Uniform Medical Plan coverage limits

Updates effective 4/1/2025

The benefit coverage limits listed below apply to these UMP plans:

- Uniform Medical Plan (UMP) Classic (PEBB)
- UMP Select (PEBB)
- UMP Consumer-Directed Health Plan (UMP CDHP) (PEBB)
- UMP Plus–Puget Sound High Value Network (UMP Plus–PSHVN) (PEBB)
- UMP Plus–UW Medicine Accountable Care Network (UMP Plus–UW Medicine ACN) (PEBB)

- UMP Achieve 1 (SEBB)
- UMP Achieve 2 (SEBB)
- UMP High Deductible Plan (SEBB)
- UMP Plus–Puget Sound High Value Network (UMP Plus–PSHVN) (SEBB)
- UMP Plus–UW Medicine Accountable Care Network (UMP Plus–UW Medicine ACN) (SEBB)

Some services listed under these benefits have coverage limits. These limits are either determined by a Health Technology Clinical Committee (HTCC) decision or a Regence BlueShield medical policy. **The table below does not include every limit or exclusion under this benefit. For more details, refer to your plan's Certificate of Coverage.**

Uniform Medical Plan Pre-authorization List

The Uniform Medical Plan (UMP) Pre-authorization List includes services and supplies that require pre-authorization or notification for UMP members.

NOTE: This document includes links to external webpages and documentation. To search inside this document, use CTRL+F for PCs or Command+F for Macs, and type in your search term.

Genetic Testing	

Uniform Medical Plan Pre-authorization List

The Uniform Medical Plan (UMP) Pre-authorization List includes services and supplies that require pre-authorization or notification for UMP members.

How to submit a pre-authorization request

Expedited requests

Use this process only when the member or his/her physician believes that waiting for a decision under the standard time frame could place the member's life, health or ability to regain maximum function in serious jeopardy.

- Availity Essentials: Read the information carefully to ensure your request meets the qualifications, then check the box on the form to attest that it is an expedited request.
- Via fax using the appropriate pre-authorization request form below

Online

- Submit an electronic pre-authorization request, and supporting clinical documentation through Availity Essentials>Patient Registration>Authorizations & Referrals>Authorizations
    - Learn more about submitting requests through Availity
- Sleep medicine: Sign in to the Carelon Medical Benefits Management (Carelon) Provider Portal
- Radiology program: Sign in to the Carelon Provider Portal or choose to be routed from Availity's electronic authorization tool via single sign-on.

Note: Check the status of your requests using the same platform you used to submit the request:

- Requests submitted through Carelon are updated on Carelon's portal: **ProviderPortal.com**.
- Requests submitted through Availity Essentials are updated in Availity: **availity.com**.

Fax

Submit the appropriate pre-authorization request form only if unable to submit online or if submitting an expedited request:

- Medical services (PDF)
- Durable medical equipment (DME) (PDF)
- Hospital Admit and Discharge Notification Form (PDF)
- NICU/PICU Notification of Admission Form (PDF)
- Skilled nursing facility (SNF), long term acute care (LTAC) and inpatient rehabilitation (PDF)
- Behavioral health facility submission forms. Tip: Download the form and then fill it out to avoid browser discrepancies.
    - Initial Request Form (PDF) (can be added to an Availity submission)
    - Concurrent Request Form (PDF)
    - Stepdown Request Form (PDF)
    - Discharge Notification Form (PDF)
- Applied Behavioral Analysis (ABA) Initial Request Form (PDF)
    - Pre-authorization is only required for UMP members age 18 and older; please see the Applied Behavioral Analysis (ABA) Therapy section below
- Applied Behavioral Analysis (ABA) Concurrent Request Form (PDF)
    - Pre-authorization is only required for UMP members age 18 and older; please see the Applied Behavioral Analysis (ABA) Therapy section below
- Transcranial Magnetic Stimulation (rTMS) Request Form (PDF) for initial and ongoing services

Direct clinical information reviews (MCG Health)

For select CPT codes, Availity's electronic authorization tool automatically routes you to MCG Health's website where you can document specific clinical criteria for your patient. If all criteria are met, you will see the approval on the Auth/Referral Dashboard soon after you click submit. Once all criteria are documented, you will then be routed back to Availity Essentials to attach supporting documentation and submit the request. Documenting complete and accurate clinical information for your patients helps to reduce the overall time it takes to review a request. View the services that may receive automated approval (PDF).

Type of service or request	Online	Phone	Fax (only if unable to submit online)
Skilled nursing facility only	Submit an electronic pre-authorization request through Availity Essentials	1 (844) 600-4376	1 (855) 848-8220
Long term acute care		1 (800) 423-6884	1 (855) 848-8220
Chemical dependency and mental health		1 (800) 780-7881	1 (888) 496-1540

Professional services and DME		1 (800) 423-6884	1 (844) 679-7763
		1 (800) 423-6884	1 (844) 679-7764
Radiology program Codes requiring authorization are listed in the Radiology section below	Request pre-authorization from Carelon View workarounds for Carelon system outages	1 (877) 291-0509	
Sleep Medicine Codes requiring authorization are listed in the Sleep Medicine section below	Request pre-authorization from Carelon View workarounds for Carelon system outages	1 (877) 291-0509	
Concurrent review notification for: • Skilled nursing facilities (SNF) • Inpatient hospital continued stay • Inpatient rehabilitation (IPR) • Long-term acute care hospitalizations (LTACH)		1 (800) 423-6884	1 (855) 848-8220
Admission or discharge notifications for inpatient hospital			1 (800) 453-4341
Admission or discharge notifications for SNF/IPRL/LTACH		1 (800) 423-6884	1 (855) 848-8220
Clinical Records for: • SNF stays • LTACH stays • IPR stays		1 (800) 423-6884	1 (844) 629-4404
Acute inpatient medical and behavioral health hospital stays require concurrent review.			

Washington State Health Technology Clinical Committee (HTCC) Assessments

Under state law, the Uniform Medical Plans (UMP Achieve 1, UMP Achieve 2, UMP Classic, UMP Select, UMP CDHP, UMP High Deductible, UMP Plus – Puget Sound High Value Network, and UMP Plus – UW Medicine ACN) must comply with decisions made by the Health Technology Clinical Committee (HTCC). The HTCC is a committee of independent health care professionals that reviews selected health technologies (services) to determine the conditions, if any, under which the service will be included as a covered benefit and, if covered, the criteria the plan must use to decide whether the service is medically necessary. These services may include medical or surgical devices and procedures, medical equipment, and diagnostic tests. In public meetings, the HTCC considers public comments and scientific evidence regarding the safety, medical effectiveness, and cost-effectiveness of the services in making its determination. Final decisions and ongoing reviews may be accessed on the HTCC website.

Criteria established by the HTCC supersede Regence Medical Policy.

Procedures that are subject to HTCC decision and require pre-authorization can be found on the UMP Pre-authorization List below.

Procedures denied due to an HTCC decision will be member responsibility.

Important pre-authorization reminders

1. Failure to pre-authorize services subject to pre-authorization requirements will result in an administrative denial, claim non-payment and provider and facility write-off. Members may not be balance billed.
2. Before requesting pre-authorization, please verify member eligibility and benefits via the Availity Portal as the member contract determines the covered benefits.
3. Verify that you are an in-network provider for each member to help reduce his or her out-of-pocket expense.
4. If services are to be rendered in a facility, the pre-authorization request submitted should designate the facility where the treatment will occur to ensure proper reconciliation with related inpatient claims.
5. HTCC Decisions, Medical policies, MCG and CMS criteria may be used as the basis for service coverage determinations, including length of stay and level of care. Visit MCG's website for information on purchasing their criteria, or contact us and we will be happy to provide you with a copy of guidelines for specific services.

6. Emergency services do not require pre-authorization, but are subject to hospital admission notification requirements (see below).
7. The member's contract language will apply.
8. Please note that a pre-authorization does not guarantee payment for requested services. (See #2 above). Our reimbursement policies may affect how claims are reimbursed. Payment of benefits is subject to pre-payment and/or post-payment review, and all plan provisions, including, but not limited to, eligibility for benefits and our Coding Toolkit clinical edits.
9. Investigational and cosmetic services and supplies are typically contract exclusions and are ineligible for payment. Unlisted codes may be used for potentially investigational services and are subject to review. Please refer to the Clinical Edits by Code list for additional information. View a sample non-covered member consent form (PDF).
10. Pre-authorization requirements are not dependent upon site of service. All CPT and HCPCS codes listed on our pre-authorization lists require pre-authorization. View list below for complete requirements.

Type of review	Timeframe	Additional time allowed for review if additional information is needed*:
Urgent/Expedited	Electronic submissions: 1 calendar day, excluding holidays Non-electronic submissions: 2 calendar days	Electronic submissions: 1 calendar day, excluding holidays Non-electronic submissions: 2 calendar days
Standard initial	Electronic submissions: 3 calendar days, excluding holidays Non-electronic submissions: 5 calendar days	Electronic submissions: 3 calendar days, excluding holidays Non-electronic submissions: 4 calendar days
Concurrent	24 hours Must notify within 24 hours for newborn intensive care unit (NICU) or pediatric	72 hours

	intensive care unit (PICU) admission. Exception: Maternity notifications are required on day 6.	
*Note that additional timeframes for review are after receipt of the requested documentation or after the timeframe for submission of the requested information has expired - whichever comes first.		

Pre-authorization review timeframes

If Pre-Authorization requests are received requesting urgent/expedited review timeframes and the documentation provided does not meet the urgent/expedited criteria, the review will be reclassified to a standard review and standard timeframes will apply.

