasound guidance. After the delivery of the adhesive, manual compression of the affected area begins and the adhesive changes into a solid to seal the varicose vein. The system is used for patients with venous reflux disease and it seals superficial varicose veins of the legs. Treating the diseased veins generally relieves symptoms. The VenaSeal System should not be used in patients with a known hypersensitivity to the

VenaSeal adhesive or cyanoacrylates, patients who have acute inflammation of the veins due to blood clots and patients with acute whole-body infection (FDA, 2015).

**06/20/2016: MTAC REVIEW**

**VenaSeal Closure System**

**Evidence Conclusion:** The search identified one study that compares VenaSeal Closure System (VSCS) with radiofrequency ablation (RFA). A non-randomized and a prospective studies assessing the efficacy and safety of VSCS were also identified but were not subject to evidence table since no comparison was made. Evidence Table 1: Randomized trial comparing cyanoacrylate embolization and radiofrequency ablation for incompetent great saphenous veins (VeClose) [2] This RCT aimed to demonstrate the non-inferiority of cyanoacrylate embolization (CAE) efficacy compared with radiofrequency ablation (RFA). The primary outcome was the total closure of the target great saphenous vein (GSV) defined as Doppler ultrasound examination (including color flow, compression, and pulsed Doppler) showing closure along the entire treated target vein segment with no discrete segments of patency exceeding 5 cm at the month 3 visit. Adverse events were also assessed. Patients were randomized to CAE performed with VenaSeal Sapheon Closure System or RFA. Patients returned to clinic at day 3, 1 and 3 months. Trial follow-up continues to 36 months after initial treatment. Vein closure was determined by Doppler ultrasound examination and confirmed by an independent vascular ultrasound core laboratory. On day 3, 100% of the GSVs treated were closed in both groups. At month 1, no patency of treated vein was identified with the VSCS vs. 15 patency observed with the RFA with closure rates of 100% and 86% respectively. The Venous Clinical Severity Score (VCSS) had improved by 3.5 points from baseline with no differences between groups. Aberdeen Varicose Vein Questionnaire (AVVQ) had improved by 8 points. Time trade-off (EQ-5D TTO) improved by 0.03 points with no differences between groups. Ecchymosis at day 3 was absent in significantly more subjects after VSCS than after RFA. Post treatment phlebitis was more frequent after VSCS. Most cases of phlebitis were mild. No difference was observed between the mean intraprocedural pain ratings of both groups (2.2 vs. 2.4 P=0.11). No deep vein thrombosis (DVT) or pulmonary embolism was observed. The authors concluded that VSCS was non inferior to RFA for the occlusion of symptomatic incompetent GSVs at 3 months. Nevertheless, the study had some limitations: Patients were not blinding raising the concern of placebo effect and increasing the risk of bias. The duration of follow-up was also short. In addition, the study was funded by Sapheon and some authors had financial interest with Sapheon. Although the assessment of the primary endpoint was objective, patient's pain assessment was subjective resulting in reporting bias. Thus, the results should be interpreted with caution.

**Additional studies:** A non-randomized study case series of 29 patients (fifty seven legs) [11] that evaluated the safety, efficacy and performance of endovenous cyanoacrylate (Sapheon Venaseal Closure System) by assessing the Great Saphenous Vein (GSV) occlusion, Venous clinical severity score (VCSS), Aberdeen Varicose Vein Questionnaire (AVVQ) and the Short Form Health Survey 36 Item (SF-36) questionnaires. Fifty seven legs were included and after one week of follow-up, obliteration was achieved in most patients. At month 1, VCSS, AVVQ and SF-36 physical and mental scores improved from 6.91, 23.66, 44.24, 54.26 to 2.43, 6.10, 43.85, and 52.50 respectively. The closure rates were 98.2% and 78.5% at week 1 and 1 year respectively. The authors conclude that VSCS was safe for the treatment of great saphenous vein reflux. A prospective study of 38 patients performed by Almeida et al [12] indicates that clinical efficacy of endovenous cyanoacrylate for closure of insufficient great saphenous veins was maintained over a period of 24 months.

**Conclusion:**

- Based on low quality evidence, manufacturer sponsored trial, cyanoacrylate embolization (CAE) performed with the VSCS was non inferior to radiofrequency ablation (RFA).
- There is a lack of evidence to determine whether the VenaSeal Closure System (VSCS) for varicose veins treatment is effective and safe compared to other alternative treatments.

**Articles:** The following article was selected for critical appraisal: Randomized trial comparing cyanoacrylate embolization and radiofrequency ablation for incompetent great saphenous veins (VeClose) See [Evidence Table 1](#).

The use of VenaSeal Closure System of Varicose Veins does not meet the Group Health *Medical Technology Assessment Criteria*.

#### Implanted Ventricular Assist Devices (VAD)

- **Post-Cardiotomy Setting/Bridge to Recovery**  
Implantable ventricular assist devices with FDA approval or clearance may be considered medically necessary in the post-cardiotomy setting in patients who are unable to be weaned off cardiopulmonary bypass.
- **Bridge to Transplant**  
Implantable ventricular assist devices with FDA approval or clearance may be considered medically necessary as a bridge to heart transplantation for patients who are currently listed as heart transplantation candidates and not expected to survive until a donor heart can be obtained, or are undergoing evaluation to determine candidacy for heart transplantation.  
  
Ventricular assist devices with FDA approval or clearance, including humanitarian device exemptions, may be considered medically necessary as a bridge to heart transplantation in children aged 5 to 16 years who are currently listed as heart transplantation candidates and not expected to survive until a donor heart can be obtained, or are undergoing evaluation to determine candidacy for heart transplantation.
- **Destination Therapy**  
Implantable ventricular assist devices with FDA approval or clearance may be considered medically necessary as destination therapy with end-stage heart failure for patients who are ineligible for human heart transplant and who meet the following criteria:
  - New York Heart Association (NYHA) Class IV heart failure for > 60 days; OR
  - Patients in NYHA Class III/IV for 28 days, received > 14 days support with intra-aortic balloon pump or dependent on IV inotropic agents, with two failed weaning attempts.
 In addition, patients must not be candidates for human heart transplant for one or more of the following reasons:
  - Age > 65 years; OR
  - Insulin dependent diabetes mellitus with end-organ damage; OR
  - Chronic renal failure (serum creatinine > 2.5 mg/dL for > 90 days); OR
  - Presence of other clinically significant condition.

## **Percutaneous Left Ventricular Assist Device (PLVAD) like Impella Recover System**

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## **Background**

### **Implanted Ventricular Assist Devices (VAD)**

Heart failure is a clinical condition characterized by the heart's inability to generate a cardiac output sufficient to meet the body's circulation demands. It is a major and growing public health problem responsible for high morbidity and mortality, in addition to the economic impact of medical costs, disability, and loss of employment. According to the Heart Failure Society of America, nearly 5 million people suffer from CHF in the United States and it is responsible for about 200,000 deaths each year (Abraham 1998).

The cause of heart failure in many patients is pump failure due to poor left ventricular systolic function, which is often due to myocardial infarction or dilated cardiomyopathy. In approximately 30% of patients with chronic heart failure, the disease process not only depresses cardiac contractility, but also affects the conduction pathways by causing a delay in the onset of right or left ventricular systole, and in turn the loss of coordination of ventricular contraction. This dyssynchronous pattern of ventricular contraction is believed to reduce the already diminished contractile reserve of the heart (Nelson 2001).

Patients in end-stage heart failure have two primary treatment options:

1. Pharmacological therapy (including digoxin, ACE inhibitors, diuretics and inotropes), and
2. Heart transplantation.

Both treatments have their limitations. Pharmacological therapy is only palliative and improves the short-term survival for patients. Moreover, as the heart failure worsens, medication becomes ineffective in treating the low contractility and pulmonary venous stasis resulting from the increased dilatation of the heart. Cardiac transplantation on the other hand, is limited to the number of available hearts, and the criteria for being a transplant candidate.

In September 1994, the FDA approved the first pneumatically driven left ventricular assist device (LVAD) from TCI for bridging end-stage patients to cardiac transplantation. Patients on these devices had to stay in the hospital connected to a pneumatic console, or could go home with extensive home health care support. (FDA News 2002). Four years later, in September 1998, the FDA approved two portable heart assist devices (HeartMate and Novocar LVAS) to support patients outside the hospital while they wait for a transplant. These two devices were approved as a bridge to transplant for patients eligible for heart transplants and waiting for an available heart. Eligible patients were those with irreversible heart failure and a rapidly deteriorating condition. In addition, they had to be on their hospital's transplant list in order to qualify for one of these devices (FDA News, September 1998).

The LVAD does not replace the heart. It works along with the patient's own heart to provide additional strength to the weakened left ventricle to pump blood throughout the body. The portable device consists of a blood pump implanted in the abdominal area and attached to both the left ventricle and the aorta. Blood from the heart flows into the device which then pumps it through the aorta to the rest of the body. The system is also connected by a cable through the skin to a small external computer (the "controller") worn on the waist. The computer can be powered by a base unit that is plugged into the wall or by batteries worn at the waist or, in the case of the HeartMate device, under the arms.

There are risks associated with the surgery to implant the HeartMate, as well as risks and complications with the device itself such as infections, bleeding, thromboembolism, and stroke. Implanting the device requires a major surgery for already seriously sick patients. Moreover, the device requires a percutaneous line that can become a medium for bacterial and fungal infections that are difficult to treat and may require a change of the device, which increases the morbidity and mortality. Another complication reported by Rose et al (2000), is aortic stenosis of variable severity that may be caused by the device. LVAD may also lead to significant changes in the systemic immunologic and thrombostatic functions of the patients (Itesu S, 2000). Failure and malfunctioning of the device may also occur which may contribute to higher morbidity, mortality, and cost.

In November 2002, the FDA expanded the use of the HeartMate device to be implanted permanently in certain terminally ill patients; those who have a severe end-stage CHF, are ineligible for heart transplant, and have a body surface area >1.5 sq. m.

It required that the manufacturer (Thoratec) conduct a post-approval study to assess the device's long-term safety and effectiveness for permanent use.

### **Percutaneous Left Ventricular Assist Device (PLVAD)**

Cardiogenic shock is a state of inadequate tissue perfusion due to cardiac dysfunction. It occurs in a variety of settings such as myocardial infarction, post-cardiotomy shock, decompensated chronic heart failure, acute valve failure, and myocarditis. Despite the major advances in the treatment and aggressive perfusion strategies, cardiogenic shock is still associated with high in-hospital mortality rates that range from 40% to 80% depending on the clinical circumstances. The Intra-Aortic Balloon Pump (IABP) is the left ventricular mechanical assistance device most commonly used to stabilize patients in cardiogenic shock. It decreases afterload, increases coronary perfusion, and improves cardiac output. However, IABP pump delivers an output of only 0.5 L/min, lacks active cardiac support, does not decrease infarct size, or improve clinical outcomes of patients with acute ST-segment elevation myocardial infarction. New technologies such as percutaneous left ventricular assist devices (LVADs) have been developed to provide more effective hemodynamic short-term support for the failing heart. The three main indications for percutaneous LVAD support include: 1. Reversible left ventricular failure to provide temporary circulatory support until recovery or revascularization, 2. Large ischemic area at risk to provide temporary circulatory support during high-risk percutaneous or surgical revascularization, and 3. Bridging therapy to provide temporary circulatory support as a bridge to a permanent surgical assist device or heart transplantation (Burkoff 2006, Windecker 2007, Seyfarth 2008, Cheng 2009).

Currently two percutaneous LVADs are available for clinical use: The TandemHeart and the Impella Recover system. The TandemHeart utilizes a drainage cannula placed via transseptal puncture into the left atrium to aspirate oxygenated blood, which is then injected through a transfugal pump into the femoral artery, establishing a left-atrial-to-femoral arterial bypass. The Impella Recover is based on a miniaturized impeller (microaxial pump) that can be advanced into the left ventricle through an arterial vascular system. It has a caged blood flow inlet that is placed retrograde into the left ventricle to aspirate oxygenated blood, which is then injected by means of a microaxial pump into the ascending aorta establishing a left ventricular to aortic by-pass. The TandemHeart requires both venous and arterial femoral access whereas the Impella Recover system requires only femoral arterial access. Currently two Impella Recover systems are available: The Impella Recover LP 2.5 and the Impella Recover LP 5.0 models. The Impella LP 2.5 (Abiomed Europe GmbH, Aachen, Germany) is a catheter suitable for percutaneous implantation, while the Impella Recover LP 5.0 catheter requires surgical cut of the femoral artery for device insertion (Windecker 2007).

The Impella Recover LP 2.5 is a catheter-based, impeller-driven, axial -flow pump. It has a diameter of 6.4 mm at the body of the pump and 7.3 mm diameter at the level of the outflow opening. A small electric motor is built into the device, and a thin 2.8 mm cable leading to the device contains the electrical power supply, which is connected to an external control unit as well as a purge line connected to a purge perfuser. Through this perfuser, heparin (in a glucose solution) is flushed continuously in the motor housing and throughout the pump, and the patient does not need systemic anticoagulation. A pressure sensor within the device continuously monitors pressure differences between inflow and outflow. The pump is inserted percutaneously in the catheterization laboratory via a standard guidewire through the femoral artery into the left ventricle. The circulatory support provided by the device can be adjusted at nine different levels of speed. At its maximal rotation speed of 50,000 rpm, the pump can deliver an output of up to 2.5 liters of blood per minute from the left ventricle into the ascending aorta. This actively unloads the ventricle, increases the cardiac output, and increases both coronary and end-organ perfusion. The Impella pumps are indicated for temporary use (up to 6 hours) however, it has been reported that the device can be safely left in place to support hemodynamics for up to 5 days. (Seyfarth 2008, Vecchio 2008, Cheng 2009, Wiktor 2010).

Impella Recover 2.5 and 5.0 devices (ABIOMED Inc) have both received FDA clearance for circulatory support for periods up to 6 hours. The current review focuses on the use of the Impella Recover 2.5.

## **Medical Technology Assessment Committee (MTAC)**

### ***LVAD in the treatment of End Stage Heart Failure***

#### **08/13/2003: MTAC REVIEW**

**Evidence Conclusion:** The REMATCH trial reviewed was conducted among a highly selected group of patients with end stage heart failure, and contraindication for heart transplantation. The trial compared the patients who received the LVAD to those who were treated medically. The methodology of the trial was generally valid, however it was not blinded. Blinding in such a trial is not possible, and non-blinding may be a source of observation bias. The authors tried to partly overcome this limitation by using independent blinded observers to measure the outcome events. In this trial survival was higher among patients receiving LVAD vs. those in the optimum medical management group. The difference between the two groups was statistically significant, at one year (NNT=4), but

not at 2 years. The two years survival among patients receiving the LVAD was only 22%, and according to the survival graph, the 26 months survival was 8%. The LVAD was associated with serious adverse events. Sepsis and device failure were responsible for the majority of deaths in the LVAD group (41.5%, and 17.1% respectively), and left ventricular dysfunction was the cause of death in 92% of the cases in the medical treatment group. The authors concluded that the quality of life was better among LVAD recipients, however the analysis of QoL was only performed among survivors who were able to complete the questionnaires (35% in the LVAD group, and 18% in the medical treatment group). In conclusion the REMATCH trial provides some evidence that LVAD may improve survival, however for a short duration, and not without serious adverse events, among a selected group of patients with and end stage heart failure, and who are not candidates for heart transplantation. It does not provide evidence that LVAD may be used as an alternative to transplantation, in patients eligible for a heart transplant.

**Articles:** The search yielded 32 articles many of which were reviews, opinion pieces, or dealt with the technical aspects of the procedure. One randomized controlled trial, 5 case series and several case reports were identified. The RCT was selected for critical appraisal. Rose EA, Gelijns AC, Moskowitz AJ, et al. Long-term use of a left ventricular assist device for end-stage heart failure. N Engl J Med 2001;345:1435-43. See [Evidence Table](#).

The use of LVAD in the treatment of End Stage Heart Failure does meet the *Group Health Medical Technology Assessment Criteria*.

**02/14/2011: MTAC REVIEW**

**Percutaneous Cardiac Support Systems**

**Evidence Conclusion:** The literature search revealed only one small randomized controlled trial that evaluated the safety and efficacy of the Impella Recover LP 2.5 for the treatment of cardiogenic shock caused by myocardial infarction. The trial compared the Impella device with the IABP, the most commonly used device to treat cardiogenic shock. However, the study was too small, blinding and randomization method were not discussed, and it was only powered to detect the difference between the two devices in hemodynamic improvements. It was not powered to evaluate impact on clinical outcomes. The results of the RCT (Evidence table 1) show that the Impella LP 2.5 resulted in better hemodynamic improvement compared to the IABP. However, this was not translated to an improvement in the 30-day survival of the patients in cardiogenic shock after an acute myocardial infarction. Patients treated with the Impella device tended to have more device-related bleeding, and more limb ischemia.

**Articles:** The literature search identified one small randomized controlled trial that compared Impella Recover LP 2.5 device to IABP for the treatment of cardiogenic shock, a meta-analysis of RCTs comparing percutaneous LVAD to IABP for the treatment of cardiogenic shock, and three other case series evaluating the feasibility and safety of the device. The meta-analysis (Cheng 2009) pooled the results of three trials; two evaluated the TandemHeart, and the third evaluated the Impella Recover 2.5 device. The RCT that compared Impella Recover LP 2.5 device to IABP for the treatment of cardiogenic shock was selected for critical appraisal. Seyfarth M, Sibbing D, Bauer I, A randomized clinical trial to evaluate the safety and efficacy of a percutaneous left ventricular assist device versus intra-aortic balloon pumping for treatment of cardiogenic shock caused by myocardial infarction. J Am Coll Cardiol 2008; 52:1584-1588. See [Evidence Table](#).

The use of percutaneous cardiac support systems in the treatment of End Stage Heart Failure does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Virtual Colonoscopy or CT Colonography

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Colorectal Cancer Screening Tests (210.3)</a>
Local Coverage Determinations (LCD)	None

##### For Non-Medicare Members

Computed tomographic (CT) colonography, also known as virtual colonoscopy, utilizes helical computed tomography of the abdomen and pelvis to visualize the colon lumen, along with 2D or 3D reconstruction. The test requires colonic preparation similar to that required for fiberoptic colonoscopy, and air insufflation to achieve colonic distention.

CT colonography is indicated only in patients having **ONE of the following** qualifying conditions:

1. Instrument colonoscopy of the entire colon is incomplete and/or contraindicated due to colon obstruction;
2. A coagulation disorder known to increase bleeding risk;
3. Lifetime anticoagulation or long-term anticoagulation therapy with increased patient risk if discontinued;
4. Significant medical or surgical complications from previous standard colonoscopy;
5. Medical condition that places the patient at increased risk with use of conscious sedation;
6. CT colonography is not a covered service when utilized in preoperative cancer staging, and in this clinical situation as standard CT or MRI is the preferred imaging study, or for screening or diagnostic evaluation in the absence of one of the above indications.

Patient personal preference or patient refusal to undergo colonoscopy, in the absence of one of the qualifying conditions noted above, even if signs or symptoms of colon disease are present, is not a covered indication for CT colonography.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Colorectal cancer is the third most common cancer and the second leading cause of cancer-related deaths in the United States. A majority of cases can be prevented with colonoscopic removal of the precursor adenomatous polyp. With early detection, patients with cancer limited to the colonic wall will have a corrected 5-year survival of around 90%, whereas for those with lymphatic spread this figure drops to 30%. Although standard colonoscopy is a total colonic examination that allows lesion biopsy and resection, it is an invasive procedure, may fail to demonstrate the entire colon in up to 5% of cases examined by an experienced gastroenterologist, and could miss up to 20% of all adenomas. (Yee J, 2001).