Urgent/expedited criteria is defined as one or more of the following:

- The member's life, health or ability to regain maximum function is in serious jeopardy.
- The member's psychological state is putting the life, health or safety of the member or others is in serious jeopardy.
- The member will be subjected to severe pain that cannot be adequately managed without the service.

Payment implications for failure to pre-authorize services

Failure to secure approval for services subject to pre-authorization or concurrent review authorization will result in claim non-payment and provider write-off. Our members must be held harmless and cannot be balance billed.

Please note the following:

- Hospital claims for elective services that require pre-authorization will be reimbursed based upon the member's contract only when the physician or other health care professional has completed and received approval of the pre-authorization for the services. We therefore strongly suggest that facilities develop a method to ensure that required pre-authorization requests have been submitted by the physician or other health care professional and approved prior to admission of the patient.
- If the physician or other health care professional follows the pre-authorization requirements outlined on our pre-authorization lists, they will not be subject to any

pre-authorization penalties for failure of the facility to provide the required inpatient admission and discharge notification. Stays that extend beyond the pre-authorized number of days require admission notification and concurrent review. If a facility fails to receive authorization for additional days, the additional days will be provider liability.

- A pre-authorization does not guarantee payment for requested services. Health Plan reimbursement policies may affect how claims are reimbursed and payment of benefits is subject to all plan provisions, including eligibility for benefits. Services must always be covered benefits and medically necessary.
- If an elective service that requires pre-authorization needs to occur during the course of an inpatient admission, and that need could not be foreseen prior to admission, the facility or provider can request pre-authorization for the service while the member is inpatient (before the service occurs). If pre-authorization does not occur during the stay, services are subject to review post-service for medical necessity.

Pre-authorization exception

There may be exceptions to obtaining pre-authorization. The six situations listed below may apply as part of our Extenuating Circumstances Policy Criteria (PDF):

1. Member presented with an incorrect member ID card or member number or indicated they were self-pay, and that no coverage was in place at the time of treatment, or the participating provider or facility is unable to identify from which carrier or its designated or contracted representative to request a pre-authorization.
2. Natural disaster prevented the provider or facility from securing a pre-authorization or providing hospital admission notification.
3. Member is unable to communicate (e.g., unconscious) medical insurance coverage. Neither family nor collateral support present can provide coverage information.
4. Compelling evidence the provider attempted to obtain pre-authorization. The evidence shall support the provider followed our policy and that the required information was entered correctly by the provider office into the appropriate system.
5. A surgery which requires pre-authorization occurs in an urgent or emergent situation. Services are subject to review post-service for medical necessity.
6. A participating provider or facility is unable to anticipate the need for a pre-authorization before or while performing a service or surgery.

Learn how to notify us about an extenuating circumstance (PDF) prior to claim submission, or how to appeal a claim that has been administratively denied.

Inpatient admissions

See below for substance use disorder and mental health admissions.

Hospital admissions

- Pre-authorization is required for elective inpatient admissions.
- Notification of hospital admission and discharge required within 1 calendar day, regardless of federal holidays or day of the week.
- Elective early delivery, prior to 39 weeks gestation, is not a covered benefit (not applicable to emergency delivery or spontaneous labor).
- Notification is required via electronic medical record, when available. If electronic medical records are not available, notifications are required via fax or by calling 1 (800) 423-6884. Providers should not call Customer Service to notify of patient admissions or discharge. Learn more about this requirement in the Facility Guidelines section of our Administrative Manual.
- Concurrent medical necessity review is required and must include diagnosis and clinical information regarding the member's current inpatient stay. A census list, admission notice, diagnosis code alone or a face sheet without clinical information is not considered adequate for concurrent review. Failure to provide required records may result in a reduction in or denial of benefits.

Inpatient hospice

- Notification of admission or discharge is necessary within 24 hours of admission or discharge (or one business day, if the admission or discharge occurs on a weekend or a federal holiday). Notification of inpatient hospice admission and discharge required within 24 hours, regardless of federal holidays or day of the week.
- Notification is required via electronic medical record, when available. If electronic medical records are not available, notifications are required via fax. Learn more about this requirement.

Long-Term Acute Care Facility (LTAC)

- Pre-authorization is required prior to patient admission.

Rehabilitation

- Pre-authorization is required prior to patient admission.

Skilled Nursing Facility (SNF)

- Pre-authorization is required prior to patient admission.

Extracorporeal Circulation Membrane Oxygenation (ECMO) for the Treatment of Respiratory Failure in Adults (PDF)

- 33946, 33947, 33948, 33949, 33952, 33954, 33956, 33958, 33962, 33964, 33966, 33984, 33986, 33987, 33988, 33989
- ECMO for UMP is subject to HTCC Decision for initiation. Regence Medical Policy is used for continued use criteria not addressed in the HTCC.
- Subject to review.

Substance use disorder and mental health

Pre-authorization is required for the services listed below. For select CPT codes, including transcranial magnetic stimulation services, Availity's electronic authorization tool automatically connects to MCG's website, where specific clinical criteria can be documented for your patient. If all criteria are met, an approval will be received on the Auth/Referral Dashboard.

- **Inpatient: Psychiatric, eating disorder, ASAM 3.7 in a hospital setting, or ASAM 4.0**
    - Pre-authorization requests should be submitted as soon as possible and are accepted if they are within 3 business days of admission.
    - Timely concurrent review will be required if additional days are requested after an initial pre-authorization is issued. Concurrent review records are due on the last covered date of a pre-authorization. Failure to follow concurrent review requirements may result in an administrative denial, claim non-payment and provider and facility write-off. Members may not be balance billed.
- **Residential levels of care (LOC)**
    - Includes chemical dependency (ASAM 3.7and ASAM 3.5) residential, mental health residential and eating disorder residential requests.
        - Pre-authorization requests must be received within 3 business days of admission.
        - Initial notification of admission of ASAM 3.7 or ASAM 3.7 LOC can be submitted prior to sending a pre-authorization request if clinical records are not available at time of admission.
- **Partial hospitalization & intensive outpatient treatment**
    - Includes mental health, eating disorder and chemical dependency (ASAM 2.5, ASAM 2.1)
        - Request for pre-authorization is required within 7 calendar days of start date.
- **Transcranial magnetic stimulation (TMS) & applied behavior analysis (ABA)**
    - Request for pre-authorization is required within 7 calendar days of start date.
    - ABA services only require pre-authorization for members over the age of 18.

Behavioral health criteria:

- The American Society of Addiction Medicine (ASAM) guide (PDF)
- Level of Care Utilization System (LOCUS) guide (PDF)
- Child and Adolescent Level of Care/Service Intensity Utilization System (CALOCUS-CASII) guide (PDF)
- Early Childhood Service Intensity Instrument (ECSII) guide (PDF)
- Health Technology Clinical Committee (HTCC) Final Findings and Decision for TMS

- Regence medical policies for review of ABA and TMS (for members under the age of 18):
    - Applied Behavior Analysis for the Treatment of Autism Spectrum Disorders (PDF)
    - Applied Behavior Analysis Initial Assessment for the Treatment of Autism Spectrum Disorders (PDF)
    - Transcranial Magnetic Stimulation as a Treatment of Depression and Other Disorders (PDF)

View our resources and forms for behavioral health facilities and our behavioral health medical policies.

Applied Behavior Analysis (ABA) Therapy

ABA Therapy is for the treatment of Autism Spectrum Disorders (ASD) when medically necessary.

- Procedure codes 0362T, 0373T, 97151, 97152, 97153, 97154, 97155, 97156, 97157, 97158
- Procedure codes 97151, 97152, and 0362T: Pre-authorization is not required when 97151, 97152, and 0362T are used for **initial** ABA assessments, but pre-authorization is required when 97151, 97152, and 0362T are used for ABA **reassessments**.
- Pre-authorization is only required for UMP members age 18 and older. Use the Availity Authorization tool if you are uncertain if pre-authorization is required for a member.

The following clinical providers, with expertise in using evidenced-based tools to establish or confirm the diagnosis of autism and experience in developing multidisciplinary autism treatment plans, can provide the diagnostic assessment, comprehensive evaluation report, and recommend treatment approach:

- Psychiatrist
- Neurologist
- Pediatric Neurologist
- Developmental Pediatrician
- Doctorate level psychologist
- Advanced registered nurse practitioner

Initial pre-authorizations must contain the following information; View specific details on what each of these below items need to contain (PDF)

- Pre-authorization request form (or equivalent information)
- Clinical evaluation, which includes confirmation of an ASD diagnosis, and recommended treatment approach from a clinician meeting the criteria above (clinical evaluation needs to have been completed within the 12 months prior to the initial pre-authorization request)
- Written Clinical Order, Directive, or Prescription for ABA Therapy services from a clinician meeting the criteria above

- ABA initial report that includes an ABA assessment treatment plan (to be completed by the Lead Behavior Therapist). This sample ABA assessment and treatment plan form (PDF) can be filled out and submitted or used as a reference tool.

A cover letter may be submitted; however, it is not required. A sample cover letter template (PDF) is provided for your reference. Other supporting documentation may be submitted.

View ABA therapy clinical considerations (PDF) for information about hours of service and documentation requirements.

Concurrent Review

The following document should be submitted within five business days prior to the end of a current authorization:

- Updated ABA assessment treatment plan (to be completed by the Lead Behavior Therapist). This sample ABA assessment and treatment plan form (PDF) can be filled out and submitted or used as a reference tool.
- A new Pre-authorization request form (PDF) (or equivalent information).

View ABA therapy clinical considerations (PDF) for information about hours of service and documentation requirements.

Following the submission of the concurrent review documentation, the plan may request additional information prepared and submitted by a clinician meeting the above clinical criteria. The plan will specify what must be included in this report which is intended to assess progress and prospective treatment in further detail and may include a written Clinical Order, Directive or Prescription for ABA Therapy services.