Computed tomography colonography, commonly referred to as virtual colonoscopy, is a new method of imaging the colon. It uses data from thin sections helical computed tomography of the clean, air-distended colon, combined with advanced imaging software to create two-dimensional and three-dimensional images of the colon that simulate the endoluminal view seen at endoscopy. Since first introduced by Vining and colleagues in 1994, its performance has improved due to the development of fast helical CT scanners, and advances in the computer software for image reconstruction.

A variety of techniques have been described, but all share the same basic principles: Full bowel cleaning, air distension of the colon using a rectal enema tube, taking thin-section images of the colon in the supine and prone positions, and image interpretation using a combination of axial and multiplanar or endoluminal reconstructions.

The concept of virtual colonoscopy is appealing and appears to many as a potentially attractive method of screening for colorectal cancer. Compared to the standard optical colonoscopy, virtual colonoscopy is less invasive, does not require sedation, analgesia, or recovery time, and allows the entire colon to be visualized in the majority of patients. It might also provide additional information by evaluating colonic wall thickness and imaging abdominal structures outside the colon and may be more acceptable to patients.

However there are a number of potential limitations to this procedure. First of all, it requires a complete and thorough colon cleansing. Poor colonic preparation or distension limits the accuracy of CT colonography. Colonic lavage preparation often results in excess residual fluid or stools in the colon, that may simulate or cover the presence of a lesion. Another significant limitation is that virtual colonoscopy may be less effective at detecting smaller polyps and flat adenomas. In addition, unlike conventional colonoscopy, virtual colonoscopy is only a diagnostic test; the detected polyps cannot be resected during the procedure. If suspicious lesions are detected, the patient undergoes further testing, usually by conventional colonoscopy. (Hawes 2002).

The original MTAC review in June 2001 evaluated virtual colonoscopy as a screening tool, and for evaluation of high-risk patients. The second review in October 2002 focused on virtual colonoscopy for detecting of colorectal polyps among high risk, elderly or frail patients. At both meetings, virtual colonoscopy failed MTAC diagnostic test criteria. The current review is on virtual colonoscopy as a screening method for average risk asymptomatic individuals and was initiated in response to the publication of the Pickhardt study on virtual colonoscopy in a screening population.

## Medical Technology Assessment Committee (MTAC)

### Virtual Colonoscopy

#### 06/13/2001: MTAC REVIEW

**Evidence Conclusion:** The available evidence suggests that virtual colonoscopy is not yet as effective as conventional colonoscopy at identifying colorectal polyps and carcinomas. Virtual colonoscopy may be relatively effective at identifying lesions  $\geq 10$  mm in size, but further study is needed to verify this. No studies to date have examined the use of virtual colonoscopy for general screening or compared the acceptability of virtual compared to conventional colonoscopy.

**Articles:** The literature search yielded 57 articles. Articles that were opinion pieces, reviews, dealt with technical aspects of virtual colonoscopy, or had small sample sizes were excluded. There were 4 empirical studies with sample sizes  $\geq 50$ . The two studies with the strongest methodologies were reviewed. Fenlon HM, Nunes DP, Schroy PC, Barish MA, Clarke PD, Ferrucci JT. A comparison of virtual and conventional colonoscopy for the detection of colorectal polyps. *N Engl J Med* 1999; 341: 1496-503. See [Evidence Table](#). Spinzi G, Belloni G, Martegani A, Sangiovanni A, Del Favero C, Minoli G. Computed tomographic colonography and conventional colonoscopy for colon diseases: A prospective, blinded study. *Am J Gastroenterol* 2001; 96: 394-400. See [Evidence Table](#).

The use of Virtual Colonoscopy for colon cancer screening failed Group Health *Medical Technology Assessment Criteria*

#### 10/09/2002: MTAC REVIEW

### Virtual Colonoscopy

**Evidence Conclusion:** Previously, virtual colonoscopy did not meet GHC Medical Technology Assessment Committee as a screening tool for colorectal polyps and carcinomas. The purpose of the current re-review is to evaluate the use of the technology among high-risk patients, the frail, and the elderly. The available literature does not provide evidence for the use of virtual colonoscopy for the elderly and frail patients. The study (Laghi 2002) currently reviewed, as well as the Fenlon study reviewed for MTAC in June 2001, show that the sensitivity of virtual colonoscopy was good for colorectal carcinomas and large colorectal polyps in the selected symptomatic or high risk patients. The two studies were appropriate for comparison of diagnostic tests and measured the performance of CT colonography relative to conventional colonoscopy. Virtual colonography was able to detect 100% of the colorectal carcinomas identified by conventional colonoscopy in the two studies. In Laghi's study the sensitivity was 92% for the detection of polyps 10 mm diameter or larger, 82% for those 6-9 mm, but as low as 50% for those less than 5 mm diameter, with an overall sensitivity of 78%. The corresponding values in Fenlon's study were almost similar with a slightly less overall sensitivity most probably because of the higher rate of the smaller polyps in the population studied. The sensitivity in Fenlon's study was (91%, 82%, 50% and 71% respectively). In both

studies the sensitivity of virtual colonoscopy dropped considerably for polyps with a diameter of 5 mm or less. There is no clear consensus as to the importance of identifying and removing such tiny polyps. The per-patient specificity was 97% in Laghi's study and 84% in Fenlon's study. These high-risk patients with detected lesions may still need to undergo conventional colonoscopy for biopsy or removal of lesions. Neither study examined the impact of CTC on colorectal cancer morbidity, mortality or patient management. The inter-observer variability was not examined or discussed.

**Articles:** The literature search yielded 84 articles. The majority were opinion pieces, reviews, or dealing with technical aspects of virtual colonoscopy. There were 5 empirical studies, one had a very small sample size and poor methodology, and two were conducted in the same center by the same researchers but one included more patients. The study with the larger size was selected for critical appraisal. The remaining two were retrospective studies conducted on frail or elderly patients, one used non-helical CT scan, and the other was conducted to evaluate the accuracy of CT scans in detecting caecal carcinomas using oral contrast media and minimal preparation. *The study critically appraised is:*

Laghi A, Iannaccone R, Carbone I, et al. Detection of colorectal lesions with virtual computed colonography. *Am J Surg* 2002;183:124-131. See [Evidence Table](#).

The use of virtual colonoscopy in colorectal screening for the frail elderly does not meet the *Group Health Medical Technology Assessment Criteria*.

## 02/11/2004: MTAC REVIEW

### Virtual Colonoscopy

**Evidence Conclusion:** The two best new studies were evaluated. Pickhardt found a higher sensitivity and specificity of virtual colonoscopy than Johnson. Both included asymptomatic populations, but individuals in the Johnson study were at higher than average risk of colorectal neoplasia (i.e. personal or strong family history of colorectal neoplasia). The difference in the study population does not explain the lower sensitivity in Johnson because any bias introduced by having a higher risk sample would tend to increase, not decrease the sensitivity. The populations in the Pickhardt and Johnson studies may actually have been quite similar. The prevalence of adenomatous polyps  $\geq 1$  cm was 4% in Pickhardt and 5% in Johnson. The better performance of virtual colonoscopy in the Pickhardt study may be due in part to the routine use of 3-D CT images by Pickhardt. Johnson generally used 2-D images, and 3-D images were used for regions with suspected abnormalities. In addition, Johnson used conventional colonoscopy as the reference standard whereas Pickhardt used a reference standard developed for the study—conventional colonoscopy enhanced by information from the virtual colonoscopy. Neither of the new studies included polyps  $< 5$ mm which many experts believe are not clinically significant. Previous studies of virtual colonoscopy evaluated by MTAC have found low sensitivity for these smaller polyps. In summary, the Pickhardt study is the first to suggest that virtual colonoscopy has comparable sensitivity and specificity to conventional colonoscopy in asymptomatic individuals. The Johnson study suggests that the sensitivity of virtual colonoscopy is relatively low and that interobserver variability is high. Replication of the findings obtained in the Pickhardt study would strengthen the evidence.

**Articles:** The search yielded 103 articles, many of which were reviews, opinion pieces or dealt with technical aspects of the procedure. There were five prospective blinded studies comparing the diagnostic accuracy of virtual colonoscopy to conventional colonoscopy in asymptomatic populations. The two largest studies, each of which had samples larger than 700 individuals, were critically appraised. The others had sample sizes of 205, 158 and 80. The following articles were reviewed: Johnson CD, Harmsen WS, Wilson LA. Prospective blinded evaluation of computed tomographic colonography for screen detection of colorectal polyps. *Gastroenterol* 2003; 125: 311-319. See [Evidence Table](#). Pickhardt PJ, Choi JR, Hwang I. et al. Computed tomographic virtual colonoscopy to screen for colorectal neoplasia in asymptomatic adults. *N Engl J Med* 2003; 349: 2191-2000. See [Evidence Table](#).

The use of virtual colonoscopy in colorectal screening does not meet the *Group Health Medical Technology Assessment Criteria*.

## 06/18/2009: MTAC REVIEW

### Virtual Colonoscopy

**Evidence Conclusion:** Diagnostic accuracy in the Regge et al., 2009 study is not dramatically different than previous studies, particularly when considering that it was conducted in a population at increased risk of CRC. There is still no high-grade evidence on the impact of screening with CT colonography on CRC mortality. Although it is not invasive like colonoscopy, CT colonography requires the same colonic preparation and involves exposure to radiation, and patients who test positive still require a colonoscopy for polyp removal.

**Articles:** Regge D, Laudi C, Galatola G et al. Diagnostic accuracy of computed tomographic colonography for the detection of advanced neoplasia in individuals at increased risk of colorectal cancer. *JAMA* 2009; 301: 2453-2461. See [Evidence Table 6](#) and [Evidence Table 7](#).

Update of evidence but the evidence does not change the previous review.

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The macula is the small area of the retina that provides the sharp central vision that is needed for reading, driving, and seeing fine details. A macular hole is a small break in the macula, which can cause blurred and distorted central vision. Macular holes are related to aging; fifty percent of macular holes occur in patients 65-74 years old. Only three percent were found to occur in patient under the age of fifty-five. The majority of holes are idiopathic; however, they can occur from eye disorders, such as high myopia (nearsightedness), macular pucker, and retinal detachment; eye diseases, such as retinopathy and Best's disease; and trauma to the eye (Solebo 2010; American Academy of Ophthalmology 2008).

The pathogenesis of idiopathic macular holes is not fully understood; however, recent histopathological and high resolution imaging studies have increased current understanding of the natural history of this condition. One theory of macular hole formation suggests that as we age, the vitreous, a gel-like substance that fills about 80 percent of the eye, shrinks and pulls away from the retinal surface creating tractional forces on the retinal and leading to macular holes (Solebo 2010). If left untreated, approximately three percent to eleven percent of macular holes close spontaneously (American Academy of Ophthalmology 2008). The treatment for macular hole is vitrectomy, which involves the surgical removal of the vitreous gel from the middle of the eye and is thought to relieve vitreofoveal traction and reactivate reparative healing mechanisms (Gupta 2009). Some surgeons instruct their patients to postoperatively maintain a face-down position from one day to three weeks to tamponade the macular hole. However, a recent study demonstrated that approximately 77% percent of macular holes close as soon as twenty-four hours after surgery (Solebo 2010). Research is lacking regarding the appropriate duration of postoperative face-down posturing and as to whether face-down positioning is needed at all.

#### Medical Technology Assessment Committee (MTAC)

##### Vitreotomy Chair

##### 04/19/2010: MTAC REVIEW

**Evidence Conclusion:** There is limited evidence regarding the effect of duration of face-down posturing on macular hole closure. The best available evidence was provided by the Tatham and Banerjee (2009) meta-analysis of five studies. This meta-analysis attempted to determine whether decreasing or eliminating face-down position time would affect surgical outcomes. Posturing for 5 to 10 days was compared to posturing for 24 hours

or less. The results from the analysis suggest that there is a 34% increased risk of anatomical failure (macular hole non-closure) when face-down posturing is reduced from 5 to 10 days to less than 24 hours. However, this difference was not statistically significant. Within the studies that comprise the meta-analysis there is diversity of study design, surgical technique used, follow-up periods, and patient characteristics. This diversity reduced the validity of the meta-analysis. Additionally, non-randomized studies were included in the analysis making it more prone to bias. Conclusion: There is insufficient evidence to determine whether the duration of face-down posturing after macular hole surgery affects macular hole closure rates. There is insufficient evidence to determine whether a vitrectomy chair will improve outcomes after surgery.

**Articles:** The literature search yielded over 100 articles. The majority of the articles were unrelated to the current review. There was only one meta-analysis regarding face-down posturing. This article was selected for critical appraisal. The search did not reveal any evidence pertaining to the use of a vitrectomy chair after surgery. Tatham A., Banerjee S. Face-down posturing after macular hole surgery: A meta-analysis. British Journal of Ophthalmology 2009. Advance online publication. doi:0.1136/bjo.2009.163741 See [Evidence Table](#).

The use of a Vitrectomy Chair for the treatment of post-operative recovery from macular surgery does not meet the *Group Health Medical Technology Assessment Criteria*.

Adjunctive Treatment for Partial Onset Epileptic Seizures	No medical necessity review is required for this service.
Treatment-Resistant Depression	MCG* B-804-T
All other diagnoses	MCG* A-0424. This service is not covered per MCG guidelines.

**MCG\* manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

The Cyberonics Vagus Nerve Stimulator (VNS) Therapy System is a device similar in design and function to a cardiac pacemaker. It consists of a constant current pulse generator implanted in the anterior chest wall and a bipolar stimulating electrode that is wrapped around the left vagal nerve in the neck. A magnet controlled by the patient can turn off the device.

In 1985, there were initial animal studies to test VNS, and devices were implanted in humans beginning in 1988. The first clinical application was to treat epilepsy. Research on epilepsy treatment suggested that VNS might reduce dysphoria in some patients. Moreover, VNS has been found to increase levels of a metabolite of serotonin in epilepsy patients, an effect similar to that seen after successful treatment of depression. These findings led to an interest in using VNS for patients with treatment-resistant depression (Goodnick et al., 2001).

In July, 1997, the FDA granted pre-market approval for the Cyberonics VNS device to be used as an adjunctive treatment for medically refractory partial onset seizures in patients over 12 years of age. In July 2005, the FDA approved the device for patients 18 and older with treatment-resistant depression who failed to respond to at least 4 courses of adequate medication or electroconvulsive therapy (ECT).

[Vagus Nerve Stimulation for Treatment-Resistant Depression](#)

## Medical Technology Assessment Committee (MTAC)

### **Vagal Nerve Stimulation (VNS) as an Adjunctive Treatment for Partial Onset Epileptic Seizures**

#### BACKGROUND

Repetitive stimulation of the vagal nerve has been shown to reduce the frequency of seizures in various animal models of epilepsy. Epilepsy is typically treated with anti-epileptic medications and in some cases surgical resection of the epileptic focus. Despite the efficacy of these treatments, 25-50% of patients with epilepsy continue to experience seizures and/or suffer harms from continued use of anti-epileptic medications. The NeuroCybernetics Prosthesis (NCP) Vagal Nerve Stimulator (VNS) is a device (similar in design and function to a cardiac pacemaker) which consists of a constant current pulse generator implanted subcutaneously in the anterior chest wall and a bipolar stimulating electrode which is wrapped around the left vagal nerve in the neck. A magnet controlled by the patient can initiate stimulation (when the patient senses the onset of a seizure) or can turn off the device depending on how it is placed against the device. The mechanism by which the VNS reduces epileptic seizures is still unknown, however it has been shown that stimulation of the vagal nerve has the ability to affect brain wave activity.

#### 02/10/1999: MTAC REVIEW

### **Vagal Nerve Stimulation (VNS) as an Adjunctive Treatment for Partial Onset Epileptic Seizures**

**Evidence Conclusion:** Recently published evidence from a large, well designed, multicenter trial of 254 patients randomized to high or low Vagal nerve stimulation demonstrates that the use of VNS in the treatment of medically refractory patients reduces seizure frequency by approximately 28% compared to baseline and 13% compared to an active control group receiving low stimulation. This translates into an average reduction of 3 seizures per week. Adverse events such as voice alteration, cough and pharyngitis during stimulation are reported to occur in 25-60 percent of subjects but are generally well tolerated. Patients receiving high VNS also reported significant improvement in their perception of well-being. A randomized controlled trial of 114 patients reports a similar beneficial effect of VNS. Data from an open extension trial of the first 67 patients exiting the RCT demonstrates that all patients chose to either continue high stimulation or switch from low to high stimulation for up to 15 months. Four out of five patients in this group demonstrated continuing clinically significant reductions in seizure frequency over 15 months with 5 drop-outs (8%) due to lack of efficacy and no drop-outs due to side effects from stimulation. **Articles:** Handforth, A et al. Vagus Nerve Stimulation Therapy for Partial Onset Seizures: A Randomized Active-Control Trial. *Neurology* 1998; 5:48-55 See [Evidence Table](#). The Vagus Nerve Stimulation Group, A Randomized Controlled Trial of Chronic Vagus Nerve Stimulation for Treatment of Medically Intractable Seizures. *Neurology*, 1995; 45:224-230. See [Evidence Table](#). Vagus Nerve Stimulation for Treatment of Partial Seizures: 3. Long-Term Follow-Up on First 67 patients exiting a Controlled Study. *Epilepsia*, 1994;35:637-643. See [Evidence Table](#).

The use of the NeuroCybernetics Prosthesis (NCP) Vagal Nerve Stimulator (VNS) for treating patients with medically refractory partial onset seizures has been approved by the FDA and therefore meets *Group Health Medical Technology Assessment Criteria*.

### **Vagus Nerve Stimulation for Treatment-Resistant Depression**

#### BACKGROUND

The Cyberonics Vagus Nerve Stimulator (VNS) Therapy System is a device similar in design and function to a cardiac pacemaker. It consists of a constant current pulse generator implanted in the anterior chest wall and a bipolar stimulating electrode that is wrapped around the left vagal nerve in the neck. A magnet controlled by the patient can turn off the device.

In 1985, there were initial animal studies to test VNS, and devices were implanted in humans beginning in 1988. The first clinical application was to treat epilepsy. Research on epilepsy treatment suggested that VNS might reduce dysphoria in some patients. Moreover, VNS has been found to increase levels of a metabolite of serotonin in epilepsy patients, an effect similar to that seen after successful treatment of depression. These findings led to an interest in using VNS for patients with treatment-resistant depression (Goodnick et al., 2001). In July, 1997, the FDA granted pre-market approval for the Cyberonics VNS device to be used as an adjunctive treatment for medically refractory partial onset seizures in patients over 12 years of age. In July 2005, the FDA approved the device for patients 18 and older with treatment-resistant depression who failed to respond to at least 4 courses of adequate medication or electroconvulsive therapy (ECT). VNS passed MTAC evaluation criteria in 1999 for epilepsy. In 2005, it was reviewed for treatment-resistant depression and failed MTAC evaluation criteria. At that time, all of the major studies were conducted by the same group of researchers (A. John Rush and colleagues) with links to the device manufacturer. There was one published RCT (Rush et al., 2005), with negative findings. A post-hoc sub-group analysis of the Rush RCT with a historical control group (George et al., 2005), a design subject to bias, found a benefit of the treatment for a selected group of patients.

FDA approval of the VNS device for depression remains controversial. Citing a lack of efficacy data and concerns about safety, an FDA review team decided not to approve the new indication for the Cyberonics device. Instead, the team recommended additional data from RCTs. The Director of the FDA's Center for Devices and Radiological Health (CDRH) overruled the team and granted pre-market approval. The Director agreed with Cyberonics researchers that it would be unethical to conduct a blinded treatment study with patients with major depression. The FDA approval in 2005 included a request to Cyberonics for additional post-marketing controlled studies (Shuchman, 2007).

#### **12/05/2005: MTAC REVIEW**

##### **Vagus Nerve Stimulation for Treatment-Resistant Depression**

**Evidence Conclusion:** There is insufficient evidence that VNS is effective therapy for treatment-resistant depression. All of the major studies were conducted by the same group of researchers. This research team has close financial links with the device manufacturer which could bias study methodology, analysis and/or results reporting. The single published RCT (Rush et al., 2005) had negative findings. There was not a statistically significant between-group difference in the primary outcome, 3-month HAM-D response, between groups receiving active and placebo VNS therapy. A subsequent non-randomized study (George et al., 2005) followed-up a portion of the RCT study patients, and compared findings to a group of depressed patients who were participating in a different study. The George study found a significant difference in the primary outcome, change in the Inventory of Depressive Symptomatology (IDS) score, favoring the VNS therapy group. The study is subject to selection bias due to the use of different patient populations, and the exclusion of patients who responded to sham treatment in the RCT. It is also subject to observation biases because patients did not receive a consistent intervention e.g. those in the VNS group had different lengths of treatment, and possible bias in the selection of the primary outcome (IDS score was the only significant efficacy outcome in the RCT). A limitation of all of the published studies was that the eligibility for participation did not match the FDA definition of treatment-resistant depression. The studies required patients to have failed a minimum of 2 courses of medication whereas the FDA approved VNS therapy for depressed patients who have failed at least 4 treatments.

**Articles:** The published empirical studies on VNS therapy for depression were conducted by a single research group with close links to the manufacturer, A. John Rush and colleagues. As described in the recent BlueCross BlueShield review (2005), these studies were: D01 : Case series with n=50 patients, D02: 3-month randomized controlled trial with n=233, D02 extension arm. 12 month follow-up of selected patients who participated in study D02, D04: Case series of patients not receiving VNS. This study was used to form a comparison group to the 12-month extension of study D02. *Articles critically appraised were:* Publication reporting the results of the RCT, D02: Rush AJ, Marangell LB, Sackeim HA et al. Vagus nerve stimulation for treatment-resistant depression: A Publication comparing 12-month outcomes in the D02 extension and the D04 comparison group: George MS, Rush AJ, Marangell LB et al. A one-year comparison of vagus nerve stimulation with treatment as usual for treatment-resistant depression. *Biol Psychiatry* 2005; 58: 364-373. See [Evidence Table](#)

The use of Vagus nerve Stimulation in the treatment of treatment-resistant depression does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **06/01/2009: MTAC REVIEW**

##### **Vagus Nerve Stimulation for Treatment-Resistant Depression**

**Evidence Conclusion:** Conclusions of the 2005 MTAC review were as follows: There is insufficient evidence that VNS is an effective therapy for treatment-resistant depression. All of the major studies were conducted by the same group of researchers that had close financial links with the device manufacturer. The single published RCT (Rush et al., 2005) had negative findings. There was not a statistically significant between-group difference in the primary outcome, 3-month HAM-D response, between groups receiving active and placebo VNS therapy. A subsequent non-randomized study (George et al., 2005) followed-up a portion of the RCT study patients, and compared findings to a group of depressed patients who were participating in a different study. The George study, which was subject to selection and observation biases, found a significant difference in the primary outcome, change in the Inventory of Depressive Symptomatology (IDS) score, favoring the VNS therapy group. As of May 2009, there is still insufficient evidence to determine whether VNS is effective for depressed patients who have failed antidepressant treatment. There were no additional RCTs or non-randomized comparative studies. A new case series (Schlaepfer) with 74 patients recruited from 9 sites in Europe found a 34% response rate at 3 months (end of active treatment period), which increased to 47% at the 12 month follow-up. The Schlaepfer case series represents a low grade of evidence. There was no comparison group, so response with a different treatment or no treatment is not known. Also, patients were not blinded, and they had regular clinic visits, both of which could affect responses to a subjective outcome measure like the HAMD.

**Articles:** The Pubmed search yielded 13 articles. Only 9 of these were actually on depression (the rest addressed epilepsy, Alzheimer’s disease or rapid-cycling bipolar disorder). Of the 9 articles on depression, 3 were reviews or opinion pieces, 3 were basic research on brain changes during VNS and 3 were empirical studies.

Two of the 3 empirical studies were subanalyses of the Rush et al. (2005) RCT. On closer inspection, neither of these analyses was eligible for MTAC review. The Nierenberg et al. (2008) study did not compare outcomes associated with active vs. sham VNS; instead the investigators compared the effects of VNS on bipolar vs. unipolar depressed participants within the Rush RCT. The other sub-analysis, Burke et al. (2006) evaluated the effect of concomitant VNS and electroconvulsive therapy (ECT) in the 14 participants in the Rush RCT who received both treatments. This was a descriptive analysis of a small number of individuals and does not aid our understanding of the effectiveness of VNS. The third new empirical study was a case series (n=74) conducted in Europe. This study was critically appraised. A Blue Cross Blue Shield technology assessment report, used for the first MTAC review, has not been updated since August, 2006. No additional published articles were identified on the Cyberonics website. The citation for the new European study is as follows:

Schlaepfer TE, Frick C, Zobel A et al. Vagus nerve stimulation for depression: efficacy and safety in a European study. Psychol Med 2008; 38: 651-661. See [Evidence Table](#).

The use of Vagus Nerve Stimulation in the treatment of treatment-resistant depression does not meet the *Group Health Medical Technology Assessment Criteria*.

#### For Non-Medicare Members

LAA appendage closure with the WATCHMAN device is approved for patients with atrial fibrillation who meet the following criteria:

- A CHA2DS2-VASc score  $\geq 3$
- A suitability for short-term warfarin but deemed unable to take long term oral anticoagulation following the conclusion of shared decision making, as LAAC is only covered as a second line therapy to oral anticoagulants.
- The patient is formally evaluated by a multidisciplinary Heart Team of medical professionals who document a collaborative recommendation for LAA occlusion.
- The procedure must be furnished in a hospital with established cardiac surgery, structural heart disease, and electrophysiology (EP) programs.
- A formal shared decision making interaction with an independent non-interventional cardiologist (not part of procedural treatment team) using an evidence-based decision tool on oral anticoagulation in patients with NVAf prior to LAAC. Additionally, the shared decision making interaction must be documented in the medical record.
- The procedure must be performed by an interventional cardiologist(s), electrophysiologist(s) or cardiovascular surgeon(s) that meet accepted CMS criteria for training/implantation ([see Medicare criteria](#))
- The patient is enrolled in, and the MDT and hospital must participate in a prospective, national, audited registry.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, affecting more than 5.5 million individuals in the US, and its prevalence is increasing with the aging population. AF leads to loss of organized atrial contractions, which results in blood stasis in the atrium and thrombus formation with the potential for embolization leading to stroke. It is reported that the risk of ischemic stroke is up to 5 times higher in patients with AF. This risk of cardioembolic stroke varies from one individual to the other based on other risk factors and comorbidities, but overall it increases considerably with age from 1.5% in patients 50-59 years of age to 23.5% for those 80-89 years of age. Stroke prophylaxis is thus an important component in managing patients with non-valvular AF (Holmes 2009, Reddy 2013, Bode 2015).

Antiarrhythmic drugs, and catheter ablation of AF may provide relief of symptoms, but do not sufficiently prevent the occurrence of thromboembolic events. Long-term oral anticoagulant therapy is the standard of care for effective stroke prevention in AF patients at high risk for thromboembolism according to clinical risk scores such as the CHADS2 and the CHA2DS2-VASc models. Warfarin is highly effective in reducing stroke in at-risk patients with AF, but is often not well tolerated by all patients, has a very narrow therapeutic range, and is associated with a high risk of bleeding. In addition, its effectiveness may vary due to its interactions with some foods and medications resulting in the need for frequent monitoring and dose adjustments. It is reported that 50% of the patients' blood test results are outside the therapeutic range. These limitations as well as intolerance or contraindications to warfarin in some patients have led to the non-use or discontinuation of the drug in a large proportion of AF patients, particularly the older patients who are at an increased risk of stroke. The more recently developed oral anticoagulant agents (NOACs) have overcome many of warfarin's limitations, but also need lifelong use and carry the potential risk of bleeding at similar or lower rates than warfarin, depending on the agent used (Sick 2007, Holmes 2009, Alli 2013, Reddy 2013, Price 2014).

Researchers have been investigating non-pharmacological alternatives for patients with intolerance or contraindication to anticoagulant therapy. It is believed (based on echocardiography and autopsy studies) that more than 90% of the atrial thrombi in patients with non-valvular AF, originate in the left atrial appendage (LAA), which is an embryonic remnant of the original embryonic left atrium. LAA is a long tubular trabeculated structure continuous with the atrial cavity. The location and the discrete nature of the LAA have led to the development of a number of techniques for excluding it from the systemic circulation. These include its surgical excision or obliteration by surgical ligation, or by the use of implantable devices via mini thoracotomy or percutaneously. These devices include the St Jude Amplatzer® cardiac plug, Coherex WaveCrest® LAA occlusion system, LARIAT® device, the PLAATO system, and the WATCHMANTM LAA system. The latter is the focus of the current review (McCabe 2009, Holmes 2009, Alli 2014). The WATCHMANTM (WM) left atrial appendage closure (LAAC) system (Boston Scientific Corp., Maple Grove, Minnesota) is the most intensely studied for LAA occlusion. It is a 3-part system consisting of a trans-septal access sheath, a delivery catheter, and an implantable nitinol (nickel titanium) device. The system is designed to facilitate the device placement through femoral venous access via transseptal route into the LAA. The implantable device is parachute-shaped and comprises a self-expanding nitinol frame structure with fixation barbs to secure it in the LAA, and a permeable polyester membrane that covers the atrial facing surface of the device. The WM implant is available in 5 sizes (21, 24, 27, 30, and 33 mm) and is typically chosen 10-20% larger than the LAA body to have sufficient compression for stable positioning to minimize the risk of device embolization. The procedure is performed in the cardiac catheterization laboratory under general anesthesia. Transseptal access is obtained using standard techniques guided by fluoroscopic or transesophageal echocardiography (TEE). Once access is gained into the left atrium (LA), a variety of approaches can be used to place the guidance sheath. A pigtail angiographic catheter is then inserted into the sheath which is advanced into the distal portion of the LAA. Once this catheter is placed, the sheath is advanced over it into the LAA. Positioning of the sheath is of critical importance as the LAA is thin-walled and fragile and may be damaged or perforated. Anticoagulation is necessary and it is also important to avoid the potential for air embolism during the procedure. WM is permeable to blood and thus the patients require post-procedure warfarin therapy for 45 days with INR between 2.0 and 3.0 for those who are legible for warfarin or other equivalent. A TEE is performed for device assessment at 45 days after which a decision is made to discontinue warfarin. After warfarin is discontinued, the patient is treated with clopidogrel 75 mg and aspirin 81-325 mg for 6 months following the implantation, after which the clopidogrel is discontinued and aspirin is used indefinitely (Sick 2007, Alli 2014, Holmes 2015).

As with other invasive procedures, the techniques and devices used for LAA closure including WATCHMANTM have potential complications including pericardial effusion, procedure-related stroke, device thrombosis, device embolization, bleeding, arrhythmia, access site complications, arteriovenous fistula, and pseudoaneurysm formation (Alli 2014). More recently on April 23, 2015, the FDA recalled the TigerPaw II (Maquet, Rastatt, Germany) LAA closure device following reports that the device could cause tearing of the left atrial wall and bleeding.

The WATCHMANTM device received FDA approval in 2015 as an alternative to commonly-used blood thinners to prevent stroke in patients with atrial fibrillation who are at an increased risk of stroke and systemic embolism based on CHADS2 or CHA2DS2-VASc and are recommended for anticoagulation therapy; are deemed by their physicians to be suitable for warfarin; and have an appropriate rationale to seek a non-pharmacologic alternative to warfarin, taking into account the safety and effectiveness of the device compared to warfarin. The FDA had initially declined the approval of the device twice before the final approval due to concerns about its safety and effectiveness, including the complications while implanting the device.

## Medical Technology Assessment Committee (MTAC)

### Watchman

#### 08/17/2015: MTAC REVIEW

**Evidence Conclusion:** The published evidence does not support the use of Watchman LAA occlusion device for the prevention of stroke in in patients with nonvalvular atrial fibrillation. Ideally a new therapy or intervention would be at least equivalent or noninferior (if not superior), to the gold standard treatment with regard to safety, efficacy, and long term outcomes. To date, LAAC closure with Watchman system in patients with nonvalvular atrial fibrillation has not fulfilled the safety requirement in the two pivotal trials, nor the efficacy requirement in the PREVAIL trial. The PROTECT AF trial showed that occluding the LAA with the Watchman device is feasible and with noninferior efficacy than warfarin in reducing the composite risk of stroke, cardiac death, or systemic embolism as primary prevention therapy in patients with CHADS2 >1. In the PREVAIL trial that included higher risk patients, the device did not reach the noninferiority level for the primary efficacy composite endpoint of ischemic or hemorrhagic stroke, cardiovascular or unexplained death, or systemic embolism. More recent long-term follow-up data from PROTECT AF show that the device remained noninferior to warfarin use as regards its efficacy but not its safety. More recent long-term follow-up data from PREVAIL trial show that the 2 first primary endpoints of the trial do not meet the prespecified noninferiority end point of the study. There is evidence from the published RCTs that the occlusion of the LAA with the Watchman device is associated with high risk of procedure-related ischemic stroke and device embolism, as well as other adverse events including serious pericardial effusion and major bleeding. There is insufficient evidence from well-designed RCTs to determine the efficacy and safety of Watchman in patients with a contraindication or intolerance to warfarin or other blood thinners.

There is insufficient published evidence from well-designed RCTs to determine the efficacy and safety of Watchman device to other LAA occluding devices or surgical interventions in patients with nonvalvular atrial fibrillation. There is no published study to date, that compared the efficacy and safely LAA occlusion to any of the NOACs, that demonstrated (from large RCTs) to be either noninferior or superior to warfarin in reducing stroke or systemic embolism with similar or lower rates of major hemorrhage. There are currently 11 ongoing trials on LAA occlusion/excision that may add more information on the safest and most effective intervention for the prevention of stroke in patients with non-valvular atrial fibrillation. WATCHMAN LAA closure device was reviewed by the Kaiser Interregional New Technologies Committee (INTC) in June 1st 2015. The Committee used the Blue Cross Blue Shield TEC Assessment Program as their primary evidence source, and updated the review with new evidence that would change the TEC results or conclusions. Both TEC and INTC concluded that the evidence was insufficient to determine that WATCHMAN LAAC is medically appropriate for stroke prevention for patients with nonvalvular atrial fibrillation.

**Articles:** The literature search identified two randomized controlled trials (PROTECT AF and PREVAIL), a nonrandomized prospective study, and a pilot observational study on Watchman LAA occlusion system. All studies were conducted mainly by the same group of principal investigators. The literature search also identified a more recent meta-analysis of the two RCTs also conducted by the same investigators, and another meta-analysis of observational studies (with no control groups) that examined different devices used in the percutaneous occlusion of the left atrial appendage. The two RCTs on Watchman LAA closure device and the meta-analysis pooling their results were selected for critical appraisal. Holmes DR, Reddy VY, Turi ZG, et al. Percutaneous closure of the left atrial appendage versus warfarin therapy for prevention of stroke in patients with atrial fibrillation: a randomised non-inferiority trial. Lancet. 2009; 374 (9689):534-542. [See Evidence Table 1](#). Holmes DR Jr, Kar S, Price M, et al. #### For Non-Medicare Members

Medical necessity review is no longer required for coverage.

See also [Automated External Defibrillators \(AED\) for Home Use by Pediatric Patients or Heartstream FR2 AED for Home Use by Adult Patients](#).

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

### Background

Sudden cardiac death (SCD) is a major cause of mortality in industrialized countries and is thought to account for 50% of deaths related to heart disease. In the majority of cases cardiac arrest caused by a ventricular tachyarrhythmia precedes sudden cardiac death (Reek 2003).

The implantable cardioverter defibrillator (ICD) introduced in the 1980s, proved to improve survival of patients with a history of a previous episode of sudden cardiac arrest, left ventricular dysfunction, and/or ventricular tachyarrhythmia induced by electrophysiological testing (Feldman 2004). The aim of the device is to continuously monitor the heart, identify malignant ventricular tachyarrhythmias, and deliver an electric counter shock to restore normal rhythm. It was reported that most patients experiencing cardiac arrest have no history of severe cardiac disease, and sudden cardiac death is frequently the first manifestation of a cardiovascular disease. Many others with considerable risk of SCD or those with temporary increased risk may not meet the current guidelines for ICD implantation. This has led to the development of automated external cardioverter defibrillators (AEDs) for individual use.

There are two types of AEDs: 1) The automated external defibrillator with integrated electrocardiogram analysis. This is similar to the manual defibrillator except that it detects and analyzes heart rhythms automatically. This AED requires an operator to initiate the delivery of shock, and 2) The wearable cardioverter defibrillator (WCD) which is also an external defibrillator with integrated electrocardiogram analysis, but in a garment type.

The WCD has defibrillation features similar to the ICD, and does not require an operator to defibrillate. It consists of a vest-like device worn under the patient's clothing and is sized to accommodate the chest size and weight of the patient. The device holds a monitor, electrodes, battery and a small alarm module. The monitor is designed to automatically sense abnormal heart rhythms and deliver a series of shocks through the electrodes. When arrhythmia is detected, the device displays a message to the patient to press and hold two response buttons to prevent unnecessary shocks. If the device continues to detect the abnormal rhythm and the patient loses consciousness, he / she involuntarily releases the response buttons and an electrical shock therapy is automatically delivered to restore the heart rhythm. Non-wearable components of the device include a battery

charger, a computer modem, modem cable, computer cable, WCNET, and the diagnostic test. The WCNET is a web based data storage and retrieval system that allows the physician to access the patient's ECG data stored in the WCD monitor. The WCD has the advantage of allowing the patient to ambulate freely, and does not require assistance from a bystander when the life threatening arrhythmic event occurs (Reek 2003). It may have limited use among patients who are unable to wear the WCD vest due to obesity, or due to skin irritation from wearing the electrode 24 hours per day.

The LIFECOR Wearable Cardioverter Defibrillator (WCD ®)2000 system, is FDA approved for its use 24 hours a day by patients at risk of a sudden cardiac arrest, and an implantable defibrillator is not wanted or not practical. It should not be used if the patient has or needs an implantable ICD, is under 18 years of age, pregnant or breast feeding, has a vision or hearing problem or taking medications that would interfere with pushing the response button on the alarm module, is unwilling or unable to wear the device continuously, is of childbearing age and not attempting to prevent pregnancy, or is exposed to excessive electromagnetic interference (FDA Web page).