Initial Treatment Request

Procedure codes: 0362T, 0373T, 97151, 97152, 97153, 97154, 97155, 97156, 97157, 97158

- Procedure codes 97151, 97152, and 0362T: pre-authorization is not required when 97151, 97152, and 0362T are used for initial ABA assessments, but pre-authorization is required when 97151, 97152, and 0362T are used for ABA reassessments during course of treatment.
- Pre-authorization is only required for members age 18 and older. Use the Availity Authorization tool, availity.com, if you are uncertain if pre-authorization is required for a member.
- ABA therapy must be recommended or prescribed by a licensed provider experienced in the diagnosis and treatment of autism.

View documentation requirements in our Applied Behavior Analysis for the Treatment of Autism Spectrum Disorder (PDF) medical policy which should include:

- Clinical evaluation, which includes confirmation of an ASD diagnosis, and recommended treatment approach from a clinician meeting the criteria above.
- ABA initial report that includes an ABA assessment treatment plan (to be completed by the Lead Behavior Therapist).

- A cover letter may be submitted; however, it is not required. A sample cover letter template (PDF) is provided for your reference. Other supporting documentation may be submitted.

Concurrent Treatment Request (Reauthorization)

- Updated clinical documents should be submitted within 14 days of end of a current authorization.
- A new Pre-authorization request form (PDF) (or equivalent information).
- Following the submission of the concurrent review documentation, the plan may request additional information prepared and submitted by a clinician meeting the above clinical criteria. The plan will specify what must be included in this report which is intended to assess progress and prospective treatment in further detail and may include a written Clinical Order, Directive or Prescription for ABA Therapy services.

Allied health

Administrative Guidelines to Determine Dental vs Medical Services (PDF)

Biofeedback (PDF)

- 90875, 90876, 90901, 90912, 90913, E0746
- We do not require pre-authorization for biofeedback for headache and migraine G43.xx, G44.201, G44.209 , G44.211, G44.219, G44.221, G44.229, R51

Cardiovascular

Carelon Cardiovascular

We partner with Carelon to administer our cardiovascular program.

- Login to Carelon's Provider Portal
- Phone 1 (877) 291-0509
- View workarounds for Carelon system outages
- **Note**: If HTCC criteria is used for pre-authorization, see below links to that criteria. If there are no HTCC criteria or HTCC is out of scope for request, Carelon criteria will apply.
- Contact Carelon to request pre-authorization for the following codes: C1721, C1722, C1764, C1777, C1785, C1786, C1882, C1895, C1896, C1899, C2619, C2620, C2621, E0616, G0448, K0606, 0823T, 0825T, 0913T, 33206, 33207, 33208, 33212, 33213, 33214, 33221, 33227, 33228, 33229, 33230, 33231, 33240, 33249, 33270, 33271, 33274, 33285, 37220, 37221, 37224, 37225, 37226, 37227, 37228, 37229, 37230, 37231, 92920, 92924, 92928, 92933, 92937, 92943, 93228, 93229, 93454, 93455,

93456, 93457, 93458, 93459, 93460, 93461, 93650, 93653, 93654, 93656, 93880, 93882, 93922, 93923, 93924, 93925, 93926, 93930, 93931, 93978, 93979

- **Effective May 1, 2025, Pre-authorization will be required for codes: C7513, C7514, C7515, C7530, 36901, 36902, 36903, 36904, 36905, 36906, 37241, 37242, 37243, 37244, 93580, 93600, 93602, 93603, 93610, 93612, 93618, 93619, 93620, 93624, 93642, 93644**
- **Effective July 1, 2025, Pre-authorization will be required for codes: C7557, C7558**
- Retrospective review is not allowed for cardiac rhythm monitors (93228 and 33285). Retrospective review is allowed for cardiac ablation and wearable and cardioverter defibrillators if records are received within 10 business days of the date of service.
- Procedures performed in an inpatient setting or on an emergent basis **do not** require pre-authorization from Carelon. Inpatient stays are subject to review by Regence for determining the appropriate length of stay.

HTCC decisions administered by Carelon:

- K0848, K0849, K0850, K0851, K0852, K0853, K0854, K0855, K0856, K0857, K0858, K0859, K0860, K0861, K0862, K0863, K0864

Stents, Drug Coated or Drug-Eluting (DES)

- Refer to Cardiac Stenting in the Surgery section below.

Sleep Medicine

- View the Sleep Medicine Management Program for notification or authorization requirements.
- Review the codes requiring authorization or notification in the Sleep Medicine section.

Genetic testing

In compliance with WA HB 1689, guideline-recommended biomarker testing in patients with recurrent, relapsed, refractory, or metastatic cancer (including stage 3 or 4) will not require pre-authorization for Washington members. This does not include non-specific molecular pathology codes (81400-81408).

Diagnosis codes Z800-Z803, Z8041 and Z8042 will no longer be exempted from pre-authorization for Washington members.

Genetic Testing for Alzheimer's Disease (PDF) - GT01

- 81401, 81405, 81406

Genetic Testing for Hereditary Breast and Ovarian Cancer and Li-Fraumeni Syndrome (PDF) - GT02

- 0235U, 81162, 81163, 81164, 81165, 81166, 81167, 81212, 81215, 81216, 81217, 81307, 81308, 81321, 81322, 81323, 81404, 81405, 81406, 81432, 81351, 81352

Apolipoprotein E for Risk Assessment and Management of Cardiovascular Disease (PDF) - GT05

- 81401

Genetic Testing for Lynch Syndrome and APC-associated and MUTYH-associated Polyposis Syndromes (PDF) - GT06

- 0238U, 81201, 81202, 81203, 81210, 81288, 81292, 81293, 81294, 81295, 81296, 81297, 81298, 81299, 81300, 81317, 81318, 81319, 81401, 81406

Genetic Testing for Cutaneous Malignant Melanoma (PDF) - GT08

- 81404

Cytochrome p450 and VKORC1 Genotyping for Treatment Selection and Dosing (PDF) - GT10

- 81225, 81401, 81402, 81404, 81405, 81418, 0070U, 0071U, 0072U, 0073U, 0074U, 0075U, 0076U, 0461U
- UMP is subject to HTCC Decision (PDF) for codes 81225, 81418, 0070U, 0071U, 0072U, 0073U, 0074U, 0075U, 0076U and 0461U.
- Codes 81225, 81418, 0070U, 0071U, 0072U, 0073U, 0074U, 0075U, 0076U, 0461U and 0533U will deny as not a covered benefit when billed with the following diagnosis: depression, mood disorders, psychosis, anxiety, ADHD and substance use disorders.

Genetic Testing; Familial Hypercholesterolemia (PDF) - GT11

- 81401, 81405, 81406, 81407

KRAS, NRAS and BRAF Variant Analysis and MicroRNA Expression Testing for Colorectal Cancer (PDF) - GT13

- 81210, 81275,81276, 81311, 81403, 81404, 0111U, 0471U

Preimplantation Genetic Testing of Embryos (PDF) - GT18

Electromagnetic Navigation Bronchoscopy

- **Effective July 1, 2025: Pre-authorization will be required for codes: 31626, 31627, C7509, C7510, C7511, C9751**

Hyperbaric Oxygen Therapy for Tissue Damage, Including Wound Care and Treatment of Central Nervous System Conditions (PDF)

- UMP is subject to HTCC Decision (PDF): 99183, G0277
- Acute/sudden sensorineural hearing loss is a covered condition for this HTCC and is no longer applicable as an exclusion.
    - Note, chronic sensorineural hearing loss remains an exclusion under this HTCC.
- Regence medical policy is used only to determine units of treatment, criteria for diabetic "standard wound therapy" and to address any conditions not addressed in the HTCC decisions under the HTCC "limitations of coverage" or "non-covered indicators".

In Vivo Analysis of Colorectal Lesions (PDF)

- 88375

Intensity Modulated Radiotherapy (IMRT)

Charged-Particle (Proton or Helium Ion) Radiotherapy

- UMP is subject to HTCC Decision (PDF) - 77520, 77522, 77523, 77525
    - Pre-authorization is not required for members under 21 years of age
- When the following codes are used for Charged-Particle (Proton or Helium Ion) Radiotherapy with SRS or SBRT, use HTCC Decision (PDF): 32701, 61796, 61797, 61798, 61799, 61800, 63620, 63621, 77301, 77338, 77371, 77372, 77373, 77432, 77435, G0339, G0340

Radioembolization, Transarterial Embolization (TAE) and Transarterial Chemoembolization (TACE) (PDF)

- 37243, 79445, C9797, S2095
- **Note**: Ovarian and Internal Iliac Vein Embolization as a Treatment of Pelvic Congestion Syndrome (PDF) is considered investigational.

Sleep Medicine

- View the Sleep Medicine Management Program for notification or pre-authorization requirements.
- Review the codes requiring pre-authorization or notification in the Sleep Medicine section.

Tinnitus: Non-invasive, non-pharmacologic treatments

- UMP is subject to HTCC Decision (PDF) for codes 0552T, 90832, 90833, 90834, 90836, 90837, 90838, 90867, 90868, 90869, 96156, 96158, 96159, 96160, 96161, 96164, 96165, 96167, 96168, 96170, 96171, S8948
- Pre-authorization is only required within tinnitus diagnosis codes: H93.11, H93.12, H93.13, H93.19, H93.A1, H93.A2, H93.A3, H93.A9
- Codes 0552T and S8948, when billed without a tinnitus diagnosis, will be denied as investigational based on Regence Medical Policy Low Level Laser Therapy
- **Note**: Codes 90867 and 90868, when billed with chronic migraine and chronic tension headaches, is not a covered benefit per HTCC Decision (PDF)

Transcranial Magnetic Stimulation as a Treatment of Depression and Other Disorders (PDF)

- UMP is subject to HTCC Decision (PDF) for codes 90867, 90868, 90869, 0889T, 0890T, 0891T, 0892T
    - Per the HTCC, TMS for treatment resistant major depressive disorder (MDD) in UMP members age 18 or older is a covered benefit with conditions.
    - TMS for treatment resistant major depressive disorder (MDD) in UMP members age 17 and younger refer to Regence medical policy.
    - TMS for treatment of obsessive-compulsive disorder (OCD), generalized anxiety disorder (GAD), post-traumatic stress disorder (PTSD), smoking cessation, and substance use disorder (SUD) are not covered for all UMP members per the HTCC.
- Apply the Regence medical policy Transcranial Magnetic Stimulation as a Treatment of Depression and Other Disorders (PDF) for code 0858T.

Gender Affirming Interventions for Gender Dysphoria (PDF)

- 11920, 11921, 15769, 15771, 15772, 15773, 15774, 15775, 15776, 15825, 15828, 15829, 17380, 17999, 19303, 19316, 19318, 19325, 19350, 21125, 21127, 21137, 21139, 21141, 21142, 21143, 21145, 21146, 21147, 21188, 21193, 21194, 21195, 21196, 21208, 53400, 53405, 53410, 53415, 53420, 53425, 53430, 54125, 54400, 54401, 54405, 54520, 54660, 54690, 55175, 55180, 55970, 55980, 56625, 56800, 56805, 57106, 57110, 57291, 57292, 57295, 57296, 57335, 57426, 58353, 58356, 58563, C1813, C2622, L8600

- Codes 55970 and 55980 are non-specific. The specific procedure code(s) must be requested in place of these non-specific codes.
- Use code 17999 to request laser hair removal.
- Gender affirming surgical interventions for gender dysphoria require pre-authorization. Codes for specific procedures might also be listed as requiring pre-authorization in other medical policies, including but not limited to:
    - Abdominoplasty - 15830
    - Adipose-derived Stem Cell Enrichment in Autologous Fat Grafting to the Breast - 15771
    - Breast Reconstruction - 19316, 19318, 19325, 19350, L8600
    - Blepharoplasty and Brow Lift - 15820, 15821, 15822, 15823, 67900, 67901, 67902, 67903, 67904, 67906, 67908, 67909, 67950
    - Chin Implants - 21120, 21121, 21122, 21123, 21209
    - Collagen Injections - 11950, 11951, 11952, 11954
    - Cosmetic and Reconstructive Procedures - 15771, 15773
    - Endometrial Ablation - 58353, 58356, 58563
    - Panniculectomy - 15830
    - Reconstructive Breast Surgery, Mastopexy, and Management of Breast Implants - 15771
    - Rhinoplasty - 30400, 30410, 30420, 30430, 30435, 30450

Pharmacy

UMP has a separate vendor – Washington State Rx Services – for their prescription drug benefit. Pre-authorization is necessary for certain injectable drugs that are not normally approved for self-administration when obtained through a retail pharmacy, a network mail-order pharmacy, or a network specialty pharmacy. These drugs are indicated on the UMP Preferred Drug List.

Drugs usually payable under the member's medical benefit and pre-authorized will continue with the same Regence process.

Hemophilia Clotting Factors

Hemophilia clotting factor codes J7170. J7201, J7202, J7203, J7204, J7205, J7207, J7208, J7210 require pre-authorization and if approved will be covered under the Medical benefits for the following groups. For all other groups please use the pharmacy link above.

- ATI Specialty Alloys and Components (group #10015713)
- WA State Health Care Authority (group # 10003948)
- Rin Tinto (grandfathered plan codes only) (groups #10021209 & 10019119)
- OTET (group #10007445)
- Northwest Evaluation Association (NWEA) (group #10002570)
- Utah Valley University (group #10042213)
- Encoder Products (group #10040552)

- Eagle Eye Produce Inc (group #10040165)

Infusion Drug Site of Care

Certain provider administered infusion medications covered on the medical benefit are subject to the Site of Care Program (dru408) medication policy (PDF). This policy does not apply to members covered under UMP Plus plans.

Radiology

Coronary Artery Calcium Scoring

- UMP is subject to HTCC Decision (PDF) : S8092
- **Note**: 75571 for Cardiac Artery Calcium Scoring is not a covered benefit - reference HTCC Decision.

Wireless Capsule Endoscopy for Gastrointestinal (GI) Disorders (PDF)

- 0651T, 91110, 91111, 91113

Carelon Radiology

We partner with Carelon to administer our Radiology Program.

- Login to Carelon's ProviderPortal
- Phone 1 (877) 291-0509
- View workarounds for Carelon system outages
- **Note**: If HTCC criteria is used for pre-authorization, see below links to that criteria. If there are no HTCC criteria or HTCC is out of scope for request, Carelon criteria will apply.
- Contact Carelon to request pre-authorization for the following codes: 70336, 70450, 70460, 70470, 70480, 70481, 70482, 70486, 70487, 70488, 70490, 70491, 70492, 70496, 70498, 70540, 70542, 70543, 70544, 70545, 70546, 70547, 70548, 70549, 70551, 70552, 70553, 70554, 70550, 71250, 71260, 71270, 71271, 71275, 71550, 71551, 71552, 71555, 72125, 72126, 72127, 72128, 72129, 72130, 72131, 72132, 72133, 72141, 72142, 72146, 72147, 72148, 72149, 72156, 72157, 72158, 72159, 72191, 72192, 72193, 72194, 72195, 72196, 72197, 72198, 73200, 73201, 73202, 73206, 73218, 73219, 73220, 73221, 73222, 73223, 73225, 73700, 73701, 73702, 73706, 73718, 73719, 73720, 73721, 73722, 73723, 73725, 74150, 74160, 74170, 74174, 74175, 74176, 74177, 74178, 74181, 74182, 74183, 74185, 74712, 75557, 75561, 75559, 75563, 75572, 75573, 75574, 75580, 75635, 76391, 77046, 77047, 77048, 77049, 77078, 77084, 78012, 78013, 78014, 78015, 78016, 78018, 78070, 78071, 78072, 78075, 78102, 78103, 78104, 78185, 78195, 78201, 78202, 78215, 78216, 78226, 78227, 78230, 78231, 78232, 78258, 78261, 78262, 78264, 78265, 78266, 78278, 78290, 78291, 78300, 78305, 78306, 78315, 78429, 78430, 78431, 78432, 78433, 78445, 78451, 78452, 78453, 78454, 78456, 78457, 78458, 78459, 78466, 78468, 78469, 78472, 78473, 78579, 78580, 78481, 78582, 78483, 78491,

78492, 78494, 78597, 78598, 78600, 78601, 78605, 78606, 78608, 78609, 78610, 78630, 78635, 78645, 78650, 78660, 78700, 78701, 78707, 78708, 78709, 78725, 78740, 78761, 78800, 78801, 78802, 78803, 78804, 78811, 78812, 78813, 78814, 78815, 78816, 78830, 78831, 78832, 93303, 93304, 93306, 93307, 93308, 93312, 93313, 93314, 93315, 93316, 93317, 93350, 93351, 0042T, 0648T, 0649T

- Procedures performed in an inpatient setting or an emergent basis **do not** require pre-authorization from Carelon. Inpatient stays are subject to review by Regence for determining the appropriate length of stay.
- HTCC decisions administered by Carelon:
    - Breast MRI
        - UMP is subject to HTCC Decision (PDF) : 77046, 77047, 77048, 77049
        - HTCC criteria applies to all member requests regardless of gender
    - Cardiac Magnetic Resonance Angiography (CMRA)
        - UMP is subject to HTCC Decision (PDF): 75557, 75561
    - Functional Neuroimaging for Primary Degenerative Dementia or Mild Cognitive Impairment
        - UMP is subject to HTCC Decision (PDF) : 70554, 70555, 78608, 78609
        - Please see Carelon criteria for pre-authorization requirements for indications other than primary degenerative dementia or mild cognitive impairment
    - Imaging for Rhinosinusitis
        - UMP is subject to HTCC Decision (PDF) : 70450, 70460, 70470, 70486, 70487, 70488, 70540, 70542, 70543
        - Please see Carelon criteria for pre-authorization requirements for indications other than Rhinosinusitis
    - Noninvasive Cardiac Imaging for Coronary Artery Disease
        - UMP is subject to HTCC Decision (PDF): 75574, 75580, 78429, 78430, 78431, 78432, 78433 78451, 78452, 78453, 78454, 78459, 78466, 78468, 78469, 78472, 78473, 78481, 78483, 78491, 78492, 78494, 93350, 93351
    - Positron Emission Tomography (PET) Scans for Lymphoma
        - UMP is subject to HTCC Decision (PDF) : 78811, 78812, 78813, 78814, 78815, 78816

Sleep Medicine

Carelon Sleep Medicine

We partner with Carelon to administer our Sleep Medicine program.