## Medical Technology Assessment Committee (MTAC)

### **Wearable Automatic Defibrillators**

#### **02/05/2007: MTAC REVIEW**

**Evidence Conclusion:** The literature search on the wearable cardioverter defibrillators revealed only small observational studies with no control or comparison groups. Two small studies (Auricchio et al, 1998, and Reek et al, 2003) tested the efficacy of the device in the electrophysiology lab among very small numbers of patients (N=15, and 12 respectively). The largest study (N=289) published by Feldman et al 2004, combined the results of two case series (WEARIT and BIROAD). They were begun as separate studies but were combined at the request of the FDA. The authors did not indicate at what stage they were grouped, but noted that they tracked the results of each group as a subpopulation. The two studies had different inclusion criteria, and different population characteristics with different implications. The WEARIT participants were patients with NYHA class III or IV heart failure and an ejection fraction <30% while BIROAD included a more heterogeneous group of patients considered at high risk after an MI or CABG surgery or were candidates of an ICD but refused the implant. The BIROAD population used the wearable defibrillator (WCD) for 4 months after which they discontinued therapy or received an ICD. The WEARIT population continued in the study until they developed a terminal heart failure requiring bed confinement, became unable to interact with the device, or experienced a definitive event as ICD implant, heart transplantation, or hospitalization for terminal heart failure. Patients in both groups could discontinue participation at any time during therapy. The follow-up duration with a mean of 3.1 months was too short, as only 8 defibrillation attempts were made, six of which were successful, 2 in the WEARIT population occurring the same patient, and four in the BIROAD population and again two occurred in the same patient. Six sudden deaths occurred in patients who were not wearing the device at the time of the event or were improperly wearing it despite the training they received and the 24-hour support they had. Over one fifth of the participants withdrew prematurely from the study, mainly due to discomfort and life style issues or due to receiving an ICD implant. In conclusion the published studies do not provide sufficient evidence to determine the efficacy and safety of the wearable cardioverter defibrillator for patients at high risk for sudden cardiac death.

**Articles:** The search yielded 95 articles on the automated external defibrillators. The majority were reviews, opinion pieces, studies on the non-wearable AEDs, and other articles not directly related to the current review. Three studies on the wearable cardioverter defibrillators were identified. All were observational, and two were very small (N=12-15). The largest study by Feldman and colleagues was selected for critical appraisal. Feldman AM, Klein H, Tchou P, et al. Use of wearable defibrillator in terminating tachyarrhythmias in patients at high risk for sudden death: results of WEARIT/BIROAD. *Pacing Clin Electrophysiol* 2004; 27:4-9. See [Evidence Table](#).

The use of Wearable Automatic Defibrillators in the prevention of sudden cardiac death does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Automated External Defibrillators (AED) for Home Use by Pediatric Patients**

#### **BACKGROUND**

Approximately half of the deaths from cardiovascular disease in the United States are sudden and unexpected. Defibrillation immediately after a witnessed ventricular fibrillation (VF) has been shown to increase survival rates from cardiac arrest. Each minute of delaying defibrillation is associated with about a 10% reduction in survival and survival rates after 10 minutes of VF are low (Marenco et al., 2001) The use of automated external defibrillators (AEDs) by lay people can reduce the time to defibrillation compared to waiting for the arrival of emergency medical personnel. AEDs, which were first introduced in 1979, are portable devices designed both to analyze cardiac rhythms via a heart rhythm analysis algorithm and to deliver shocks. Shock treatment is appropriate when the patient is in ventricular fibrillation. The devices indicate to the operator via text and/or voice prompts whether shock treatment is recommended. AEDs were first approved by the FDA for use in adults. In May, 2001, the FDA

approved the Heartstream FR2 with attenuated defibrillation pads (Agilent Technologies, Seattle, WA) for use in infants and children with ventricular fibrillation. The Heartstream FR2 is specifically designed for children who are 8 years old or younger, weigh 55 pounds or less, and are not responsive and not breathing. The attenuated pads deliver a shock that is about one-third the strength delivered to adults (FDA Web site). There is interest in having the Heartstream FR2 available at home at school for children with known heart disease. In order to be effective, the pediatric AED device must accurately detect shockable and non-shockable rhythms and must deliver an appropriate level of shock. Moreover, the device must be able to be used properly by parents and school personnel. In addition, AEDs are only applicable when patients are in ventricular fibrillation. Children in cardiac arrest may be less likely than adults to be in VF, although data are few and conflicting. The largest study, an analysis of 10,992 non-traumatic cardiac arrests in Seattle/King County between 1976 and 1992 (Appleton et al., 1995), found that VF was the first recorded rhythm in only 12/412 (3%) of patients 0-7 years old. In adults 30 years or older, the rate of VF was 42%. In another report of Seattle/King County data (Mogayzel et al., 1995), VF was the initial rhythm in 12 out of the 24 emergency medical services patients under 20 years old whose arrest was due to a cardiac cause and 2 out of 8 patients with congenital heart disease. Evidence on the technical accuracy of the Heartstream FR2 and the ability of AEDs to reduce mortality in practice will be reviewed.

**12/11/2002: MTAC REVIEW**

**Automated External Defibrillators (AED) for Home Use by Pediatric Patients**

**Evidence Conclusion:** The findings from a study by Cecchin et al suggest that the Heartstream FR2 AED can effectively distinguish between shockable and non-shockable rhythms in children. Limitations of this study are possible bias in selecting children for inclusion, variability in data collection and the first author being a consultant to the device manufacturer. Shocks were not actually delivered in the Cecchin study, so the appropriateness of the intensity of shock could not be examined. No evidence was available on the effectiveness of the device at reducing mortality in practice.

**Articles:** The search yielded 28 articles. Many of the articles were reviews, dealt with technical issues or addressed the use of AEDs in public places. There were no articles on clinical outcomes (e.g. mortality) of pediatric patients or on the actual use of AEDs for pediatric patients at home or at school. There was one article on the ability of the Heartstream FR2 to accurately detect arrhythmias in children (Cecchin et al., 2001) and no articles on the appropriateness of the shock delivered by the device to pediatric patients. The Cecchin article was critically appraised: Ceccin F, Jorgenson DB, Berul CI et al. Is arrhythmia detection by automatic external defibrillator accurate for children? *Circulation* 2001; 103: 2483-2488. See [Evidence Table](#).

The use of AED in the prevention of sudden death in the home from ventricular fibrillation does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Mobility Assistive Devices

- Associated Special Parts
- Manual Wheelchairs
- Power Wheelchairs
- Scooters

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

### Criteria

#### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<b>Mobility Assist Devices</b> ( <a href="#">280.3</a> )
Local Coverage Determinations (LCD)	<b>Manual Wheelchair Bases</b> <a href="#">L33788</a> <b>Power Mobility Devices</b> <a href="#">L33789</a> <b>Wheelchair Options/Accessories</b> <a href="#">L33792</a>
Local Coverage Articles	<b>Wheelchair Seating</b> ( <a href="#">A52505</a> ) Wheelchair Options/Accessories – Non-Medically Necessity Coverage and Payment Rules ( <a href="#">A52504</a> )

#### For Non-Medicare Members

##### Wheelchair, 2-Gear (aka MAGICWHEELS® 2-Gear Wheelchair Drive)

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

#### Documentation Requirements:

See [45 Day Visit Documentation Requirements](#)

#### MANUAL WHEELCHAIRS

Group Health has elected to use the Manual Wheelchair (GHC-0354) MCG\* for medical necessity determinations.

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Most recent note from requesting provider
- Most recent Physical Therapy mobility assessment
- If recent discharge from SNF/IPR, include therapy notes
- Vender assessment and itemized codes if applicable

#### POWER OPERATIVE VEHICLES (POV)/SCOOTERS

Group Health has elected to use the Scooter (GHC-0352) (MCG)\* for medical necessity determinations.

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

**If requesting this service, please send the following documentation to support medical necessity:**

- Most recent note from requesting provider
- Most recent Physical Therapy mobility assessment
- If recent discharge from SNF/IPR, include therapy notes
- Vender assessment and itemized codes if applicable

**I. POWER WHEELCHAIR**

- A. Mobility Assistive Device (MAE) is reasonable and necessary for patients who have a personal mobility deficit sufficient to impair their performance of Mobility-Related Activities of Daily Living (MRADL) such as toileting, feeding, dressing, grooming, and bathing in customary areas in the home and coverage is considered when the following has been applied:
1. The patient has a mobility limitation that significantly impairs his/her ability to participate in one or more MRADLs in the home. A mobility limitation is one that:
    - Prevents the patient from accomplishing the MRADLs entirely, or,
    - Places the patient at reasonably determined heightened risk of morbidity or mortality secondary to the attempts to participate in MRADLs, or,
    - Prevents the patient from completing the MRADLs within a reasonable time frame.
- B. These other limitations can be ameliorated or compensated sufficiently such that the additional provision of MAE will be reasonably expected to significantly improve the patient's ability to perform or obtain assistance to participate in MRADLs in the home.
1. A caregiver\*\*, for example a family member, may be compensatory, if consistently available in the patient's home and willing and able to safely operate and transfer the patient to and from the wheelchair and to transport the patient using the wheelchair. The caregiver's need to use a wheelchair to assist the patient in the MRADLs is to be considered in this determination.
  2. The amelioration or compensation requires the patient's compliance with treatment, for example medications or therapy, substantive non-compliance, whether willing or involuntary. This can be justification for denial of wheelchair coverage if it results in the patient continuing to have a significant limitation. It may be determined that partial compliance results in adequate amelioration or compensation for the appropriate use of MAE.
- C. The patient or caregiver demonstrates the capability and the willingness to consistently operate the MAE safely.
1. Safety considerations include personal risk to the patient as well as risk to others. The determination of safety may need to occur several times during the process as the consideration focuses on a specific device.
  2. A history of unsafe behavior in other venues may be considered.
- D. If a manual wheelchair or POV does not meet the mobility needs of the patient, and all of the following features provided by a power wheelchair are needed to allow the patient to participate in one or more MRADLs,
1. The pertinent features of a power wheelchair compared to a POV are typically controlled by a joystick or alternative input device, lower seat height for slide transfers, and the ability to accommodate a variety of seating needs.
  2. The type of wheelchair and options provided should be appropriate for the degree of the patient's functional impairments.
  3. The patient's home should provide adequate access, maneuvering space and surfaces for the operation of a power wheelchair.
  4. Assess the patient's ability to safely use a power wheelchair.
  5. The patient has had a face to face evaluation by the prescribing physician within the past 45 days which assesses his/her mobility status, and the need for the power wheelchair.

\*\*Note: If the patient is unable to use a power wheelchair, and if there is a caregiver who is available, willing, and able to provide assistance, a manual wheelchair is appropriate. A caregiver's inability to operate a manual wheelchair can be considered in covering a power wheelchair so that the caregiver can assist the patient.

**Home Assessment:**

Coverage for the use of an electric wheelchair is determined solely for the needs within the home. An on-site evaluation of the member's home is necessary to verify that the member can adequately maneuver the device that is provided considering the physical layout, doorway width, doorway thresholds, and surfaces. There must be a written report of this evaluation available upon request.

**Associated Special Parts:**

The options/accessories are necessary for the patient to perform one or more of the following activities:

- 1) Function in the home.
- 2) Perform instrumental activities of daily living.

An option/accessory that is beneficial primarily in allowing the patient to perform leisure or recreational activities is non-covered.

Anti-rollback device (E0974)	<ul style="list-style-type: none"> <li>• The patient propels himself/herself and needs the device because of ramps.</li> </ul>
Arm of Chair	<ul style="list-style-type: none"> <li>• Adjustable arm height option (E0973, K0017, K0018, K0020) is covered if the patient requires an arm height that is different than that available using nonadjustable arms and the patient spends at least 2 hours per day in the wheelchair.</li> <li>• An arm trough (E2209) is covered if patient has quadriplegia, hemiplegia, or uncontrolled arm movements.</li> </ul>
Fully reclining back (E1226) Has one or more:	<ul style="list-style-type: none"> <li>• Quadriplegia</li> <li>• Fixed hip angle</li> <li>• Trunk or lower extremity casts/braces that require the reclining back feature for positioning</li> <li>• Excess extensor tone of the trunk muscles and/or</li> <li>• The need to rest in a recumbent position two or more times during the day and transfer between wheelchair and bed is very difficult</li> </ul>
Elevating Leg Rests (E0990, K0046, K0047, K0053, K0195)	<ul style="list-style-type: none"> <li>• The patient has a musculoskeletal condition or the presence of a cast or brace which prevents 90 degree flexion at the knee or</li> <li>• The patient has significant edema of the lower extremities that requires having an elevated leg rest or</li> <li>• The patient meets criteria for and has a reclining back on the wheelchair</li> </ul>
Mechanically linked leg elevation feature (E1009) Power leg elevation feature (E1010)	<ul style="list-style-type: none"> <li>• Meet criteria for elevating leg rest</li> <li>• And is receiving a <b>covered</b> power seating system</li> </ul>
Hook-on headrest extension	<ul style="list-style-type: none"> <li>• Has weak neck muscles and needs headrest for support OR</li> <li>• Meets criteria for and has reclining back on wheelchair</li> </ul>
Non-standard seat frame (E2201-E2204, E2340-E2343)	<ul style="list-style-type: none"> <li>• A nonstandard seat width and/or depth is covered only if the patient's dimensions justify the need.</li> </ul>
Electronic Interface (E2351)	<ul style="list-style-type: none"> <li>• An electronic interface to allow a speech generating device to be operated by the power wheelchair control interface is covered if the patient has a <b>covered</b> speech generating device.</li> </ul>
Swingaway, retractable, or removable hardware (E1028)	<ul style="list-style-type: none"> <li>• Needed to move the component out of the way so the patient can perform a slide transfer AND</li> <li>• The sole reason is not to allow the patient to move close to desks or other surfaces</li> </ul>
Tilt-in-space seat Power tilt seating system (E1002) Power reclining seat system (E1003-E1005) Power tilt and reclining seat system (E1006-E1008)	<ul style="list-style-type: none"> <li>• Has documented weak upper extremity strength or a disease that will lead to weak upper extremities. AND</li> <li>• Is at risk for skin break down because of inability to reposition body in chair to relieve pressure areas.</li> </ul>
The following are not covered because they are not primarily medical in nature	<ul style="list-style-type: none"> <li>• Power seat elevation feature (E2300)</li> <li>• Power standing feature (E2301)</li> <li>• Attendant control (E2331)</li> <li>• Electrical connection devices (E2310 or E2311) with the sole function of connection for a power seat elevation or power stand feature.</li> <li>• Electrical interface used to control lights or other electrical devices</li> </ul>
E1399, K0108	<ul style="list-style-type: none"> <li>• Any part that is requested using either of these miscellaneous codes is subject to review for medical necessity.</li> </ul>

The following wheelchair options are not covered

- “Ability to balance on two wheels” feature for a PWC
- Any wheelchair, option, or accessory that is primarily for the purpose of allowing the individual to perform leisure or recreational activities
- Articulating (telescoping) elevating leg rests: considered for patients with long legs
- Back support systems: Back support systems have a plastic frame which is padded and covered with cloth or other material; they are designed to be attached to a wheelchair base, but do not completely replace the wheelchair back. These back support systems are considered convenience items, because they are not generally necessary to provide trunk support in members in wheelchairs. An adequate seating system would allow the member to function appropriately in the wheelchair.
- Battery charger: A battery charger for a power wheelchair is included in the allowance for a power wheelchair base. A dual mode battery charger for a power wheelchair is considered a convenience item and is not covered.
- Canopies
- Clothing guards to protect clothing from dirt, mud, or water thrown up by the wheels (similar to mud flaps for cars)
- Commode seat, wheelchair (HCPCS code E0968)
- Crutch or cane holder: May need to help safely transfer
- Electronic balance feature for a PWC
- Flat-free inserts (zero pressure tubes): Flat free inserts have a removable ring of firm material that is placed inside of a pneumatic tire. Flat free inserts are intended to allow the wheelchair to continue to move if the pneumatic tire is punctured.
- Home modifications: Modifications to the structure of the home to accommodate wheelchairs are not considered treatment of disease and are not covered. Examples of home modifications and installations that are not covered include wheelchair ramps, wheelchair accessible showers, elevators, and lowered bath or kitchen counters and sinks.
- Identification devices (such as labels, license plates, name plates)
- Lighting systems
- Powered seat elevator attachments for electric, powered, or motorized wheelchairs(HCPCS code E2300)
- Power or manual standing options or standing wheelchairs (HCPCS code E2301, E2230)
- Powered wheelchair seat cushions (HCPCS code E2610)
- Remote operation feature for a PWC
- Rental or purchase of more than one mobility assistive device at a time
- Seat elevator wheelchairs (HCPCS code K0830, K0831)
- Shock absorbers
- Speed conversion kits
- Stair-climbing wheelchairs, computerized or gyroscopic mobility systems (e.g., INDEPENDENCE™ IBOT™ Mobility System, Independence Technology, LLC, Warren, NJ) (K0011)
- Transport chairs or rollabout chairs (HCPCS code E1031, E1037, E1038, E1039)
- Warning devices, such as horns and backup signals
- Wheelchair accessory, tray & half-lap tray (HCPCS code E0950)
- Wheelchair lifts (e.g., Wheel-O-Vator, trunk loader) -- devices to assist in lifting wheelchair up stairways, into car trunks, or in vans (see CPB 0459 - Seat Lifts and Patient Lifts)
- Wheelchair rack for automobile (auto carrier) -- car attachment to carry wheelchair
- Wheelchair tie downs (transit options)
- Miscellaneous items needed to adapt to the outside environment for convenience, work, leisure or recreational activities including, but not limited to:
  - accessory holder: flag, cup, speech generating device
  - auto carriers
  - baskets, backpacks, bags, seat pouches used to transport personal belongings
  - firearm/weapon holder/support
  - gloves
  - lifts for car trunk, stairways, seat lifts and individual lifts
  - lowered seat elevator attachments for powered or motorized wheelchairs
  - ramps
  - snow tires for wheelchairs
  - support or mounting frames for cellular phone & tablets

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

## Background

In 2000, almost 1.7 million people in the United States used wheelchairs due to a disability. Of these, 1.5 million people used a manual wheelchair (Kaye et al., 2000). Manual wheelchairs require extensive use of individuals' upper limbs for mobility, transfer and other daily functional activities. This repetitive weight-bearing use of the arms and shoulders may cause upper-extremity problems, and reports of shoulder pain are common. In a recent survey of individuals with thoracic spinal cord injuries, 40% of respondents reported current shoulder pain associated with wheelchair use (Alm et al. 2008).

One way to address shoulder pain in manual wheelchair users is with stretching and strengthening exercises. Several small trials have tested specific exercise programs and found statistically significant reduction in shoulder pain (Nawoczenski et al., 2006; Curtis et al., 1999).

Another option, for individuals who want to continue using manual wheelchairs, is to reduce the force put on the upper extremities by modifying the wheelchair. One modification is the addition of battery-powered wheels that can be fitted to standard manual wheelchairs. These wheels add a motorized boost, or "torque multiplier" allowing the user to go further with the same amount of force. A disadvantage of the battery-powered wheels is that the currently available products are heavy. For example, the Alber E-Motion weighs 53 pounds, excluding the wheelchair (Frankmobility.com). Newer, lighter products are being developed. The Quickie Xtend power assist product weighs 38 pounds (Quickie-wheelchairs.com). Another potential disadvantage of power-assisted wheels is that the batteries need to be recharged, sometimes frequently, which can be disruptive to daily activities.

A different modification to the manual wheelchair is to use the 2-gear wheelchair drive produced by MagicWheels, Inc. (Seattle, WA). The wheelchair drive adapts to most standard wheelchairs and does not include batteries or motors. By sliding a switch, the user can change from a conventional 1:1 gear ratio to a 2:1 ratio. The added weight is lighter than the battery-powered assist products. Depending on options, the additional weight per pair of wheels varies from 8.2-10.5 pounds. The gear shifting is designed to reduce upper body stress and assist the user to navigate ramps, hills and uneven terrain. Newer models include an automatic hill holding feature preventing the wheelchair from sliding backwards between pulls while going uphill, and a downhill assisted braking feature. MagicWheels was founded in 1996 by several partners. The University of Washington, where initial product development research took place, owns stock in MagicWheels as part of a patent licensing agreement.