- Login to Carelon's Provider Portal
- Phone 1 (877) 291-0509
- View workarounds for Carelon system outages
- **Note**: If HTCC criteria is used for pre-authorization, see below links to that criteria. If there are no HTCC criteria or HTCC is out of scope for request, Carelon criteria will apply. Also refer to the Surgery section for additional information about pre-

authorization requirements related to surgery for Sleep Apnea Diagnosis and Treatment.
- Contact Carelon to request pre-authorization for the following codes: 95782, 95783, 95805, E0470, E0471
- Carelon uses HTCC to pre-authorize sleep medicine diagnosis and equipment. Also refer to the Surgery section for additional information about pre-authorization requirements related to surgery for Sleep Apnea Diagnosis and Treatment.
- Procedures performed in an inpatient setting or on an emergent basis **do not** require pre-authorization from Carelon. Inpatient stays are subject to review by Regence for determining the appropriate length of stay.
- HTCC decisions administered by Carelon:
    - Sleep Apnea – Diagnosis and Equipment
        - UMP is subject to HTCC Decisions (PDF): 95807, 95808, 95810, 95811, E0561, E0562, E0601
        - Please see Carelon criteria for indications other than Sleep Apnea

Surgery

Ablation of Primary and Metastatic Liver Tumors (PDF)

- 47370, 47371, 47380, 47381, 47382, 47383

Adipose-derived Stem Cell Enrichment in Autologous Fat Grafting to the Breast (PDF)

- 15769, 15771, 15772, 11950, 11951, 11952, 11954
- **Note**: Codes 19380 and 19499 do not require pre-authorization but are considered, and will deny as, investigational when used for autologous fat grafting and adipose-derived stem cell enrichment for augmentation or reconstruction of the breast

Anterior Abdominal Wall (Including Incisional) Hernia Repair (PDF)

- 15734, 49591, 49593, 49595, 49613, 49615, 49617, 49621
- Pre-authorization for 15734 required only with diagnosis code K42.0, K42.1, K42.9 K43.0, K43.1, K43.2 K43.6, K43.7, K43.9, K45.0, K45.1, K45.8, K46.0, K46.1, K46.9 or M62.0 for component separation technique (CST)
- Pre-authorization for codes 49591, 49593, 49595, 49613, 49615, 49617, 49621 only required with diagnoses codes K42.9, K43.2 and K43.9 for ventral hernia repair

Autologous Chondrocyte Implantation for Focal Articular Cartilage Lesions (PDF)

- J7330, S2112

Balloon Dilation of the Eustachian Tube (PDF)

- 69705, 69706

Balloon Ostial Dilation for Treatment of Sinusitis (PDF)

- 31295, 31296, 31297, 31298

Bariatric Surgery (PDF)

- 43771, 43848, 43860, 43886
- UMP is subject to HTCC Decision (PDF): 43644, 43645, 43772, 43773, 43774, 43775, 43820, 43843, 43845, 43846, 43847, 43887, 43888, C9784, C9785, S2083
- **Note**: Intragastric ballons will not be a covered benefit and the following codes will not be covered: 43290, 43291, 0813T
- Bariatric surgery and HTCC guidelines apply, in order to establish eligibility for surgery and medical necessity.

Benign Prostatic Hyperplasia Surgical Treatments (PDF)

- 0421T, 53854, C2596

Blepharoplasty, Repair of Blepharoptosis, and Brow Ptosis Repair (PDF)

- 15820, 15821, 15822, 15823, 67900, 67901, 67902, 67903, 67904, 67906, 67908, 67909, 67950

Bronchial Valves (PDF)

- 31647, 31648, 31649, 31651

Extracranial Carotid Angioplasty and Stenting (PDF)

- C7563
- UMP is subject to HTCC Decision (PDF): 37215, 37216, 37217, 37246, 37247, C7532

Cervical Fusion for Degenerative Disc Disease

- UMP is subject to HTCC Decision (PDF): 22551, 22552, 22554, 22853, 22854, 22859, 22600

Chemical Peels (PDF)

- 15788, 15789, 15792, 15793, 17360

Cochlear Implant (PDF)

- For Bilateral Cochlear Implants, UMP is subject to HTCC Decision (PDF)
- For Unilateral Cochlear Implants and replacement requests, UMP follows Regence Medical Policy:
- 69930, L8614, L8619, L8627, L8628

Cosmetic and Reconstructive Procedures (PDF)

- 11920, 11921, 11922, 11950, 11951, 11952, 11954, 15769, 15771, 15772, 15773, 15774, 17106, 17107, 17108, 19355, 21230, 21244, 21245, 21246, 21248, 21249, 21295, 21296, 41510, 49250, 54360, 67950, 69300, G0429
- Pre-authorization is required EXCEPT when services are rendered in association with breast reconstruction and nipple/areola reconstruction following mastectomy for breast cancer.
- **Note**: Codes 19380 and 19499 do not require pre-authorization but are considered, and will deny as, investigational when used for autologous fat grafting and adipose-derived stem cell enrichment for augmentation or reconstruction of the breast

Cryosurgical Ablation of Miscellaneous Solid Tumors Outside of the Liver (PDF)

- 31641, 32994, 50542

Deep Brain Stimulation (PDF)

- 61850, 61860, 61863, 61864, 61867, 61868, 61885, 61886, C1820, L8679, L8680, L8685, L8686, L8687, L8688, L8682, L8683
- Deep brain stimulation is not a covered benefit for treatment-resistant depression, per HTCC Decision (PDF).
- **Note**: HTCC decision applies to UMP members age 18 and older. Refer to Regence Medical Policy for UMP members age 17 and younger

Discography

- UMP is subject to HTCC Decision (PDF) : 62290, 72295

Endometrial Ablation (PDF)

- 58353, 58356, 58563

Facet Neurotomy

- UMP is subject to HTCC Decision (PDF): 64633, 64634, 64635, 64636

Gastric Electrical Stimulation (PDF)

- 43647, 43881, 64590, 64595, E0765, C1767, L8679, L8680, L8685, L8686, L8687, L8688

Gastroesophageal Reflux Surgery (PDF)

- 43279, 43280, 43281, 43282, 43325, 43327, 43328, 43332, 43333, 43334, 43335, 43336, 43337

Hip Surgery for Femoroacetabular Impingement Syndrome (FAI)

- UMP is subject to HTCC Decision (PDF): 29914, 29915, 29916

Hypoglossal Nerve Stimulation (PDF)

- 64568, 64582, 64583, C1767

Implantable Peripheral Nerve Stimulation and Peripheral Subcutaneous Field Stimulation (PDF)

- 64585, 64590, 64595, 64596, 64597, 64598, L8679, L8680, L8683

Laser Treatment for Port Wine Stains (PDF)

- 17106, 17107, 17108

Left-Atrial Appendage Closure Devices for Stroke Prevention in Atrial Fibrillation (PDF)

- 33340

Lumbar Fusion for Degenerative Disc Disease (PDF)

- UMP is subject to HTCC Decision (PDF): 22533, 22558, 22612, 22630, 22633, 22853, 22854, 22859
- Lumbar Fusion for degenerative disc disease uncomplicated by comorbidities is not a covered benefit per HTCC Decision; This includes diagnosis codes M51.35, M51.36, M51.37
  Note: This decision does not apply to patients with the following conditions: For indications or populations not addressed in the HTCC, the Regence Medical Policy will apply. This includes but is not limited to the following: radiculopathy, spondylolisthesis (>grade 1), severe spinal stenosis, acute trauma or systemic disease affecting spine, e.g., malignancy
- UMP is subject to HTCC Decision (PDF) for Bone Morphogenic Protein
- Bone morphogenetic protein-7 (rhBMP-7) is not a covered benefit
- HTCC for bone morphogenetic protein does not apply to those under age 18

Magnetic Resonance (MR) Guided Focused Ultrasound (MRgFUS), and High Intensity Focused Ultrasound (HIFU) Ablation, and Transurethral Ultrasound Ablation (TULSA) (PDF)

- 55880, 61715

Microwave Tumor Ablation (PDF)

- 32998, 50592

Negative Pressure Wound Therapy for Home Use (NPWT)

- UMP is subject to HTCC Decision (PDF): 97605, 97606, 97607, 97608, A6550, E2402
- View the HTCC Decision: Definition of "Complete Wound Therapy Program" (PDF)
- View the NPWT FDA Safety Communication
- **Note**: Medical necessity for negative pressure wound therapy devices must be established prior to requesting pre-authorization for clinical care and supplies related to the device.

Occipital Nerve Stimulation (PDF)

- 61885, 61886, 64553, 64568, 64569, 64585, 64590, 64596, 64597, 64598
- C1820, L8679, L8680, L8682, L8683, L8685, L8686, L8687, L8688
- Occipital Nerve Stimulation is considered investigational for all indications, including but not limited to headaches
- **Note**: These codes may overlap with the codes in the Vagus Nerve Stimulation Medical Policy so to ensure proper adjudication of your claim, please call for pre-authorization on all of the above codes.

Orthognathic surgery (PDF)

- 21085, 21110, 21120, 21121, 21122, 21123, 21125, 21127, 21141, 21142, 21143, 21145, 21146, 21147, 21150, 21151, 21154, 21155, 21159, 21160, 21188, 21193, 21194, 21195, 21196, 21198, 21206, 21208, 21209, 21210, 21215, 21230, 21295, 21296
- Codes 21145, 21196, 21198 require pre-authorization EXCEPT when the procedure is performed for oral cancer diagnosis codes: C01, C02-C02.9, C03-C03.9, C04-C04.9,

C05-C05.9, C06, C06.2, C06.9, C09-C09.9, C10-C10.0, C41-C41.1, C46.2, D00-D00.00, D10, D10.1-D10.9, D16.4-D16.5, D37-D37.0, D49-D49.0

Osteochondral Allograft/Autograft Transplantation (OAT)

- UMP is subject to HTCC Decision (PDF): 27415, 27416, 29866, 29867

Ovarian, Internal Iliac and Gonadal Vein Embolization, Ablation, and Sclerotherapy (PDF)

- 37241

Percutaneous Angioplasty and Stenting of Veins (PDF)

- 37238, 37239, 37248, 37249

Panniculectomy (PDF)

- 15830

Pectus Excavatum and Carinatum Surgery (PDF)

- 21740, 21742, 21743

Phrenic Nerve Stimulation for Central Sleep Apnea (PDF)

- C1823

Radiofrequency Ablation (RFA) of Tumors Other Than the Liver (PDF)

- 20982, 31641, 32998, 50542, 50592, 58580, 58674, 60660, 60661

Reconstructive Breast Surgery/Mastopexy, and Management of Breast Implants (PDF)

- 11920, 11921, 15769, 15771, 15772, 19316, 19318, 19325, 19328, 19330, 19340, 19342, 19350, 19355, 19370, 19371, L8600
- Pre-authorization is required EXCEPT when services are rendered in association with breast reconstruction and nipple/areola reconstruction following mastectomy for breast cancer. However, if autologous fat grafting with adipose-derived stem cell enrichment is used for augmentation or reconstruction of the breast it would be considered investigational.
- **Note**: Codes 19380 and 19499 do not require pre-authorization but are considered, and will deny as, investigational when used for autologous fat grafting and adipose-derived stem cell enrichment for augmentation or reconstruction of the breast.