The gear shifting is designed to reduce upper body stress and assist the user to navigate ramps, hills and uneven terrain. Newer models include an automatic hill holding feature preventing the wheelchair from sliding backwards between pulls while going uphill, and a downhill assisted braking feature. MagicWheels was

founded in 1996 by several partners. The University of Washington, where initial product development research took place, owns stock in MagicWheels as part of a patent licensing agreement. The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations. Mechanical wheelchairs and wheelchair components are Class 1 devices according to the FDA. Class 1 devices are subject to general controls such as product listing and labeling requirements, but are exempt from the pre-market approval process including safety and effectiveness evaluation.

## 12/01/2008: MTAC REVIEW

### Wheelchair, 2-Gear (aka MAGICWHEELS® 2-Gear Wheelchair Drive)

**Evidence Conclusion:** There is insufficient evidence to draw conclusions about the impact of the MagicWheels 2-gear wheelchair on functional ability and shoulder and arm pain. There was only one published empirical study on the MagicWheels wheelchair product. The study (Finley et al., 2007) was a small interrupted time series. 17 individuals started the study, and 12 completed the 5-month intervention phase. The study found improvement in shoulder pain, but not overall functional ability, or performance on an incline test when patients used MagicWheels. Shoulder pain decreased when MagicWheels was introduced, and increased again after a return to standard wheels. Findings are subject to bias such as the Hawthorne effect (see evidence table for study details).

**Articles:** The PubMed search yielded 8 articles. Seven of these were on different related clinical topics, with the words “magic” and “wheels” included in the abstract or other part of the citation. No additional articles were identified via the “related articles” function in PubMed. There was only one published empirical article on the MagicWheels wheelchair, and this study was critically appraised: Finley MA, Rodgers MM. Effect of 2-speed geared manual wheelchair propulsion on shoulder pain and function. Arch Phys Med Rehabil 2007; 88: 1622-1627. See [Evidence Table](#).

The use of 2-gear wheelchairs does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Whole Body Computed Tomography Scan

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	<a href="#">Computed Tomography (220.1)</a> .
Local Coverage Determinations (LCD)	None
Local Coverage Article	None

##### For Non-Medicare Members

There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Computed tomography (CT) is a diagnostic procedure that uses x-rays to obtain cross-sectional images of the body. The images are based on the absorption of x-rays by different body tissues. Many CT systems allow imaging of multiple slices simultaneously so larger volumes of anatomy can be imaged in less time. Whole-body screening is a non-tailored, non-specific CT scan. It has recently been promoted as a general screening test to healthy individuals who have no symptoms or suspicion of disease. The purpose of screening is to prevent or delay, by means of early detection, the development of advanced disease and its adverse side effects. (From Kaiser Technology Assessment material.)

Currently some medical imaging facilities are promoting a new use of computed tomography (CT), also called computerized axial tomography (CAT) scanning. This use is referred to as whole-body CT scanning or whole-body CT screening, and it is marketed as a preventive or proactive health care measure to healthy individuals who have no symptoms or suspicion of disease. **At this time the FDA knows of no data demonstrating that whole-body CT screening is effective in detecting any particular disease early enough for the disease to be managed, treated, or cured and advantageously spare a person at least some of the detriment associated with serious illness or premature death.** Any such presumed benefit of whole-body CT screening is currently uncertain, and such benefit may not be great enough to offset the potential harms such screening could cause. (From the FDA consumer Web site.)

#### Medical Technology Assessment Committee (MTAC)

##### Whole Body Computed Tomography

###### 07/14/2004: MTAC REVIEW

**Evidence Conclusion:** (Kaiser conclusions) No studies have been published that evaluate the efficacy of whole body CT screening of asymptomatic individuals.

**Articles:** (From Kaiser materials) Medline was searched through January 2004 with the search terms "whole body computed tomography" and "disease screening" - with variations. Screening of articles: (From Kaiser materials) No published studies were identified. Additional references: INTC Agenda packet, April 19, 2004. Included materials from Kaiser, Southern California and Hayes, Inc.

The use of whole body computed tomography scanning in the general screening of healthy individuals does not meet the *Group Health Medical Technology Assessment Criteria*.

## Clinical Review Criteria

### Wound Care Treatments

- Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Procuren)
- Electrical Stimulation and Electromagnetic Therapy
- Low Frequency, Noncontact, Nonthermal Ultrasound Wound Therapy
- Maggot Debridement Therapy (MDT)
- Medihoney Dressing for Wound Management
- Noncontact Normothermic Wound Therapy
- OASIS Wound Dressing
- Tissue Engineered Skin Substitutes
- Warm-Up Wound Therapy

**A Separate Criteria Document Exists for the Following:**

**[Negative Pressure Wound Therapy Pumps \(NPWT\)](#)**

**[Platelet Rich Plasma Injections for the Treatment of Non-Healing Fractures and Tendinopathy](#)**

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. #### **Skin Substitutes** – HCPCS Q4100 – Q4160

Medicare considers these codes wound care dressings and not separately billable. They do not need to go for Medical Review. See the [Noridian ASC Payment System – January 2016 Update Section F](#)

#### For Non-Medicare Members

Treatment	Criteria Used
Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Autogel, Procuren, SafeBlood)	MCG* A-0630

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Noncontact Normothermic Wound Therapy	MCG* A-0351 <b>If requesting this service, please send the following documentation to support medical necessity:</b> <ul style="list-style-type: none"> <li>Last 6 months of clinical notes from requesting provider &amp;/or specialist</li> </ul>
Electrical Stimulation and Electromagnetic Therapy	MCG* A-0242 <b>If requesting this service, please send the following documentation to support medical necessity:</b> <ul style="list-style-type: none"> <li>Last 6 months of clinical notes from requesting provider &amp;/or specialist</li> </ul>
Medihoney Dressing for Wound Management  Warm-Up Wound Therapy  Low Frequency, Noncontact, Non Thermal Ultrasound Wound Therapy	There is insufficient evidence in the published medical literature to show that this service/therapy is as safe as standard services/therapies and/or provides better long-term outcomes than current standard services/therapies.
Maggot Debridement Therapy (MDT)	No medical necessity review required for this service.
<p>Tissue Engineered Skin Substitutes</p> <p>Tissue-engineered skin substitute may be indicated for <b>ONE or more of the following:</b></p> <p>1. Diabetic ulcers, as indicated by <b>ALL of the following:</b></p> <ul style="list-style-type: none"> <li>Treated foot has adequate blood supply as evidenced by either the presence of a palpable pedal pulse or an ankle-brachial index (ABI) of <math>\geq 0.70</math>)</li> <li>Receiving conventional wound care and optimal glycemic management to continue during treatment</li> <li>Diabetes mellitus (type 1 or type 2)</li> <li>Full-thickness foot ulcer with location on plantar, medial, or lateral area, and no exposure of tendon, muscle, capsule, or bone (Full thickness ulcer extends thru dermis and epidermal layers. Subcutaneous fat may be visible but bone, tendon or muscle are not exposed.)</li> <li>Ulcer history, as indicated by <b>ONE or more of the following:</b> <ul style="list-style-type: none"> <li>Duration greater than 3 weeks (prior to Apligraf, (Graftskin))</li> <li>Duration greater than 6 weeks (prior to Dermagraft)</li> </ul> </li> <li>No allergy to bovine products</li> <li>No response to conventional therapy, including <b>ALL of the following:</b> <ul style="list-style-type: none"> <li>No weight-bearing (off loading, so there is no pressure on the wound)</li> <li>Optimal glycemic management ( HbA1c of 7% (0.07) or less)</li> <li>Saline-moistened dressings</li> <li>Sharp debridement</li> </ul> </li> <li>No wound infection</li> <li>No slough or eschar in the wound bed</li> </ul> <p>Only the following products are approved for treatment of diabetic ulcers – Dermagraft Q4106, Apligraf Q4101, Oasis Wound Matrix Q4102, Oasis Ultra Tri-Layer Matrix Q4124, GraftJacket Regenerative Tissue Matrix Q4107 Epifix Amniotic Membrane(Cigna), TheraSkin® Q4121</p> <p>2. Venous insufficiency ulcers, as indicated by <b>ALL of the following:</b></p> <ul style="list-style-type: none"> <li>Treated foot has adequate blood supply as evidenced by either the presence of a palpable pedal pulse or an ankle-brachial index (ABI) of <math>\geq 0.70</math>)</li> <li>Receiving concurrent conventional wound care, to include compression of extremity (e.g. compression stocking, ace bandage, lymphedema pump – if meets criteria)Receiving concurrent optimal glycemic management, if patient is also diabetic</li> <li>Duration greater than 1 month</li> <li>Full-thickness ulcer due to venous insufficiency</li> <li>No allergy to bovine products</li> <li>No response to conventional therapy, including <b>ALL of the following:</b></li> </ul>	

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

- Saline-moistened dressings
- Sharp debridement
- No wound infection
- Compression
- No slough or eschar in the wound bed

Only the following products are approved for treatment of venous insufficiency ulcers - Oasis Wound Matrix Q4102, Apligraf Q4101, Epifix Amniotic Membrane Q4131, Oasis® Ultra Tri-Layer Matrix Q4124, TheraSkin® Q4121

**Apligraf®**

When the above medical necessity criteria are met, the following conditions of coverage apply:

- treatment is limited to one initial application
- additional applications at a minimum of one week intervals, for up to a maximum of four in 12 weeks are considered medically necessary when evidence of wound healing is present (e.g., signs of epithelialization and reduction in ulcer size)

Additional applications beyond 12 weeks are considered not medically necessary regardless of wound status.

**Dermagraft® and Epifix Amniotic Membrane Q4131**

When the above medical necessity criteria are met, the following conditions of coverage apply:

- treatment is limited to one initial application
- additional applications for up to a maximum of eight in 12 weeks when there is evidence of wound healing (e.g., signs of epithelialization and reduction in ulcer size)

Additional applications beyond 12 weeks are considered not medically necessary regardless of wound status.

In regards to the following products, there is insufficient evidence in the published medical literature to show that these skin substitutes are more efficacious or provide better longer outcomes than the preferred products for the conditions listed above:

- Active barrier
- ActiveMatrix
- Acuseal
- Adherus Dural Sealant;
- Affinity
- AlloMax for indications other than breast reconstruction; for AlloMax for breast reconstruction, see Breast Reconstruction or Breast Protheses criteria
- Allopatch for soft tissue augmentation and all other indications;
- Alloskin RT;
- Alloskin;
- AlloSource cryopreserved human cadaver skin;
- Allowrap – Aetna (Cigna)
- Allowrap DS
- Amnioband
- AmnioCare;
- Amnioclear
- Amnioclear LTC flowable
- AmnioExCel;
- AmnioFix;
- Amniomatrix;
- AmnioMTM;
- AmnioShield;
- Amniotic fluid injection for corneal wound healing and for prevention of adhesions after orthopedic surgery;
- AmnioX (human embryonic membrane) for tarsel tunnel repair and all other indications;
- Architect ECM;
- Architect PX;
- Architect™ Biomatrix;
- Artelon (poly[urethane urea] elastomer) for anterior cruciate ligament reconstruction, rotator cuff repair, trapezio-metacarpal joint osteoarthritis and all other indications;
- Arthres GraftRope for acromio-clavicular joint separation reconstruction;
- Arthroflex (FlexGraft);

- Autologous fat for the treatment of scars;
- Avance nerve graft
- Avotermin for improvement of skin scarring;
- Axogen 2 nerve wrap;
- Biodesign® (Surgisis® ) Hiatal Hernia Matrix;
- Biodesign® (Surgisis® ) Inguinal Hernia Matrix;
- Biodesign® (Surgisis® ) RVP Recto-Vaginal Fistsula Plug;
- BioDexcel;
- BioDfactor/BioDfence human amniotic allograft;
- BioFix
- Biostat Biologx fibrin sealant for wound healing and all other indications;
- Biotape reinforcement matrix for soft tissue augmentation and all other indications;
- Biovance
- CellerateRX;
- Clarix® Flo Integumental;
- Clarix® Regenerative Matrix;
- CollaFix;
- Conexa reconstructive tissue matrix;
- CorMatrix Patch for cardiac tissue repair and all other indications;
- C-QUR biosynthetic mesh;
- CRXa;
- CryoSkin®
- Cymetra injectable allograft for wound healing
- Dermacell;
- DermaClose RC continuous external tissue expander for facilitation of wound closure and all other indications;
- Dermagraft for chronic foot ulcer secondary to necrotizing fasciitis;
- DermaMatrix for wound healing and other indications other than breast reconstruction; for DermaMatrix for breast reconstruction, see Breast Reconstruction or Breast Prosthesis criteria
- Dermapure
- DermaSpan;
- Dermavest
- DryFlex (human amnion allograft) for shoulder repair and all other indications;
- Duraform™
- DuraGen Plus dural regeneration matrix for surgical repair of soft tissue deficiencies and all other indications;
- DuraGuard;
- DuraMatrix™
- DuraSeal;
- Durepair Regeneration Matrix®;
- Endoform;
- ENDURAGen;
- Epidex;
- EPIFLO transdermal continuous oxygen therapy for wound healing;
- Equine-derived decellularized collagen products (e.g., OrthADAPT, Unite, and Unite® Biomatrix);
- Evicel fibrin sealant for repair of cerebrospinal fluid leakage and all other indications;
- Excellagen®;
- E-Z Derm for wound healing and all other indications;
- FlexHD acellular dermal matrix for wound healing; for FlexHD for breast reconstruction, see Breast Reconstruction or Breast Prosthesis criteria
- FloGraft;
- Fortaderm Antimicrobial;
- Fortaderm™;
- Gammagraft skin substitute for wound healing and all other indications;
- Gore Bio A Tissue reinforcement
- GORE BIO-A Fistula Plug;
- Grafix Core and Grafix Prime;
- Graftjacket express injectable allograft for wound healing and all other indications;

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

- Guardian;
- Hyalomatrix (hMatrix);
- HydroFix;
- Inforce;
- Integra Neural Wrap for peripheral nerve repair and all other indications
- Integra Wound Matrix and Integra Flowable Wound Matrix for the management of wounds including partial and full-thickness wounds, pressure ulcers, venous ulcers, diabetic ulcers, chronic vascular ulcers, tunneled/undermined wounds, surgical wounds (e.g., donor sites/grafts, post-Mohs surgery, post-laser surgery, podiatric, wound dehiscence), trauma wounds (e.g., abrasions, lacerations, second-degree burns, skin tears) and draining wounds and all other indications;
- Integra™ Flowable Wound Matrix;
- LiquidGen;
- Marigen
- Matriderm;
- MatriStem wound micromatrix powder;
- Matrix HD™
- Medeor;
- MediHoney;
- Mediskin™
- Memoderm;
- Menaflex Collagen Meniscus Implant - see Collagen Meniscus Implant criteria
- Meso BioMatrix;
- Neoform Dermis for wound healing; for NeoForm for breast reconstruction - see Breast Reconstruction or Breast Prostheses criteria
- Neox 100;
- Neox 1K;
- Neox® Wound Matrix;
- Neoxflo;
- Neuragen;
- NeuraWrap
- Neuroflex;
- NeuroMatrix collagen nerve cuff for peripheral nerve repair and all other indications
- NeuroMend collagen nerve wrap for peripheral nerve repair and all other indications
- NuCel liquid wound covering;
- NuShield, NuShield Orthopaedics, and NuShield Spine;
- Oasis burn matrix for wound healing and all other indications;
- Orcel®
- OrthADAPT Bioimplant (type I collagen scaffold) for tendon repair and all other indications;
- OrthADAPT™ Bioimplant
- OsseoGuard;
- Ovation;
- PalinGen membrane for wound healing;
- PalinGen® Flow
- PalinGen® Xplus
- Parietex Composite (PCO) Mesh for the treatment of genito-urinary (e.g., uterine or vaginal vault) prolapse;
- Peri-Guard Repair Patch;
- Peri-Strips Dry, and Peri-Strips Dry with Veritas Collagen Matrix;
- Permacol Biologic Implant for soft tissue surgical repairs, including hernia repair, muscle flap reinforcement, rectal prolapse (including intussusception), rectocele repair, abdominal wall defects, plastic and reconstructive surgery, complex abdominal wall repair and all other indications;
- Porcine-derived decellularized collagen products (e.g., Collamend, Cuffpatch, Pelvicol, and Pelvisoft);
- Porcine-derived decellularized fetal skin products (e.g., Mediskin);
- Porcine-derived polypropylene composite wound dressing (e.g., Avaulta Plus);
- Preclude® Dura Substitute
- Preclude® Pericardial Membrane
- Preclude® Vessel Guard
- PriMatrix acellular dermal tissue matrix for wound healing and all other indications;

Date Sent: February 28, 2017

- Suprathel;
- SurgiMend for plastic and reconstructive surgery, muscle flap reinforcement, hernia repair, reinforcement of soft tissues repaired by sutures or suture anchors, during tendon repair surgery (including reinforcement of the rotator cuff, patellar, Achilles, biceps, quadriceps, or other tendons), and all indications other than breast reconstruction; for SurgiMend for breast reconstruction - see Breast Reconstruction or Breast Prostheses criteria
- Surgisis (including Surgisis AFP Anal Fistula Plug, Surgisis Gold Hernia Repair Grafts, and Surgisis Biodesign);
- Talymed;
- TenoGlide tendon protector sheet (Tendon Wrap™ tendon protector) for the management and protection of tendon injuries and all other indications;
- TenSix (acellular dermal matrix) for tendon repair and all other indications;
- TissueMend for the repair or reinforcement of soft tissues repaired by sutures or suture anchors during tendon repair surgery, including reinforcement of the rotator cuff, patellar, Achilles, biceps, quadriceps, or other tendons, and all other indications;
- Tornier BioFiber Absorbable Biological Scaffold, and Tornier Collagen Coated BioFiber Scaffold;
- Unite® Biomatrix;
- Vascu-Guard®;
- Vaso Shield;
- Veritas collagen matrix for use as an implant in the surgical repair of soft tissue deficiencies and all other indications;
- VersaShield™
- Vitagel surgical hemostat for wound healing and all other indications;
- WoundEx® Flow
- WoundEx® Membrane
- XCM Biologic;
- Xelma;
- XenMatrix
- X-Repair

**\*MCG Manuals are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

## Background

Date Sent: February 28, 2017

These criteria do not imply or guarantee approval. Please check with your plan to ensure coverage. Preauthorization requirements are only valid for the month published. They may have changed from previous months and may change in future months.

Chronic wounds, wounds with long healing time, and wounds with frequent recurrence are a major health problem. They are a problem for the patient who suffers from them, the clinician who treats them, and the health care system that is overburdened by their cost. It is estimated that chronic wounds affect approximately 2% of the American population at an estimated cost of US \$20 billion per year. Many factors can impede wound healing, including chronic disease, venous insufficiency, arterial insufficiency, neuropathy, nutritional deficiencies and local features such as pressure, edema, and infection (Fonder, 2008, Rizzi 2010).

No single regimen is universally accepted as the best modality for treating chronic wounds. They are managed through conventional wound care procedures performed by primary care providers, community nurses, pharmacists, and others. In the early 2000s, the concept of wound bed preparation has been proposed as a means of providing a structured and systemic approach to the management of chronic wounds. It is believed to accelerate endogenous healing and/or facilitate the effectiveness of other therapeutic measures. Wound bed preparation involves ongoing wound debridement, management of exudates, and resolution of bacterial imbalance (Schulz 2003, Ramundo 2008).

Wound debridement is defined as the removal of devitalized or contaminated tissue as well as foreign material from the wound bed until healthy tissue is exposed. Efficient debridement reduces the necrotic burden, achieves healthy granulation tissue, and reduces wound contamination and tissue destruction. This can be performed by different enzymatic, autolytic, sharp/surgical, biological, and mechanical techniques. Each has its own advantages and limitations, and the methods that are most efficient at removal of debris, may at the same time be the most detrimental to fragile new growth (Schulz 2003, Beitz, 2005, Ramundo 2008).

Tissue-engineered skin substitutes (i.e., human skin equivalents [HSE]), also referred to as artificial skin, are bioengineered skin products and may be either acellular or cellular. Acellular (i.e., cadaveric human dermis with cellular material removed) products contain a matrix or scaffold composed of materials such as collagen, hyaluronic acid, and fibronectin. The construction of the matrix allows easy access by host cells during the healing process. Cellular products contain living cells such as fibroblasts and keratinocytes within a matrix. The cells contained within a matrix may be allogeneic (i.e., obtained from another individual) or autologous (i.e., obtained from the same individual). Some products are derived from other species (e.g., bovine, porcine) and are referred to as a xenograft. Skin substitutes are generally comprised of epidermal cells, dermal cells or may be composites (i.e., a combination of dermal and epidermal). The substitutes can be used as either temporary or permanent wound coverings. Grafting techniques utilized to apply skin substitutes include autografting (i.e., tissue transplanted from one part of the body to another), allografting (i.e., transplant from one individual to another of the same species), and xenografting (i.e., a graft from one species to another unlike species). Skin substitutes have been proposed for the treatment of multiple conditions including breast reconstruction and chronic wounds nonresponsive to standard therapy.

During breast reconstruction, acellular dermal skin substitutes (i.e., AlloDerm, AlloMax) are primarily used in the setting of tissue expander and breast implant reconstruction. Patients should be in overall good health and have no underlying condition that would restrict blood flow or interfere with the normal healing process (e.g., uncontrolled diabetes, hypertension, previous surgery). These matrixes may be indicated when there is insufficient tissue expander or implant coverage by the pectoralis major muscle and additional coverage is required, as may be the case in a very thin patient; if there is viable but compromised or thin post-mastectomy skin flaps that are at risk of dehiscence or necrosis; or if there is a need to re-establish the inframammary fold and lateral mammary fold landmarks. When used in appropriate candidates, these skin substitutes are proposed to improve control over placement of the inframammary fold and final breast contour, enhance use of available mastectomy skin, reduce the number of expander fills necessary, reduce time to complete expansion and eventual implant exchange, potential improved management of a threatened implant, reduce the need for explantation and the potential for reduction in the incidence of capsular contracture. However, there are ongoing concerns regarding the increased risk of seroma and infection, a higher risk of an implant having to be removed, and tissue flap death.

### ***Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Procuren)***

#### BACKGROUND

Wound healing is a dynamic process that involves a complex interaction of several cellular and biochemical events. Tissue repair begins with a clot formation and platelet degranulation which release the growth factors necessary for wound repair. Generally, the process of normal healing takes few days to 2 weeks and involves three phases that may overlap in time: 1. inflammatory phase, 2. proliferative phase, and 3. remodeling phase. If any of these phases is compromised, healing will be delayed. Treatment of chronic non-healing cutaneous wounds has challenged health care providers for generations, and various strategies including devices, biologics and drug have been used to accelerate the healing process. These agents are designed to affect one of processes involved in healing (Robson 1999). Advances in biology of wound healing, showed that macrophages and platelets are the chief regulatory cells in the repair process. Platelets are known for their role in haemostasis where they help prevent blood loss at site of vascular injury. They adhere, aggregate, and form a procoagulant surface leading to thrombin generation and fibrin formation. Activated platelets release potent locally acting growth factors substances that initiate division and migration of fibroblasts and formation of new capillaries promoting wound healing (Knighton 1986, Fu 2005). Becaplermin, a topical treatment with platelet derived growth factor as its active ingredient was approved by the FDA in 1997 to treat diabetic foot and leg ulcers that extend into the subcutaneous tissue or beyond and have adequate blood supply. Platelet derived growth factor (Procuren) for the treatment of non-healing cutaneous wounds was reviewed by MTAC in February 1999, and failed MTAC evaluation criteria due to the lack of scientific evidence to determine its safety and efficacy. It is being re-reviewed based on requests for coverage from Eastern WA. ***Bone Fracture Healing (GEM 21STM)*** Bone fracture healing is a biological process that involves both local and systemic acute phase reactants. The physiological events occurring at the site of injury include hematoma formation, recruitment and transformation of mesenchymal cells, induction of angiogenesis, and the production and remodeling of the extracellular matrix. Radiographic healing of a bone fracture is normally achieved in 4-13 months depending on type and location of the fracture. The rate of bone union also depends on several other factors as patient's health, compliance, nutritional status, stability of the fracture and others. Disruption of any of these factors would lead to delayed or non-union of the fracture. It was reported that approximately 10% of the bone fractures in the US are complicated by impaired healing, which has a high impact on the quality of life and burden of health costs. Several compounds and technologies have been, and are being developed to enhance fracture healing and accelerate repair. These include prostaglandins, gene therapy, growth hormone, parathyroid hormone, and growth factors. Among the growth factors studied are the bone morphologic proteins, transforming growth factor B, vascular endothelial growth factor, and platelet derived growth factor (PDGF) (Axelrad 2007, Hollinger 2008). In vitro and animal studies indicate that PDGF has the potential of accelerating the bone healing process. The experimental studies showed that PDGF receptors increase in osteoblasts as they mature, but that the response varies inversely to the number of receptors. This indicates that there is an optimal concentration and time during bone regeneration to deliver the PDGF in order to be effective (Axelrad 2007). The GEM 21STM a device for bone grafting material containing a therapeutic tri-calcium phosphate or PDGF was approved by the FDA for periodontally related defects in November 2005.

***Tendinopathy*** Tendinopathy is a general term that is used to describe a tendon injury. It is characterized by pain, stiffness, and loss of strength in the affected area. Treatments for tendinopathy include, but are not limited to: rest, anti-inflammatory medication, analgesia, orthotics, physical therapy, and local steroid injections. Another more recent technology that has been proposed for the treatment of tendinopathy is platelet rich plasma injections into the ailing tendon (Kampa 2010). Platelets are small nonnucleated blood cells that are involved in wound healing. The exact mechanism by which platelet rich plasma promotes tendon healing is unclear; however, it is thought that the growth factors and cytokines contained in the platelets speed tissue regeneration and healing. Platelets contain alpha granules and dense granules, which when stimulated release growth factors and cytokines. The alpha granules release: platelet-derived growth factor, transforming growth factor-beta, vascular endothelial growth factor, epidermal growth factor, insulin-like growth factor I and II, and fibroblast growth factor. These factors play an important role in cellular proliferation, chemotaxis, cellular differentiation, extracellular matrix production, and angiogenesis. The dense granules contain adenosine, serotonin, histamine, and calcium, which play a role in tissue modulation and regeneration (Foster 2009, Maffulli 2010). Platelet rich plasma is derived from anti-coagulated autologous whole blood, which is centrifuged to concentrate platelets in plasma. Normal platelet counts in the blood range from 150,000-350,000  $\mu$ L. The goal of the devices used to create platelet rich plasma is to raise the concentration to at least one million platelets per  $\mu$ L. After separation, the platelet rich plasma must be clotted to allow for delivery to the desired site. This clotting leads to platelet activation, resulting in the release of growth factors and cytokines. Bovine thrombin, calcium chloride, and type I collagen are different agents used to stimulate platelet activation (clotting) (Foster 2009). One of the advantages of this approach is that because the platelet rich plasma is derived from the patient's own blood there is a low chance of rejection. However, the optimal dose range has not been defined. The injection of platelet rich plasma is a procedure and therefore not

regulated by the FDA. However, several devices used in the preparation of platelet rich plasma have received FDA approved.

#### **02/10/1999: MTAC REVIEW**

##### **Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Procuren)**

**Evidence Conclusion:** The published evidence on the effect of Procuren for treating non-healing cutaneous wounds consists of two small randomized controlled trials, one of which reports improvements in wound healing for Procuren as compared to placebo and the other trial reports worse outcomes with Procuren. The available evidence does not allow any conclusion about the effects of Procuren on non-healing cutaneous wounds.

**Articles:** Knighton DR, et al. Stimulation of repair in chronic, nonhealing cutaneous ulcers using platelet-derived wound healing formula. *Surgery, Gyn, Obstet* 1990;170:56-60. The use of platelet derived growth factors for the treatment of non-healing cutaneous wounds is approved by the FDA and therefore GHC Criteria 1 is met.

There is insufficient scientific evidence that Procuren is medically effective and therefore *Group Health Medical Technology Assessment Criteria*.

#### **06/04/2008: MTAC REVIEW**

##### **Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Procuren)**

**Evidence Conclusion:** Wound Healing (Procuren) The reviewer's conclusion in the previous MTAC report of 1999 was, "The published evidence on the effect of Procuren™ for treating non-healing cutaneous wounds consists of two small randomized controlled trials, one of which reports improvements in wound healing for Procuren™ as compared to placebo, and the other trial reports worse outcomes with Procuren™. The available evidence does not allow any conclusion about the effects of Procuren™ on non-healing cutaneous wounds." The literature search for the current review did not reveal any additional evidence that would determine the efficacy and safety of platelet derived growth factor for the treatment of non-healing cutaneous wounds. Bone Fracture Healing (GEM 21STM) There insufficient published evidence to determine the efficacy and safety of autologous platelet derived wound healing factors for the treatment of non-healing fractures.

**Articles:** *Wound Healing* The search yielded around 100 articles. Many were review articles or publications not related to the current review. No meta-analyses of empirical studies, randomized or non-randomized controlled studies, published after the last review, were identified. *Bone Fracture Healing* The literature search did not reveal any empirical studies on the use of PDGF for bone fractures. The published studies were all related to the use of PDGF for of dental implants, periodontal wounds, defects, or bone turnover during periodontal repair. None was selected for critical appraisal.

The use of Autologous Platelet Derived Wound Healing Factors in the treatment of Non-Healing Wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

The use of Autologous Platelet Derived Wound Healing Factors in the treatment of Non-Healing Fractures does not meet the *Group Health Medical Technology Assessment Criteria*.

#### **02/14/2011: MTAC REVIEW**

##### **Autologous Platelet Derived Wound Healing Factors for Non Healing Cutaneous Wounds (Procuren)**

**Evidence Conclusion:** *Achilles tendinopathy* A recent double-blind, placebo-controlled RCT evaluated the effects of adding a platelet rich plasma (PRP) injection to an eccentric exercise program in 54 patients with chronic midportion Achilles tendinopathy. The primary outcome measures were pain and activity level, measured using the Victorian Institute of Sports Assessment-Achilles (VISA-A). In both groups, VISA-A scores improved significantly after 24 week; however, there was no significant difference in VISA-A score between the two groups. With regard to safety, no microbial growth was found in the collected PRP samples, and no complications (infections, hematomas, or ruptures) were reported after the treatment (de Vos 2010). *Lateral epicondylitis (tennis elbow)* A double-blind RCT that included 100 subjects compared the efficacy of a platelet rich plasma injection to a corticosteroid injection for the treatment of lateral epicondylitis in patients who had failed non-operative treatment. In addition to a platelet rich plasma injection or a corticosteroid injection subjects also participated in an eccentric exercise program. The primary outcome measures were pain, measured using the visual analog scale (VAS), and disability, measured using the disability of the arm, shoulder, hand (DASH) outcome measure. Successful treatment was defined as more than a 25% reduction in VAS or DASH without a re-intervention after 1 year. According to the VAS, treatment was successful for 73% of subjects in the platelet rich plasma group and 49% in the corticosteroid group (P<0.001). When using the DASH, treatment was successful for 73% of subjects in the platelet rich plasma group and 51% in the corticosteroid group (P=0.005). This trial did not address safety. Results from this study should be interpreted with caution as there are several methodological limitations (Peerbooms 2010). **Conclusion:** There is insufficient evidence to support the use of platelet rich plasma injection for the

treatment of Achilles tendinopathy. There is evidence from one small RCT that supports the use of this technology for patients with lateral epicondylitis; however, because of methodological limitations results from this trial are insufficient to determine the safety and efficacy of this procedure. Several trials are currently underway to determine the safety and efficacy of platelet rich plasma injections for the treatment of tendinopathy.

**Articles:** Studies were selected for review if they included at least 25 subjects and assessed either the safety or efficacy of platelet rich plasma injections for the treatment of tendinopathy. Studies were excluded if they lacked a valid comparison group. Two RCTs were selected for review. The following studies were critically appraised: de Vos RJ, Weir A, van Schie HTM, et al. Platelet-rich plasma injection for chronic Achilles tendinopathy. *JAMA* 2010; 303:144-149. See [Evidence Table](#). Peerbooms JC, Sluimer J, Bruijn DJ, and Gosens T. Positive effect of an autologous platelet concentrate in lateral epicondylitis in a double-blind randomized controlled trial. *Am J Sports Med* 2010; 38:255-262. See [Evidence Table](#).

The use of Autologous Platelet Derived Wound Healing Factors in the treatment of Tendinopathy does not meet the *Group Health Medical Technology Assessment Criteria*.

### ***Bilaminare Skin Substitutes***

#### **BACKGROUND**

Venous ulcers are a chronic recurring condition associated with long-standing venous hypertension of the lower extremities. They occur in approximately 1-3 patients per thousand in the general population with the incidence rising to 20 per thousand in individuals over 80 years old. The chronicity of care required to treat this condition involves significant time and resources and often treatment is unsuccessful in producing complete venous ulcer healing. Typical treatments include frequent dressing changes, compression bandages, antibiotic and antiseptic use, and mechanical debridement. One proposed treatment of chronic venous ulcers involves covering the ulcer with a natural bilayer skin substitute that is hypothesized to protect the wound and promote healing.

#### **08/11/1999: MTAC REVIEW**

##### **Bilaminare Skin Substitutes**

**Evidence Conclusion:** The best, published article reporting original data on the effect of using Apligraf on non-healing venous ulcers is a randomized controlled trial of 309 patients recruited from 5 wound treatment centers. The results of this randomized controlled trial indicate that venous ulcers resolve more quickly when treated with compression and human skin equivalent than when treated with compression alone. The results also suggest that patients treated with compression/human skin equivalent are more likely to have complete healing of a venous ulcer than those who are treated only with compression. The bias introduced by the failure to perform an intention-to-treat analysis could explain some of the differences between treatment groups. The results cannot be generalized to patients with conditions that are associated with poor wound healing or to patients with large venous ulcers. Additionally, the probability of ulcer recurrence after 12 months for patients treated with compression/human skin equivalent relative to that of patients treated only with compression remains unknown. This study has not defined the risk of clinically relevant immunologic rejection of human skin equivalent for patients with venous ulcers.

**Articles:** Falanga, V et al, *Arch. Dermatol.* 1998;134:292-300 See [Evidence Table](#).

The use of Apligraf human skin equivalent for the treatment of non-healing venous ulcers has been approved by the FDA and therefore meets GHC criteria 1. There is sufficient scientific evidence that Apligraf is medically effective and therefore *Group Health Medical Technology Assessment Criteria*.

### ***Electrical Stimulation and Electromagnetic Therapy***

#### **BACKGROUND**

Chronic wounds have been traditionally known as wounds that take prolonged time to heal, do not heal completely, or recur frequently. There is no agreed upon definition for chronic wounds; Lazarus et al (1994) defined them as wounds of at least 8 weeks in duration that have failed to proceed through an orderly and timely process that produces anatomic and functional integrity. Troxler et al (2006) defined them as wounds that fail to heal with 'standard therapy' in an orderly and timely manner. More recently Fonder and colleagues (2008) defined chronic skin wounds as break in the skin of long duration (>6 weeks), or frequent recurrence. Generally, the process of normal healing takes few days to 2 weeks and involves three phases that may overlap in time: 1. inflammatory phase, 2. proliferative phase, and 3. remodeling phase. If any of these phases is compromised, healing will be delayed. Chronic wounds are predominantly due to chronic venous insufficiency, atherosclerosis, pressure sores, or peripheral neuropathy. Chronic ulceration can affect any anatomic region of the body, but the majority is seen in the lower limbs. Pressure sores also known as pressure ulcers are the most common of all chronic wounds, and venous ulcers account for the majority of leg ulcers (70-85%). Diabetic foot ulcers and ischemic ulcers contribute to a significant proportion of the rest (Eaglestein 1997, Simon 2004, Jones 2007, Fonder 2008). Management of chronic wounds has challenged health care providers for generations, and various

strategies have been used to accelerate the healing process. Standard care includes debridement of necrotic or infected tissue, maintenance of a moist wound environment, control of infection, wound dressing, nutritional support, and treatment of concurrent conditions that may delay healing. Adjuncts to wound care include several established or emerging therapies. These include compression therapy, pressure relieving beds or cushions, hyperbaric oxygen therapy, topical negative pressure devices, growth factors, skin substitutes, and topical or systemic medications. Selection of therapy is based on the individual patient's clinical condition, and type and cause of wound. A whole range of other adjunctive treatment modalities, such as laser, ultrasound, and electricity have also been applied to chronic wounds (Cullum 2000, de Araujo 2003, Fonder 2008). Electrical stimulation (ES) or electrotherapy for wound healing is defined as the application of electrical current from electrodes placed directly within a wound or on skin in a close proximity to it. ES has been a topic for research for decades, and is often used by physical therapists to promote healing. There are four basic treatment regimens for ES therapy: low intensity direct current (LIDC), high voltage pulsed current (HVPC), alternating current (AC), and transcutaneous electrical nerve stimulation (TENS). Electromagnetic therapy is a related therapy but is distinct from other forms of electrotherapy in that it uses an electromagnet to generate the electric current. It has a field effect not a direct effect or a form of irradiation. It covers a wide range of wavelengths including radio-waves and X-rays. Short wave diathermy (SWD) is a non-ionizing radiation present in the radio-waves portion of the electromagnetic spectrum. The frequency of the short- wavelength radio-waves ranges from 10 to 100 MHz. The radiofrequency wave band of 27.12 MHz is used for therapeutic effect in continuous SWD. Electromagnetic therapy can also be delivered in short bursts of energies called Pulsed Short Wave Diathermy or PSWD (gardener 1999, Ojingwa 2002, Stiller 1992, Olyae 2006, Callaghan 2008). In vitro and animal studies have showed that electrical stimulation can increase the DNA and collagen synthesis, direct epithelial, fibroblast, and endothelial cell migration into wound sites, inhibit growth of some wound pathogens, and increase tensile strength of wound scar (Bassett 1974, Gordon 2007). Several devices have been used off-label to deliver ES or electromagnetic therapy to cutaneous wounds. The FDA approved electric stimulators as Class III devices for deep brain and bone stimulation, and cleared them as class II devices for muscle stimulation. Electromagnetic devices were also FDA cleared for the treatment of selected medical conditions including relief of pain, muscle contracture, joint contractures, and others. None of the ES or electromagnetic devices has been cleared by the FDA, to date, for the treatment of wounds. The objective of this review is to determine whether electric stimulation and /or electromagnetic therapies are effective adjunctive treatments for chronic skin wounds. The technology has not been previously reviewed by MTAC for this indication.