Reduction Mammaplasty (PDF)

- 19318

Responsive Neurostimulation (PDF)

- 61850, 61860, 61863, 61864, 61885, 61886, 61889, 61891, L8680, L8686, L8688

Rhinoplasty (PDF)

- 30120, 30400, 30410, 30420, 30430, 30435, 30450

Sacral Nerve Neuromodulation (Stimulation) for Pelvic Floor Dysfunction (PDF)

- 0786T, 0787T, 0788T, 0789T, 64561, 64581, 64585, 64590, 64595, 64596, 64597, 64598, C1767, L8679, L8680, L8682, L8683, L8685, L8686, L8687, L8688
- **Note**: Please submit your pre-authorization request for the temporary trial period of sacral nerve neuromodulation AND the permanent placement at the same time, as these are treated as one combined episode.
- Treatment of chronic neuropathic pain is not a covered benefit, per HTCC Decision (PDF) for codes 0786T, 0787T, 0788T, 0789T

Sacroiliac Joint Fusion (PDF)

- UMP is subject to HTCC Decision (PDF): 27278, 27279, 27280, C1737
- For indications not addressed in the HTCC, the Regence Medical Policy will apply

Spinal Cord and Dorsal Root Ganglion Stimulation (PDF)

- 0784T, 0785T, 0786T, 0787T, 0788T, 0789T, 63650, 63655, 63685, C1767, C1820, C1822, C1826, L8679, L8680, L8685, L8686, L8687, L8688
- Spinal cord stimulation for the treatment of complex regional pain syndrome is not a covered benefit, per HTCC Decision (PDF) for the following procedure and device codes; 0784T, 0785T, 0786T, 0787T, 0788T, 0789T, 63650, 63655, 63685, C1767, C1820, C1822, C1826, L8679, L8680, L8685, L8686, L8687, L8688 when associated diagnosis codes are included:
    - G56.40, G56.41, G56.42, G56.43, G57.70, G57.71, G57.72, G57.73, G90.50, G90.511, G90.512, G90.513, G90.519, G90.521, G90.522, G90.523, G90.529, G90.59
- **Note**: Spinal cord stimulation for the treatment of the following is not a covered benefit:
    - Life expectancy less than one (1) year
    - Hemoglobin A1C (HbA1C) >10 (for PDN)
    - Body mass index (BMI)>45
    - Maximum daily morphine milligram equivalent (MME) ≥120
    - Concurrent, untreated, substance use disorder (including alcohol, prescription or illicit drugs) per American Society of Addiction Medicine (ASAM) guidelines
    - Active, substantial chronic pain in other regions that have required treatment in the past year
    - Related or pending worker's compensation claim (for FBSS and NSRBP)
    - Pending or existing litigation for the condition being treated with SCS
- If treatment is for other than this indication, Regence medical policy applies.

Spinal Injections

- Spinal Injections for UMP members are subject to HTCC Decision (PDF)
- **Notes**:
    - 62292 for Therapeutic Medial Branch Nerve Block, Intradiscal and Facet Spinal Injections are not a covered benefit, reference the HTCC Decision (PDF) :

- 27096, 62320, 62321, 62322, 62323, 64451, 64479, 64480, 64483, 64484, 64490, 64491, 64492, 64493, 64494, 64495 and G0260 may be subject to HTCC Decision. Pre-authorization is not required but may be subject to HTCC Decision (PDF) and require a provider attestation.
- Attestation is needed for timely and accurate processing of claims
  - Use the electronic authorization tool on the Availity Portal and select the attestation criteria during the clinical documentation process on MCG Health
  - If an attestation is not completed pre-service using the Availity tool, fax the completed attestation form (PDF) to 1 (877) 357-3418
- This coverage policy does not apply to those with systemic inflammatory disease such as ankylosing spondylitis, psoriatic arthritis or enteropathic arthritis

Spinal Surgery - Artificial Disc Replacement

- UMP is subject to HTCC Decision (PDF): 22856, 22858, 22861, 0095T, 0098T
- Lumbar artificial disc is not a covered benefit: 22857, 22860, 22862, 22865, 0163T, 0164T, 0165T

Stereotactic Radiation Surgery and Stereotactic Body Radiation Therapy

- UMP is subject to HTCC decisions Stereotactic Radiation Surgery and Stereotactic Body Radiation Therapy (PDF) and Stereotactic body radiation therapy (SBRT) (PDF): 32701, 61796, 61797, 61798, 61799, 61800, 63620, 63621, 77301, 77338, 77371, 77372, 77373, 77432, 77435, G0339, G0340, G0563
- The HTCC Decision (PDF) is specific to the treatment of cancer of stereotactic radiation surgery and SBRT for cancers of spine/paraspinal structures, and CNS tumors.
- **Notes**:
  - HTCC Decision (PDF) applies for osteosarcoma of the spine
  - Stereotactic radiation surgery is not covered for conditions other than Central Nervous System (CNS) and Metastatic tumors
- HTCC Decision (PDF) is specific to the treatment of localized prostate cancer, non-small cell and small cell lung cancer, pancreatic adenocarcinoma, oligometastatic disease, hepatocellular carcinoma, cholangiocarcinoma, Central Nervous System (CNS) primary and metastatic tumors, cancers of spine/paraspinal structures, renal cancers, as well as primary bone, head and neck, adrenal, melanoma, Merkel cell, breast, ovarian, and cervical cancers.
- Regence medical policies apply for any condition not mentioned specific to the HTCC determinations above:
  - Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy of Intracranial, Skull Base, and Orbital Sites (PDF) (PDF)
  - Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy for Tumors Outside of Intracranial, Skull Base, or Orbital Sites (PDF)

Surgery for Lumbar Radiculopathy

- UMP is subject to HTCC Decision (PDF): CPT 62380, 63030, 63035, 63042, 63044, 63047, 63048, 63056, 63057, 63090, 63091
- **Notes**:
    - Pre-authorization is required only with diagnosis codes M47.20, M47.25, M47.26, M47.27, M47.28, M51.15, M51.16, M51.17, M51.26, M51.27, M54.10, M54.15, M54.16, M54.17, M54.18, M54.30, M54.31, M54.32, M54.40, M54.41, M54.42
    - CPT 62380 when billed without one of the listed diagnosis will be denied as an investigational denial based on Regence Medical Policy Automated Percutaneous and Percutaneous Endoscopic Discectomy

Surgical Site of Care - Hospital Outpatient

- Pre-authorization is required on codes 10060, 10061, 10080, 10081, 10120, 10121, 10140, 10160, 10180, 11000, 11010, 11012, 11042, 11044, 11200, 11310, 11402, 11403, 11404, 11406, 11420, 11421, 11422, 11423, 11424, 11426, 11440, 11441, 11442, 11443, 11444, 11446, 11450, 11451, 11462, 11463, 11470, 11471, 11601, 11602, 11603, 11604, 11606, 11620, 11621, 11622, 11623, 11624, 11626, 11640, 11641, 11642, 11643, 11644, 11646, 11730, 11750, 11755, 11760, 11765, 11770, 11772, 11900, 12001, 12002, 12011, 12020, 12031, 12032, 12034, 12035, 12037, 12041, 12042, 12051, 13120, 13121, 13131, 13132, 13151, 13152, 13160, 14020, 14040, 14060, 15120, 15220, 15240, 15760, 15851, 17000, 17110, 17111, 17311, 17313, 19020, 19101, 19110, 19112, 19120, 19125, 20200, 20205, 20220, 20225, 20240, 20520, 20525, 20670, 20680, 20693, 20694, 20912, 21011, 21012, 21013, 21014, 21029, 21030, 21031, 21040, 21046, 21048, 21315, 21320, 21325, 21330, 21335, 21336, 21337, 21356, 21550, 21552, 21554, 21555, 21556, 21557, 21920, 21930, 21931, 21932, 22900, 22901, 22902, 22903, 23030, 23071, 23075, 23140, 23150, 23415, 23450, 23460, 23465, 23515, 23550, 23615, 23630, 23655, 23665, 24000, 24006, 24065, 24066, 24071, 24073, 24075, 24076, 24101, 24105, 24110, 24120, 24130, 24147, 24200, 24201, 24305, 24340, 24341, 24342, 24343, 24345, 24346, 24357, 24358, 24359, 24366, 24505, 24516, 24530, 24538, 24545, 24546, 24575, 24579, 24586, 24605, 24620, 24635, 24655, 24665, 24666, 24685, 25000, 25071, 25073, 25075, 25076, 25085, 25107, 25109, 25111, 25112, 25118, 25120, 25130, 25210, 25215, 25240, 25260, 25270, 25280, 25290, 25295, 25310, 25320, 25350, 25360, 25390, 25447, 25505, 25515, 25545, 25565, 25574, 25575, 25600, 25605, 25606, 25607, 25608, 25609, 25628, 25645, 25652, 25825, 26011, 26020, 26055, 26070, 26080, 26105, 26110, 26111, 26113, 26115, 26121, 26123, 26145, 26160, 26180, 26200, 26210, 26236, 26320, 26340, 26350, 26356, 26357, 26370, 26410, 26418, 26426, 26432, 26433, 26440, 26445, 26480, 26500, 26516, 26520, 26525, 26530, 26540, 26541, 26542, 26608, 26615, 26650, 26665, 26676, 26725, 26727, 26735, 26746, 26756, 26765, 26785, 26841, 26850, 26860, 26862, 26951, 26952, 27006, 27043, 27045, 27047, 27048, 27062, 27310, 27323, 27324, 27327, 27328, 27329, 27335, 27337, 27339, 27340, 27345, 27347, 27424, 27605, 27606, 27612, 27613, 27614, 27618, 27620, 27625, 27626, 27632, 27634, 27638, 27640, 27650, 27652, 27654, 27659, 27675, 27676, 27680, 27685, 27687, 27690, 27691, 27695, 27696, 27698, 27705, 27720, 27752, 27762, 27766, 27769, 27781, 27784, 27786, 27788, 27792, 27810, 27814, 27818, 27822, 27823, 27840, 28002, 28005,