#### **04/09/2008: MTAC REVIEW**

##### **Electrical Stimulation and Electromagnetic Therapy**

**Evidence Conclusion:** There is limited evidence on the effect of electric stimulation (ES) or electromagnetic (EM) therapy on the healing of chronic wounds. The body of evidence on ES therapy mainly consists of small randomized and nonrandomized controlled trials that used the therapy off-label to treat chronic wounds, as well as a meta-analysis that pooled the results of 15 randomized and nonrandomized studies. The literature on EM therapy was more limited. There were very few small trials that also used the therapy off-label. Due to this limited number of studies, the authors of the Cochrane reviews were unable pool the results in a meta-analysis. Although a number of the published RCTs were randomized, controlled, blinded, and had clinical outcomes, all had their limitations: they were too small, with short follow-up durations, and with no standardized dose, frequency, or duration for the electric stimulation (ES) or electromagnetic (EM) therapy. Moreover, several studies used the change in ulcer size rather than incidence of /or time to complete healing as their outcome. No adjustments were made for potential confounding factors, and analyses were not based on intention to treat. The results of these trials suggest that electrotherapy might be associated with improved healing, but the evidence is insufficient to draw any conclusions on the benefits of therapy on complete healing or health outcomes. Gardener and colleagues' (1999) pooled the results of nine small RCTs to quantify the effect of ES on chronic wound healing. They showed a healing rate of 22% per week among patients treated with ES therapy compared to 9% healing rate per week among the controls. There were several differences among the studies included in the patients' characteristics, types of wounds, and devices used to deliver the ES therapy, as well as dose, frequency and duration of therapy. The two Cochrane reviews on EM therapy (Ravaghi 2006, and Manesh 2006) on venous leg ulcers, and pressure ulcers respectively, could not pool the results due to the limited number of included trials. In conclusion, there is insufficient evidence to determine whether the use of ES or EM therapy as adjunctive treatments would lead to healing of chronic wounds or improve the patients' health outcomes.

**Articles:** The literature search revealed over 90 articles. Several were reviews or non-related to the current report. There was a meta-analysis of randomized and non-randomized controlled studies on ES therapy for chronic wounds, and two small RCTs that were not included in the meta-analysis. There were also two Cochrane reviews on electromagnetic therapy for treating pressure ulcers and venous leg ulcers. The reviews however did not pool the results in meta-analyses due to the limited number of studies. A review by TEC of Blue Cross Blue Shield on electric stimulation and electromagnetic therapy for chronic skin ulcers (2005), and an ECRI report (1996) on electrical stimulation for the treatment of chronic wounds were also identified by the search. The meta-analysis

and the two more recent RCTs on ES, as well as the two Cochrane reviews on electromagnetic therapy were critically appraised. Gardener SE, Frantz R, Schmidt FL. Effect of electrical stimulation on chronic wound healing: a meta-analysis. *Wound Rep Reg* 1999;7:495-503. See [Evidence Table](#). Ravaghi H, Flemming K, Cullum NA, et al. The use of Electrical stimulation and electromagnetic therapy in the treatment of chronic skin wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Low Frequency, Noncontact, Nonthermal Ultrasound Wound Therapy**

#### **BACKGROUND**

Chronic wounds, wounds with long healing time, and wounds with frequent recurrence are a major health problem. They are a problem for the patient who suffers from them, the clinician who treats them, and the health care system that is overburdened by their cost. It is estimated that chronic wounds affect approximately 2% of the American population at an estimated cost of US \$20 billion per year. Many factors can impede wound healing, including chronic disease, venous insufficiency, arterial insufficiency, neuropathy, nutritional deficiencies and local features such as pressure, edema, and infection (Fonder, 2008, Rizzi 2010). No single regimen is universally accepted as the best modality for treating chronic wounds. They are managed through conventional wound care procedures performed by primary care providers, community nurses, pharmacists, and others. In the early 2000s, the concept of wound bed preparation has been proposed as a means of providing a structured and systemic approach to the management of chronic wounds. It is believed to accelerate endogenous healing and/or facilitate the effectiveness of other therapeutic measures. Wound bed preparation involves ongoing wound debridement, management of exudates, and resolution of bacterial imbalance (Schulz 2003, Ramundo 2008). Wound debridement is defined as the removal of devitalized or contaminated tissue as well as foreign material from the wound bed until healthy tissue is exposed. Efficient debridement reduces the necrotic burden, achieves healthy granulation tissue, and reduces wound contamination and tissue destruction. This can be performed by different enzymatic, autolytic, sharp/surgical, biological, and mechanical techniques. Each has its own advantages and limitations, and the methods that are most efficient at removal of debris, may at the same time be the most detrimental to fragile new growth (Schulz 2003, Beitz, 2005, Ramundo 2008). Noncontact, low frequency ultrasound therapy was recently introduced as a modality for promoting wound healing through wound cleansing and maintenance debridement. The therapy is thought to produce a number of biophysical effects that are associated with wound healing. These include increased protein and collagen synthesis, angiogenesis, production of growth hormone by macrophages, endothelial production of nitric oxide synthesis; and leukocyte adhesion. One of the main mechanisms of action for ultrasound therapy, as shown by in vitro studies, is achieved through the process of cavitation. This involves the production and vibration of micron-sized bubbles within the coupling medium and fluids in the tissues. As the bubbles collect and condense, they are compressed before moving to the next area. This movement and compression can potentially cause changes in the cellular activities of the tissues subjected to the ultrasound. Acoustic streaming is another mechanism by which ultrasound generates biologic activity producing a unidirectional movement of fluid along and around cell membranes. A more recent hypothesis known as the frequency resonance theory uses the above concepts at the protein and genetic level, and result in a broad range of cellular effects that promote healing. Ultrasound energy is also believed to have a direct bactericidal action caused by the cavitation effects produced by the ultrasound waves (Ennis 2005 Ramundo 2008). The sound waves generated by the therapeutic ultrasound devices have lower frequencies than those generated by diagnostic devices (25-40 kHz vs. 200,000-400,000 kHz respectively). Ultrasound MIST therapy devices use saline to couple the ultrasound energy to tissue within the wound bed. This is accomplished by the noncontact non-thermal application of a fine oxygenated fluid (sterile saline) stream spray to the wound bed through which the ultrasound energy is transmitted from the applicator tip to the wound tissue. This noncontact ultrasound is believed to provide cellular stimulation, increase blood flow, and reduce bioburden with much less pain or thermal effect than other direct contact devices. It is usually applied three times a week for a duration dependent on the wound dimensions. The therapy should be performed in a closed environment area to avoid spread of microbes, and the clinician delivering the therapy should wear protective gear (Ramundo 2008, FDA webpage). Ultrasound MIST therapy (Celleration, Inc, Eden Prairie, MN), was cleared by the FDA in 2004 to promote healing of wounds through wound cleansing and maintenance debridement by the removal of yellow slough, fibrin, tissue exudates and bacteria. Its use is contraindicated for malignant wounds, radiation wounds, for tissue previously treated with radiation, and for patients with bleeding disorders, or thrombophlebitis.

## 02/01/2010: MTAC REVIEW

### Low Frequency, Noncontact, Nonthermal Ultrasound Wound Therapy

**Evidence Conclusion:** The literature search revealed two published RCTs on the low frequency noncontact ultrasound therapy for the treatment of wounds. The two trials were funded by the manufacturer. In one trial, Ennis and colleagues, 2005, compared the ultrasound therapy to a sham device for the treatment of patients with diabetic foot ulcers. Patients in the two treatment groups also received wound conventional therapy. The trial was randomized and controlled, and had clinically important outcome. However, it had several methodological flaws which limit generalization of its results. The study had a very low completion rate (41%) due to dropouts or violations of the protocol, and the ulcers in the sham treatment group were significantly larger in size and with a longer duration than those in the investigational group, which are potential sources of bias and confounding. The results show significant difference in the wound closure favoring the ultrasound therapy group when the analysis included only those who completed the trials, but no significant differences were observed when the analysis was based on intention to treat. Kavros and colleagues, 2007, compared the effects of the ultrasound therapy plus standard wound care to standard wound care alone in 70 patients with non-healing ischemic lower-extremity wounds. The trial was also randomized and controlled, but was not blinded, and the outcomes were mainly based on measurements which are subject to potential error, and observational bias. Moreover, the authors did not discuss if there were any dropouts, rate of compliance, or adverse events associated with the intervention. Overall, the results of the trial show that patients managed with MIST therapy in addition to standard treatment, achieved a significantly higher >50% wound closure rate in 12 weeks than those managed with standard therapy alone. A secondary analysis of the trial showed that patients with critical limb ischemia with baseline TcPO<sub>2</sub> <20 with dependency were significantly less likely to achieve >50% healing by week 12, using standard treatment with or without MIST therapy. In conclusion, the published literature does not provide sufficient evidence to determine that non-thermal, noncontact, low frequency ultrasound therapy "Mist therapy" is safe to use, or that it has similar or better outcomes than those achieved by other debridement methods or standard wound care management procedures.

**Articles:** The literature search yielded two RCTs, on the low frequency ultrasound therapy using the MIST therapy system for the treatment of chronic wounds, one non-randomized retrospective comparative study and prospective case series. The two RCTs were critically appraised. Ennis WJ, Formann P, Mozen N, et al. Ultrasound therapy for recalcitrant diabetic foot ulcers: Results of a randomized, double-blind, controlled, multicenter study. *Ostomy Wound Management*. 2005;51:24-39. See [Evidence Table](#). Kavros SJ, Miller JL, Hanna SW. Treatment of ischemic wounds with noncontact, low-frequency ultrasound The Mayo Clinic experience, 2004-2006. *Adv skin Wound Care* 2007;20:221-226. See [Evidence Table](#).

The use of Low frequency, noncontact, nonthermal ultrasound therapy for the treatment of wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

### **Maggot Debridement Therapy (MDT)**

#### BACKGROUND

Chronic wounds, wounds with long healing time or frequent recurrence, are major health care and quality of life burdens. Approximately 1-2% of individuals in the United States are likely to be affected by leg ulceration at some time in their life. Many factors can impede wound healing, including chronic disease, vascular insufficiency, nutritional deficiencies and local features such as infection, pressure and edema (Fonder et al., 2008). Preparation of the wound bed is an important component of optimal healing. Proper preparation includes debridement of nonviable tissue, management of inflammation and infection, and establishment of proper moisture balance. Wound debridement serves several purposes. It removes necrotic tissue which can present physical barriers to healing, decreases the potential for infection, enhances the ability to assess wound depth, and helps to remove bacteria that may prevent healing (Beitz, 2005). Debridement methods include hydrogels, enzymatic agents, dextranomer polysaccharide beads or paste, adhesive zinc oxide tape, and sharp debridement. A systematic review of studies on different debridement methods concluded that there was insufficient evidence to recommend one method of debridement over another (Bradley et al., 1999). Maggot debridement therapy (MDT) is another method for wound debridement. Maggot or larval therapy has been used in some form for centuries, including treating battle wounds in Napoleon's army in the 1550s. Dr. William Baer, often called the founder of modern maggot therapy, observed the effects of maggots on the wounds of soldiers during World War I and he later refined the technique to use sterile maggots under controlled conditions. MDT increased in popularity after WWI and, by the 1930s, was widely used in the U.S. and Europe. Its use decreased after the advent of antibiotics in the 1940s. As of the late 1990s there has been resurgence in interest due to antibiotic resistance, particularly methicillin-resistant *Staphylococcus aureus* (MRSA) and the lack of other reliably effective methods (Gupta, 2008). Modern MDT involves the use of specially bred larvae, most commonly of the green-bottle fly *Lucilia sericata* species. Larvae 1-2 mm long larvae hatch from eggs in 12-24 hours and, when they feed on necrotic

tissue in the moist environment of wounds, they mature in 4-5 days, at which time they measure about 10mm. Larvae need to be sterile to prevent contamination, and should be used within 8 hours of hatching or stored in refrigerator at 8-10o C to slow their metabolism. They require an optimal body temperature, moist environment and adequate oxygen supply. The general procedure is to introduce larvae to the wound at a density of 5-8 per cm<sup>2</sup> and cover with a containment dressing that allows oxygen to pass through. Dressings are generally changed once a day to avoid build-up of secretions, and the larvae are changed every 2-3 days. Wounds commonly require 2-6 treatment cycles for complete debridement (Gupta et al., 2008; Chan et al., 2007; FDA materials). The exact mechanisms by which maggots debride wounds are not fully understood. It is generally believed that there is a combination of: 1) Mechanical action: probing from the maggots' pair of mandibles/hooks may facilitate debridement; 2) Enzymatic action: Three proteolytic enzymes have been identified in maggot excretions/secretions (ES) that can degrade extracellular matrix components, including laminin and fibronectin. The ES also have antibacterial substances which appear to have an inhibitory effect on Gram-positive and Gram-negative bacteria including MRSA. Maggots may also secrete cytokines which aid in wound healing; 3) Digestion: Maggots appear to ingest bacteria and kill them in their alimentary tract (Chan et al., 2007). There are no reports that MDT is associated with major adverse effects or complications. Minor discomfort has been reported, and excessive pressure on the wound may kill some of the maggots, resulting in uneven healing. There is also the issue of social acceptance of larval therapy, the widely-cited "yuck" factor, for patients and providers. In 2004, FDA cleared Medical Maggots (Monarch Labs, Irvine, CA) for commercial production as a Class II medical device. The approved indication is debridement of non-healing necrotic skin and soft tissue wounds.

#### **04/06/2009: MTAC REVIEW**

##### **Maggot Debridement Therapy (MDT)**

**Evidence Conclusion:** There is fair evidence from one RCT that wound debridement is significantly faster with maggot debridement therapy than hydrogel, but that there is no significant difference in time to complete wound healing (Dumville et al., 2009). In the RCT, median time to healing was 236 days in the larvae therapy groups and 245 in the hydrogel group. Time to debridement was 14 days in the group receiving loose larvae, 28 days in the bagged larvae group and 72 days in the hydrogel group. The efficacy of maggot therapy for debridement is supported by the results of a retrospective cohort study, and several case series. The RCT found significantly higher reports of ulcer-related pain in the larvae therapy groups in the 24 hours before removal of the first treatment compared to hydrogel, and did not report on pain during subsequent treatments. There is insufficient evidence on the efficacy of maggot therapy for MRSA eradication compared to standard wound care approaches. The number of MRSA-positive wounds in the RCT was too small to draw conclusions about eradication.

**Articles:** The search yielded two RCTs, one of which had a sample size of 12 patients and was excluded from further review. There was also one non-randomized comparative study and several case series. The larger RCT, cohort study and the three largest case series (n>50) were critically appraised. Citations are as follows: Dumville JC, Worthy G, Bland JM et al. Larval therapy for leg ulcers (VenUS II): randomized controlled trial. *BMJ* 2009; 338; online first. See [Evidence Table](#). Larva therapy in wound management. *J Royal Soc Med* 2000; 93: 72-73. See [Evidence Table](#).

The use of maggot debridement therapy for the treatment of chronic and infected wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

##### **Medihoney Dressing for Wound Management**

###### **BACKGROUND**

Honey has been used in wound care for thousands of years. The ancient Egyptians, Greeks, Romans, Chinese, and other early cultures used it as a remedy for wounds either alone or in combination with other ingredients. Its healing benefits were passed from generation to generation, and honey is still traditionally used in many parts of the world. Recently there has been a resurgent interest by the medical profession in using topical honey for wound treatment, mainly due to the increasing number of bacterial strains developing resistance to antibiotics. It is only in the last few decades that researchers started to investigate honey's mechanism of action in wound healing (Molan 2008, Lay-flurrie 2008). Honey is a viscous supersaturated sugar solution derived from nectar gathered and modified by the honeybee. It contains approximately 30% glucose, 40% fructose, 5% sucrose, 20% water and many other substances as amino acids, vitamins, minerals, and enzymes. In-vitro and animal studies indicate that honey has several therapeutic potentials. Its high osmolarity due to the sugar content causes bacterial cell wall shrinkage and inhibition of growth. Many bacteria grow and multiply in a neutral pH environment (6.5-7.0), and cannot thrive in the acidic pH of honey which ranges from 3.2 to 4.2. Researchers have reported that it in addition

to its antibacterial properties, honey enhances tissue growth by drawing fluid from the underlying circulation providing both a moist environment and topical nutrition to the tissues. They also found that honey leads to cytokine release, promote autolytic debridement, deodorize malodorous wounds, and stimulates anti-inflammatory activity that reduces pain, edema, and exudate, and minimizes scarring (Molan 1999, Sato 2000, White 2005, Bell 2007). There are many different types of honey but the Manuka honey, a monofloral honey derived from the leptospermum tree species known as tea trees in Australia and New Zealand, has received particular interest for wound healing. Some researchers claim that it has a broad spectrum antibacterial activity and is exceptionally effective for several bacterial species that commonly infect surgical wounds as *Staphylococcus aureus* and *Pseudomonas aeruginosa* (Lusby 2002, Visavadia 2008). Therapeutic honey is typically raw and does not undergo heat treatment like culinary honey. It is sterilized by gamma irradiation which destroys any bacterial spores while retaining its biologic activities. Honey dressings are available in various commercial preparations such as honey gel ointment, honey-impregnated tulle dressings, honey impregnated calcium alginate dressings, and honey-based sheet hydrogel dressings (Molan 1999, Lusby 2002 Visavadia 2008, Eddy 2008, Lay-flurrie 2008). Derma Sciences Medihoney Dressing with Active Manuka Honey received FDA approval for providing a moist environment conducive to wound healing. These are tulle dressings comprised of 95% Active Manuka Honey and 5% calcium alginate, and are offered in several sizes including 0.5, 1, and 1.5 ounces. According to the FDA, Medihoney dressings are indicated for the management of light to moderately exuding wounds as: diabetic foot ulcers, venous or arterial leg ulcers, partial or full thickness pressure ulcers/sores, first and second partial thickness burns, and traumatic and surgical wounds. Honey dressings should be avoided in patients with a known history of allergy to either honey or bee venom. It was also reported (Lay-flurrie 2008) that patients with diabetes should have their blood sugar monitored as they may be at higher risk of hyperglycemia due to the sugar content of honey.

## **12/01/2008: MTAC REVIEW**

### **Medihoney Dressing for Wound Management**

**Evidence Conclusion:** To date, there are no published high quality studies to support the use honey in wound dressings. Jull and colleagues performed a systematic review (Cochrane review) of 19 randomized and quasi-randomized trials to determine the efficacy of honey on the healing of acute and chronic wounds. The meta-analysis had generally valid methodology. However, its strength is only as good as the trials it includes, and the majority was of low methodological quality. Moreover, 11 of the 19 studies were conducted by one and the same author in a single center. There was significant clinical and statistical heterogeneity between the studies which did not enable pooling of the results in the meta-analysis. Overall, the results of subgroup meta-analyses only showed a significant benefit of honey dressings (2 trials, n=992) in reducing time to complete healing of mild to moderate partial thickness burns vs. conventional dressings. The Jull et al's RCT, 2008 compared the effect of Manuka honey dressings to usual care for the treatment of venous ulcers. It was randomized, controlled and multicenter, and analysis was based on intention to treat. However, the trial was open-label, and a range of dressings were used in the control group, which are potential sources of bias. Its results showed no statistically significant differences between the honey dressing and the usual care in rate or time to complete healing. On the other hand, honey dressings were associated with significantly higher rates of overall adverse events, ulcer pain (NNH=7), and ulcer deterioration (NNH=10). Gethin and colleagues' trial compared Manuka honey to hydrogel dressings used for the treatment of venous ulcers. The trial was unblinded, small, and did not recruit the predetermined number of patients required to provide sufficient statistical power. The results of the trial showed no statistically significant differences between the Manuka honey and hydrogel therapy in desloughing the wound (percent of wound area covered by slough), or rate of slough removal in venous ulcers at 4 weeks. There was however, a higher rate of ulcer healing in the Manuka honey group (44%) vs. the hydrogel group (33%) with a risk ratio of 1.38, and NNT =9 in 12 weeks. The authors did not discuss how they defined wound healing. Conclusion: There is insufficient good quality evidence to determine whether the use of Medihoney dressings would improve the rate of healing in acute wounds as burns and traumatic wounds. There is insufficient evidence to determine whether the use of Medihoney improves the rate of healing in chronic wounds including venous ulcers, arterial ulcers, diabetic ulcers, and pressure ulcers.