28008, 28010, 28011, 28022, 28035, 28039, 28041, 28043, 28045, 28047, 28060, 28062, 28080, 28086, 28090, 28092, 28100, 28103, 28104, 28110, 28112, 28113, 28116, 28118, 28119, 28120, 28122, 28124, 28126, 28160, 28190, 28192, 28200, 28208, 28230, 28232, 28234, 28238, 28250, 28270, 28272, 28285, 28288, 28289, 28291, 28292, 28295, 28296, 28297, 28298, 28299, 28300, 28304, 28306, 28308, 28310, 28313, 28315, 28322, 28415, 28445, 28465, 28475, 28476, 28485, 28505, 28515, 28525, 28555, 28585, 28615, 28645, 28666, 28715, 28725, 28740, 28750, 28755, 28810, 28820, 28825, 29834, 29835, 29837, 29838, 29844, 29846, 29848, 29900, 29901, 30000, 30020, 30100, 30110, 30115, 30117, 30118, 30130, 30140, 30220, 30310, 30520, 30580, 30630, 30801, 30802, 30901, 30903, 30930, 31020, 31030, 31032, 31200, 31205, 31525, 31238, 31526, 31528, 31529, 31530, 31535, 31536, 31540, 31541, 31545, 31570, 31571, 31574, 31575, 31576, 31578, 31591, 31611, 31622, 31623, 31624, 31625, 31628, 31652, 31820, 32408, 32555, 32557, 36010, 36215, 36246, 36556, 36569, 36571, 36581, 36582, 36589, 36590, 37607, 38221, 38222, 38500, 38505, 38510, 38520, 38525, 38740, 38760, 40490, 40510, 40520, 40525, 40530, 40808, 40810, 40812, 40814, 40816, 41010, 41100, 41105, 41108, 41110, 41112, 41113, 41116, 42100, 42104, 42106, 42330, 42335, 42405, 42408, 42410, 42415, 42420, 42425, 42440, 42450, 42500, 42650, 42800, 42804, 42808, 42810, 42821, 42826, 42831, 42870, 43191, 43195, 43197, 43211, 43212, 43213, 43214, 43215, 43216, 43217, 43220, 43226, 43227, 43229, 43231, 43232, 43233, 43240, 43241, 43243, 43244, 43245, 43246, 43247, 43248, 43249, 43250, 43251, 43253, 43254, 43260, 43261, 43266, 43270, 43450, 43453, 44340, 44360, 44361, 44364, 44369, 44376, 44377, 44380, 44381, 44382, 44385, 44386, 44388, 44389, 44391, 44392, 44394, 44408, 45100, 45171, 45172, 45190, 45305, 45330, 45331, 45332, 45333, 45334, 45335, 45337, 45338, 45340, 45341, 45342, 45346, 45347, 45349, 45350, 45378, 45379, 45380, 45381, 45382, 45384, 45385, 45386, 45388, 45389, 45390, 45391, 45392, 45393, 45398, 45505, 45541, 45560, 45905, 45910, 45915, 45990, 46020, 46030, 46040, 46045, 46050, 46060, 46080, 46083, 46200, 46220, 46221, 46230, 46250, 46255, 46257, 46258, 46260, 46261, 46262, 46270, 46275, 46280, 46285, 46288, 46320, 46606, 46607, 46610, 46612, 46615, 46700, 46750, 46910, 46917, 46922, 46924, 46930, 46940, 46945, 46946, 47000, 49082, 49083, 49422, 49500, 49505, 49507, 49520, 49521, 49525, 49550, 49553, 49650, 49651, 49900, 50435, 50575, 50590, 50688, 51040, 51102, 51600, 51610, 51702, 51710, 51715, 51720, 51726, 51728, 51729, 52000, 52001, 52005, 52007, 52204, 52214, 52224, 52234, 52235, 52240, 52260, 52265, 52275, 52276, 52281, 52282, 52283, 52285, 52287, 52300, 52310, 52315, 52317, 52318, 52320, 52325, 52327, 52330, 52332, 52341, 52344, 52351, 52352, 52353, 52354, 52356, 52450, 52500, 52601, 52630, 52640, 53020, 53200, 53230, 53260, 53265, 53270, 53440, 53445, 53450, 53500, 53605, 53665, 54001, 54055, 54057, 54060, 54065, 54100, 54110, 54150, 54161, 54162, 54163, 54164, 54300, 54450, 54512, 54530, 54600, 54620, 54640, 54700, 54830, 54840, 54860, 55000, 55040, 55041, 55060, 55100, 55110, 55120, 55250, 55400, 55500, 55520, 55540, 55700, 56405, 56420, 56440, 56441, 56442, 56501, 56515, 56605, 56620, 56700, 56740, 56810, 56821, 57000, 57061, 57065, 57100, 57130, 57135, 57210, 57240, 57250, 57260, 57268, 57282, 57283, 57287, 57300, 57400, 57410, 57415, 57420, 57421, 57425, 57452, 57454, 57456, 57461, 57500, 57505, 57510, 57513, 57520, 57522, 57530, 57700, 57720,

- **NOTE**: Pre-authorization is not required when procedures performed in an ambulatory surgery center, physician office, or emergency facility for urgent services or when the member is age 17 or younger
- If faxing a pre-authorization for these services, submit the Surgical Site of Care Additional Information Form (PDF) with the Medical Services (PDF) pre-authorization request form.

Surgical Treatments for Hyperhidrosis (PDF)

- 32664, 64818, 69676
- Code 32664 only requires pre-authorization for hyperhidrosis diagnoses L74.510 L74.511, L74.512, L74.513, L74.519, L74.52, R61

Surgical Treatments for Lymphedema and Lipedema (PDF)

- Code 15832, 15833, 15834, 15835, 15836, 15837, 15838, 15839, 15876, 15877, 15878, 15879 requires pre-authorization for Lipedema only with diagnosis codes Q82.0, R60.0, R60.9

Sleep Apnea Diagnosis and Treatment

- UMP is subject to HTCC Decision (PDF): 21121, 21122, 21141, 21145, 21196, 21198, 21199, 21685, 41120, 42140, 42145, 42160
- Codes 21145, 21196, 21198, 41120, 42160 do not require pre-authorization when the procedure is performed for oral cancer diagnosis codes: C01, C02-C02.9, C03-C03.9, C04-C04.9, C05-C05.9, C06, C06.2-C06.9, C09-C09.9, C10-C10.0, C41-C41.1, C46.2, D00-D00.00, D10, D10.1-D10.9, D16.4-D16.5, D37-D37.0, D49-D49.0
- HTCC does not apply to those under age 18. See Regence medical policy Surgeries for Snoring, Obstructive Sleep Apnea Syndrome, and Upper Airway Resistance Syndrome (PDF)

Temporomandibular Joint (TMJ) Surgical Interventions

- Visit MCG's website for information on purchasing their criteria, or contact us for a copy of the specific guideline.
- 21010 - MCG A-0522
- 21050 - MCG A-0523
- 29800, 29804 - MCG A-0492
- 21240, 21242, 21243 - MCG A-0523

Transcatheter Aortic-Valve Implantation for Aortic Stenosis (PDF)

- 33361, 33362, 33363, 33364, 33365, 33366

Transcatheter Heart Valve Procedures for Mitral or Tricuspid Valve Disorders excluding Transcatheter Edge-to-Edge Repair (TEER) (PDF)

- 0483T, 0484T

Transcutaneous Bone Conduction and Bone-Anchored Hearing Aids (PDF)

- 69714, 69710, 69716, 69717, 69719, 69726, 69729, 69730, L8690, L8691, L8692, L8694

Transesophageal Endoscopic Therapies for Gastroesophageal Reflux Disease (GERD) (PDF)

- 43192, 43201, 43236
- **Note**: Codes 43201 and 43236 may also be used for the administration of Botox for indications unrelated to GERD. Botox requires pre-authorization by Regence. Learn more about submitting a pre-authorization request for Boxtox.

Upper Endoscopy for Gastroesophageal Reflux Disease (GERD) and Gastrointestinal (GI) Symptoms

- Upper Endoscopy for GERD and GI Symptoms for UMP members are subject to HTCC Decision (PDF)
- CPT 43200, 43202, 43235, 43237, 43238, 43239, 43242 and 43259 do not require pre-authorization, but may be subject to HTCC Decision and require a provider attestation
- Attestation is needed for timely and accurate processing of claims for adults (members 18 years and older):
    - Use the electronic authorization tool on Availity Essentials and select the attestation criteria during the clinical documentation process on MCG Health
    - If an attestation is not completed pre-service using the Availity tool, fax the completed attestation form (PDF) to 1 (877) 357-3418.