**Articles:** The search revealed over 120 articles on the use of honey for wound care. The number of published articles dropped to just over 20 articles when the search was limited to Manuka or Medihoney. Many were review articles or opinion pieces on the benefits of honey in wound management. There was a Cochrane review on honey as a topical treatment of wounds, and a number of RCTs on the use of honey in the treatment of acute wounds due to burns. The majority of the latter trials were conducted in one center, and by one and the same author. The literature on the use of honey for chronic ulcers was limited. There were three RCTs on honey dressings for venous ulcers, two of which were conducted by the same investigators (Gethin and colleagues 2008) among the same group of patients, but reported different outcomes. No randomized controlled trials on the use of honey in diabetic foot ulcers, ischemic, or pressure ulcers were identified. There were only very small non-randomized trials, case series and case reports. The Cochrane review and the three trials on the use of honey for venous ulcers were critically appraised: Jull AB, Rodgers A, Walker N. Honey as a topical treatment for wounds Cochrane

Database of Systematic Reviews 2008, Issue4. Art No.:CD005083.DOI10.1002/14651858.CD005083pub2: 16:1085-1100. See [Evidence Table](#). Jull A, Walker N, Parag V, et al. Manuka honey vs. hydrogel –a prospective, open label, multicenter, randomized controlled trial to compare desloughing efficacy and healing outcomes in venous ulcers. *J Clin Nurs* 2008; August 23 See [Evidence Table](#). Gethin G, Cowman S. Bacteriological changes in sloughing venous leg ulcers treated with Manuka honey or hydrogel: an RCT. *J wound Care* 2008;17:241-247 See [Evidence Table](#).

The use of medihoney dressing in the treatment of wound management does not meet the *Group Health Medical Technology Assessment Criteria*.

## **OASIS Wound Dressing**

### **BACKGROUND**

OASIS® Wound Matrix (Cook Biotech, Inc.) is a biosynthetic skin substitute that is derived from porcine small intestine submucosa. This material is approximately 0.15 mm thick and consists primarily of a collagen-based extracellular matrix. However, unlike other purified collagen wound care products, biologically important components of the extracellular matrix such as glycosaminoglycans, proteoglycans, fibronectin, basic fibroblast growth factor, and transforming growth factor  $\beta$  are retained in the small intestine submucosa (Barber 2008, Chern 2009, Limová 2010). OASIS® Wound Matrix has a shelf life of 24 months and is FDA approved for use in patients with various partial- and full-thickness wounds such as trauma wounds, ulcers, tunneled/undetermined wounds, draining wounds, and surgical wounds. It is not approved for use in patients with third-degree burn or with known allergies to porcine materials. According to the manufacturer's Web site, side-effects of OASIS Wound Matrix include: infection, chronic inflammation, allergic reaction, excessive redness, pain, swelling, and blistering. Additionally, the initial application of the wound dressing may be associated with transient, mild, localized inflammation (Cook Biotech, Inc 2011).

### **10/11/2000: MTAC REVIEW**

#### **OASIS Wound Dressing**

**Evidence Conclusion:** Given the fact that there are no peer-reviewed articles on this topic, there is insufficient (no) evidence to determine the efficacy of this type of the Oasis Cook® wound care dressing.

**Articles:** Articles were selected based on study type. There were no peer-reviewed articles, so no articles were reviewed. Informational materials on the company's Web site ([www.cookgroup.com](http://www.cookgroup.com)) were reviewed, but no evidence tables were created.

The use of OASIS Wound Dressing in the treatment of non-healing partial thickness dermal wound does not meet the *Group Health Medical Technology Assessment Criteria*.

### **06/20/2011: MTAC REVIEW**

#### **OASIS Wound Dressing**

**Evidence Conclusion:** *OASIS® versus usual care* - The first RCT included 50 subjects and compared the efficacy and tolerability of OASIS® Wound Matrix versus petrolatum-impregnated gauze in patients with difficult to heal mixed arterial/venous or venous leg ulcers. Results from this study suggest that patients treated with OASIS® have faster healing times, were more likely to experience complete wound closure, and required fewer dressing changes compared to usual care. Additionally, after 8 weeks patients treated with OASIS® had significantly more granulation tissue compared to usual care. No adverse events were observed in either treatment group. Results from this study should be interpreted with caution as it had several methodological limitations (Romanelli 2010). *OASIS® versus Hyaloskin®* - The second RCT included 54 subjects and compared the effectiveness of OASIS® Wound Matrix versus Hyaloskin® for the treatment of mixed arterial/venous leg ulcers. Results from this study suggest that patients treated with OASIS® Wound Matrix were more likely to experience wound closure compared to patients treated with Hyaloskin®. Additionally, patients treated with OASIS® Wound Matrix reported greater comfort, less pain, and required fewer dressing changes. No adverse events were observed in either treatment group. Results from this study should be interpreted with caution as it had several methodological limitations (Romanelli 2007). *OASIS® plus compression therapy versus compression therapy alone* - The third RCT included 120 subjects and compared the effectiveness of OASIS® Wound Matrix plus compression versus compression therapy alone for the treatment of chronic leg ulcers. The primary outcome was complete wound closure. Results from this study suggest that subjects who received OASIS® Wound Matrix plus compression therapy were significantly more likely to experience complete wound closure compared to standard care plus compression therapy. There was no significant difference in adverse events between the two groups. The most frequently occurring complications were allergic reaction or intolerance to secondary dressing and wound infection. Results from this study should be interpreted with caution as it had several methodological limitations (Mostow 2005).

**Conclusion:** Evidence from three RCTs suggest that OASIS® Wound Matrix may be a safe and effective treatment for leg ulcers; however, results from these studies should be interpreted with caution as all of the trials had methodological limitations. For example, two of the trials were funded by the manufacturers of OASIS® Wound Matrix. Only one study performed an intent-to-treat analysis and assessed power and none of the studies provided confidence intervals.

**Articles:** The literature search revealed several RCTs that evaluated the safety and efficacy of OASIS® Wound Matrix for the treatment of various partial- and full-thickness wounds. Three recent RCTs were selected for review. Two of these studies were performed by the same investigator. Another trial was excluded because it did not have sufficient power (Niezgoda 2005). The following studies were critically appraised:

Romanelli M, Dini V, and Bertone M. Randomized comparison of OASIS® Wound Matrix versus moist wound dressing in the treatment of difficult-to-heal wounds of mixed arterial/venous etiology. *Adv Skin Wound Care* 2010; 23:34-38. See [Evidence Table](#). Romanelli M, Dini V, Bertone M, et al. OASIS® Wound Matrix versus Hyaloskin® in the treatment of difficult-to-heal wounds of mixed arterial/venous aetiology. *Int Wound J* 2007; 4:3-7. See [Evidence Table](#). Mostow EN, Hataway D, Dalsing M, et al. Effectiveness of an extracellular matrix graft (OASIS® Wound Matrix) in the treatment of chronic leg ulcers. *J Vasc Surg* 2005; 41:837-843. See [Evidence Table](#).

The use of OASIS Wound Dressing in the treatment of non-healing partial thickness dermal wound does not meet the *Group Health Medical Technology Assessment Criteria*.

## **Warm-Up Wound Therapy**

### **BACKGROUND**

Noncontact normothermic wound therapy (The Warm-up therapy system) is used for the treatment of partial- and full-thickness wounds such as pressure ulcers, venous ulcers, diabetic ulcers, surgical wounds, and arterial wounds. Noncontact normothermic wound therapy is intended to speed the healing of wounds and venous ulcers by warming the wound and thereby increasing blood flow and allowing sufficient moisture in the wound to help cells grow and divide. The Warm-up therapy system consists of the following components: a noncontact wound cover, a temperature control unit with an AC adapter and a warming card. The non-contact wound cover is placed over the wound; the cover is raised so it does not touch the wound. It is designed to maintain warmth and humidity and to absorb exudate. There is space to insert the warming card into the wound cover. The temperature control unit, which is portable, controls the temperature of the warming card. The manufacturer recommends three warming sessions per day, heating the wound to 38°C (Augustine Medical Web site). Anodyne Therapy is another treatment for increasing the rate of wound healing; it is also used to treat patients with peripheral neuropathy. Treatment consists of monochromatic near-infrared photo energy (MIRE). The recommended course of treatment is 12 sessions of MIRE. For patients with peripheral neuropathy, the intention is to increase local circulation and restore sensation. MIRE has been shown to increase nitric oxide (NO) in the blood and plasma of normal adults (Horwitz, 1999). An elevation in NO may be beneficial for wound healing and increased circulation.

### **10/08/2003: MTAC REVIEW**

#### **Warm-Up Wound Therapy**

**Evidence Conclusion:** *Noncontact Normothermic Therapy (Warm-up wound therapy)* - Combining the evidence from the current and previous MTAC reviews, four randomized controlled trials comparing Warm-up wound therapy to standard care were critically appraised (McCulloch and Kloth in the current review, Warwick and Price from the 2002 review). All of the studies were subject to selection bias due to the limited sample sizes (the treatment groups are likely to be dissimilar on characteristics that may affect outcome). The Price study had the strongest methodology and did not find a statistically significant difference in healing rates in an intention to treat analysis; the study may have been underpowered. The other three RCTs found statistically significant improvement in healing according to one or more outcome variables, but were subject to biases including improper randomization, lack of intention to treat analysis, potential data manipulation and funding by the manufacturer.

**Articles:** *Noncontact Normothermic Therapy* - The search yielded 8 articles. There were four new RCTs, sample sizes were n=16, n=20, n=36 and n=40. The two RCTs with the larger sample sizes were critically appraised: McCulloch J, Knight A. Noncontact normothermic wound therapy and offloading in the treatment of neuropathic foot ulcers in patients with diabetes. *Ostomy/Wound Management* 2002; 48: 38-44. See [Evidence Table](#). Kloth LC, Berman JE, Nett M et al. A randomized controlled clinical trial to evaluate the effects of noncontact normothermic wound therapy on chronic full-thickness pressure ulcers. *Adv SkinWound Care* 2002; 15: 270-276. See [Evidence Table](#).

The use of Warm-up Wound Therapy in the treatment of partial and full-thickness wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

### **04/10/2002: MTAC REVIEW**

## Warm-Up Wound Therapy

**Evidence Conclusion:** Two relatively small RCTs evaluating the efficacy of noncontact normothermic wound therapy (Warm-up® Therapy System) for accelerating the healing rate of pressure ulcers were reviewed. The Price study, which had the stronger methodology, found no significant differences in healing rates in an intention to treat analysis. Patients receiving Warm-up wound therapy took an average of 5 fewer days for their wound to be reduced to 25% of original size. This difference was not have been statistically significant but the study may have been under-powered. Whitney found a statistically significant improvement in the linear rate of healing using Warm-up wound therapy. However, the Whitney study had substantial threats to validity (e.g. no power analysis, substantial dropout; no intention to treat analysis). The absolute difference in healing was 0.008 cm/day. The clinical significance of this difference in healing rates needs to be considered. The two RCTs reviewed had pressure ulcers as the outcome; no conclusions can be drawn about the effectiveness of this treatment for other types of wounds.

**Articles:** The search yielded 6 articles on this treatment, all of which were empirical and had small sample sizes (most had sample sizes of 20 or less). There were three RCTs with clinical outcomes. One had n=13 and was not reviewed. The other two RCTs (n=40 and n=58) were critically appraised: Whitney JD, Salvadalena G, Higa L, Mich M. Treatment of pressure ulcers with noncontact normothermic wound therapy: healing and warming effects. J WOCN 2001;28:244-52. See [Evidence Table](#). Price P, Bale S, Crook H, Harding KGH. The effect of a radiant heat dressing on pressure ulcers. J Wound Care 2000;9:201-205. See [Evidence Table](#).

The use of Warm-up Wound Therapy in the treatment of partial and full-thickness wounds does not meet the *Group Health Medical Technology Assessment Criteria*.

GroupHealth®

## Clinical Review Criteria

### Spinal Decompression Device

- Coflex
- DIAM
- Wallis
- X-Stop

Group Health Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Group Health reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Group Health's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Group Health Customer Service to determine coverage for a specific medical service.**

#### Criteria

##### For Medicare Members

GH Medicare will cover the placement of the X-Stop® Interspinous Process Decompression System for Medicare members for the treatment of neurogenic intermittent claudication secondary to lumbar spinal stenosis (LSS).

The system is indicated for use in patients aged 50 years and older who have undergone at least 6 months of non-surgical treatment with physical therapy, nonsteroidal anti-inflammatory drugs, and/or spinal injections. The maximum of two lumbar levels may be covered in accordance with FDA approval of the device.

The payment for X-Stop® using 22899 will be an inclusive payment, including all work and practice expenses. No additional codes for approach or hardware placement will be paid.

The patient's medical records must clearly document the procedure performed and that the conditions for coverage have been satisfied. Review of compliance will be conducted through post-payment audits.

##### For Non-Medicare Members

Group Health has elected to use the MCG\* Spinal Distraction Devices (A-0494) for medical necessity determinations. This service is covered not per MCG guidelines.

**MCG\*are proprietary and cannot be published and/or distributed.** However, on an individual member basis, Group Health can share a copy of the specific criteria document used to make a utilization management decision. If one of your patients is being reviewed using these criteria, you may request a copy of the criteria by calling the Group Health Clinical Review staff at 1-800-289-1363.

#### If requesting this service, please send the following documentation to support medical necessity:

- Last 6 months of clinical notes from requesting provider &/or specialist (orthosurgeon, orthopedics, chiro, physiatrist, neurosurgeon)
- Most recent back/spine imaging

The following information was used in the development of this document and is provided as background only. It is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations.

#### Background

Lumbar spinal stenosis refers to the narrowing of the spinal canal resulting in compression of the spinal cord. The decrease in size of the spinal canal is believed to be due to a combination of degenerative processes including bulging of the intervertebral disc, hypertrophy of the liamentum flavum, facet joint hypertrophy with bone spurring and spondylolisthesis. Symptoms include pain and numbness in the lower back, legs and buttocks after lumbar extension and walking. Symptoms are generally relieved by flexion of the lower back or sitting. Spinal stenosis is the most prevalent diagnosis for spinal surgery; it affects approximately 0.5% of Americans older than 50 (Batt & Carlson, 2006; CTAF technology assessment).

Functional loss associated with lumbar spinal stenosis is typically slow and thus an initial course of non-surgical therapy is recommended. Conservative management is particularly indicated for patients with mild to moderate symptoms. Initial recommended therapies are activity modification (e.g. avoiding aggravating activities) and use of

oral medications such as NSAIDs and salicylates. Other medications that have been found to be helpful for some patients are oral corticosteroids, tricyclic antidepressants and salmon calcitonin. Epidural steroid injections are another commonly used conservative treatment. These can reduce the radicular pain associated with acute exacerbations of neurogenic claudication (leg or buttock pain). In addition to the various types of pain relief or pain reduction discussed above, physical therapy can be helpful, especially flexion-based exercises. Surgical treatment, specifically decompression surgery, may be appropriate for selected patients. Patients whose function is limited (e.g. limitations in walking and activities of daily living) are potential surgical candidates. Intractable pain, especially neurogenic claudication, not responding to non-surgical therapies, is another reason for considering surgery. Laminectomy is considered the “gold standard” for decompression in patients with lumbar spinal stenosis (Yuan et al., 2005).

The X-Stop Interspinous Process Decompression System (St. Francis Medical Technologies, Alameda, CA) is proposed as a minimally invasive alternative to surgical treatment of lumbar spinal stenosis in patients with a moderate level of symptoms. Patients with severe symptoms are not eligible to receive this device and may be candidates for laminectomy. X-Stop consists of an oval titanium implant that fits between the adjacent spinous processes at the level of spinal stenosis and a wing assembly that prevents the implant from moving from side-to-side. The spinous processes are thin projections from back of spinal bones to which muscles and ligaments are attached. X-Stop is designed to remain permanently in place without attaching to the bones and ligaments in the back. The device is intended to slightly flex the affected area and to prevent extension to avoid nerve root impingement (manufacturers’ materials; FDA materials; CTAF technology assessment).

The device is usually implanted under local anesthesia with fluoroscopy guidance. The procedure involves making a 4-5 cm midline incision over the spinous processes of the affected levels. An attempt is made to keep the supraspinous and interspinous ligaments intact. The implant size is determined (it is available in 5 sizes) and an appropriately sized implant is inserted. After fastening the wing assembly, the incision is closed (manufacturers’ materials; FDA materials; CTAF technology assessment).

X-Stop was approved by the FDA in November 2005. As specified in the FDA premarket application (PMA) approval letter, X-Stop:

- Is indicated for patients age 50 and older with neurogenic intermittent claudication secondary to a confirmed diagnosis of lumbar spinal stenosis;
- Is indicated for patients with moderately impaired physical function who experience relief in flexion from leg, buttock and/or groin pain, with or without back pain, and have undergone at least 6 months of non-operative treatment;
- May be implanted at 1 or 2 lumbar levels in patients for whom surgery is indicated (no more than 2 levels).
- Is not currently indicated for patients with mildly impaired physical function.

As part of the approval agreement, the manufacturer agreed to conduct a study on the long-term safety and effectiveness of X-Stop.

Prior to FDA approval, the FDA’s Orthopedic and Rehabilitation Devices Advisory Panel recommended disapproval in August, 2004. A majority of committee members felt that the pivotal clinical trial (discussed below in evidence summary) had substantial threats to validity. After the panel decision, the company submitted additional data to the FDA and defended their study methodology including the use of a relatively new self-report instrument as the primary outcome.

## Medical Technology Assessment Committee (MTAC)

### *X-stop Interspinous Process Decompression System*

#### **02/05/2007: MTAC REVIEW**

**Evidence Conclusion:** There is one published RCT that evaluated the safety and effectiveness of the X-Stop system. This was the pivotal clinical trial presented to the FDA. The investigators, who included the device inventors, reported that patients who received the X-Stop had significantly better clinical outcomes than patients receiving non-operative treatment. The study had numerous threats to validity including a lack of blinding, use of subjective outcomes, an inappropriate comparison group and possibly inadequate randomization, and thus provides insufficient evidence for concluding that X-Stop is safe and effective. In addition, there is no comparative pain or functional outcome data beyond two years.

**Articles:** The safety and efficacy of the X-Stop system compared to standard treatment for patients with the FDA approved indication for device use. The ideal study would be a randomized, double-blind controlled trial comparing the X-Stop system to the best-accepted alternative treatment or a sham intervention.

The search yielded one unblinded RCT that compared X-Stop with conservative management. There were no double-blind trials or trials comparing X-Stop to a sham intervention. Five publications were identified based on the single RCT. The two articles that reported primary clinical outcomes were critically appraised. Zucherman et al. (2004) reported 1 year outcomes and Zucherman et al., 2005 reported 2 year outcomes. Other publications using RCT data include a case series analysis on a sub-set of treated patients (Kondrashov 2006 ), another sub-analysis on patients with lumbar degenerative spondylolisthesis (Anderson et al., 2006 ) and an in-depth look at the quality of life outcomes that were reported in the main outcome papers (Hsu et al., 2006 ). The secondary publications from the RCT and small case series identified in the search were not reviewed. *The articles that were critically appraised (in a single evidence table) were:* Zucherman JF et al. A prospective randomized multi-center study for the treatment of lumbar spinal stenosis with the X-Stop interspinous implant: 1-year results. Eur Spine J 2004; 12:22-31. Zucherman JF et al. A multicenter, prospective, randomized trial evaluating the X-Stop interspinous process decompression system for the treatment of neurogenic intermittent claudication: 2-year follow-up results. Spine 2005; 30: 1351-1358. See [Evidence Table](#).

The use of X-stop Interspinous Process Decompression System in the treatment of lumbar spinal stenosis does not meet the *Group Health Medical Technology Assessment Criteria*.