Vagus Nerve Stimulation (PDF)

- 0720T, 61885, 61886, 64553, 64568, 64569, C1822, E0735, L8679, L8680, L8682, L8683, L8685, L8686, L8687, L8688, C1827
- UMP is subject to HTCC Decision (PDF): for treatment of epilepsy and depression: 0720T, 61885, 61886, 64553, 64568, C1822, E0735, L8679, L8680, L8682, L8683, L8685, L8686, L8687, L8688, C1827
- If treatment is for other than these indications, Regence medical policy applies.

- The HTCC does not apply to members under age 4. Please use Regence Medical Policy for requests for members under age 4.

Varicose Vein Treatment (PDF)

- UMP is subject to HTCC Decision (PDF): 0524T, 36465, 36466, 36470, 36471, 36475, 36476, 36478, 36479, 36482, 36483, 37700, 37718, 37722, 37735, 37760, 37761, 37765, 37766, 37780, 37785, S2202
- Notes:
    - Requests for multiple treatment sessions should refer to Regence medical policy
    - Code 37241 is not appropriate to use in the coding of varicose vein treatment

Transplants and ventricular assist devices

Transplants - Cell

- 38205, 38206, 38232, 38240, 38241, 38242, S2140, S2142, S2150
- Stem Cell Therapy for Musculoskeletal Condition is subject to HTCC Decision (PDF) criteria: 38205, 38206, 38212, 38215, 38230, 38232, 38240, 38241
- Regence medical policy criteria will be used for codes and conditions not reviewed by the HTCC criteria

Transplants - Islet Transplantation (PDF)

- 48160, 0584T, 0585T, 0586T, G0341, G0342, G0343

Transplants - Heart (PDF)

- 33945

Transplants - Heart-Lung (PDF)

- 33935

Transplants - Lung and Lobar Lung (PDF)

- 32851, 32852, 32853, 32854, S2060

Transplants - Small Bowel, Small Bowel/Liver, and Multivisceral Transplant (PDF)

- 44135, 44136, 47135, 48554, S2053, S2054, S2152

Transplants - Liver Transplant (PDF)

- 47135

Transplants - Pancreas Transplant (PDF)

- 48554, S2065, S2152

Ventricular Assist Devices and Total Artificial Hearts (PDF)

- 33927, 33928, 33929, 33975, 33976, 33977, 33978, 33979, L8698

Utilization management

Air Ambulance Transport (PDF)

- A0435, A0430, S9960
- Pre-authorization is required prior to elective fixed wing air ambulance transport.
- Emergency air ambulance transports may be reviewed retrospectively for medical necessity.
- **Effective July 1, 2025: HCPCS codes A0431, A0436, S9961 will be reviewed post-service**

Clinical Edits by Code List
Complete List
Applies to Uniform Medical Plan (UMP)

Based on Medical Policy, potential investigational codes may be denied as Investigational (member liability) or not medically necessary (provider liability).

****In addition, some cosmetic codes may be denied as cosmetic (member liability) or not medically necessary (provider liability).****

Code	Description	Edit Type	Comment
0001F	Heart Failure Composite	Non-Reimbursable Services	Not considered a payable service. Will be denied provider write-off.
0002M	ASH FibroSURE LapCorp	Investigational Denial	Always considered investigational; investigational services are denied member liability.
0002U	measure of subst in urine to predict polyps large intestine	Investigational Denial	Always considered investigational; investigational services are denied member liability.
0003M	NASH FibroSURE LapCorp	Investigational Denial	Always considered investigational; investigational services are denied member liability.

ABA Concurrent Request

Original start date of ABA: _____. Current Authorization Number: _____.

Expedited request ☐
Defined as: when the member or his/her provider believes that waiting for a decision within the standard timeframe could place the member's life, health, or ability to regain maximum function in serious jeopardy.
Explanation required:

Note: There is very little evidence to support the efficacy of ABA for people 13 years and older. If you are requesting ABA for someone 13 or older, please provide additional justification for this (e.g., severe risk of injury to self or others related to ASD or self-injurious stereotypical movement disorder).

Clinical updates and progress:

Documentation:

Please include a completed Individualized Treatment Plan (ITP) with your request that includes:

1. A detailed description of specific behaviors targeted for therapy. Targeted behaviors must be those which prevent the member from participating in age-appropriate home or community activities and/or are presenting a safety risk to self or others; and
2. For each targeted behavior, an objective baseline measurement using standardized instruments that include frequency, intensity, and duration; and
3. A detailed description of treatment interventions and techniques specific to each of the targeted behaviors, including the frequency and duration of treatment for each intervention which is designed to improve the member's ability to participate in age-appropriate home or community activities and/or reduce the safety risk to self or others; and
4. Where there was a prior course of ABA therapy, documentation will specify the anticipated benefit of an additional course of treatment; and
5. A description of training and participation of family (parents, legal guardians and/or active caretakers as appropriate) in setting baseline and demonstrating progress toward treatment goals that directly support member's ITP; and
6. Clinical justification for the number of days per week and hours per day of direct ABA services provided to the member and the family, and the hours per week of direct face-to-face supervision of the treatment being delivered and observation of the child in their natural setting; and
7. Individualized and measurable discharge and/or transition criteria.

☐ Please include data on targeted behaviors and information regarding how the treatment plan is address these targeted behaviors. Please include details such as most recent treatment plan updates.

☐ Please indicate progress toward each of the defined goals in the ITP. Please document progress as it relates to each of the targeted behaviors on the ITP.

☐ Objective measurements using standardized instruments that include frequency, intensity, and duration and evaluation. Please include details such as dates, measurements used, and scores.

Request Details

Authorization start date: _____.

- Please note that the below CPT codes are the Regence approved CPT codes for ABA services.
- Authorizations are for 6 months (26 weeks).
- Please list requested units for 6 months. Each unit is for 15 minutes.
  Example: Services for 97153 are provided for 10 hours per week. This would total 40 units per week and 1040 units per 6 months (26 weeks).
- Place of Service (i.e.: home, school, specify other setting).

  School is not an approved/eligible POS for Federal Employee Program (FEP) policies.

Extenuating Circumstances

This policy is modeled after the Best Practice Recommendations that support Washington State Senate Bill 5346 and regulatory requirements of WAC 284-43-2060.

This policy and process is applicable to all plans issued or renewed on or after January 1, 2018 by Regence with exception of Extenuating Circumstances Criteria #7 below. *Extenuating Circumstances criteria # 7 is applicable to plans issued on or after January 1, 2018 by Regence in WA State only excluding Medicare Advantage and FEP.

This policy does not apply to prescription drug services.

Overview

Obtaining required pre-authorization prior to service delivery is the optimal practice to mitigate provider and member financial risk, however several extenuating circumstances may make it impossible, before treating the member, to obtain a prior authorization.

Claims will not be administratively denied for lack of prior authorization so long as we are contacted before the claim is submitted, the specific extenuating circumstance is documented (suggested supporting documentation is outlined below) and such circumstance meets at least one of the Extenuating Circumstances criteria outlined below. If we are contacted after the claim is submitted, the administrative denial may be disputed as an extenuating circumstance via the appeal process if the specific extenuating circumstance is documented, as noted above, and such circumstance meets at least one of the Extenuating Circumstances criteria outlined below.

NOTE: If we are contacted after the claim is submitted but still in process, the administrative denial on the claim must be disputed via the appeal process post claim denial. We are unable to stop claims processing.

In addition, even if the service(s) meet the below Extenuating Circumstances criteria, we will still review for appropriateness, level of care, medical necessity and benefit coverage under the criteria for the applicable plan based on the information available to the provider or facility at the time of treatment.

The criteria and procedures that participating providers and facilities must follow to notify Regence of an extenuating circumstance pre-claim submission or to dispute a claim denied for no pre-authorization are outlined below.

Extenuating Circumstances Criteria

The following seven exceptions to obtaining pre-authorization may qualify as an Extenuating Circumstance:

1. **Member presented with an incorrect member ID card or member number or indicated they were self-pay, and that no coverage was in place at the time of treatment, or the participating provider or facility is unable to identify from which**

carrier or its designated or contracted representative to request a pre-authorization.

Examples:

- The provider verified that no medical coverage was in place at time of treatment. It was later determined that medical coverage was in place. In some cases, patients prefer to pay out of pocket rather than initiate COBRA coverage and pay the ongoing premium. However, a second care encounter could change the patient's mind and COBRA coverage would be initiated retroactively to the beginning to the month, thus providing coverage for a treatment that has already been delivered.
- The provider asked the patient about current coverage prior to the service, the patient provided current insurance coverage information and the provider verified that the coverage was in force at time of treatment. After the patient was treated, it was discovered that another health plan takes precedent and is responsible for coverage.
- Coverage retrospectively determined to not be related to an accident or work-related injury. During the scheduling process, these patients indicate that their condition is accident related. During or after treatment, the provider discovers that the service is not accident/work related.
- Other primary insurance retrospectively discovered: Coverage for these patients is verified with the health plan of record prior to treatment and any pre-authorization/admission notification requirements are met. After the patient is treated, the provider is notified that another health plan is primary. Two examples: a. Before treatment, Department of Social and Health Services (DSHS) benefits are verified with no other insurance on file at that time. Later, DSHS notifies the provider that commercial coverage was in place. b. Before treatment, the patient's father's health plan verifies eligibility. Later, the health plan notifies the provider that the other parent has coverage and that coverage is primary.

This DOES NOT INCLUDE when the provider could communicate with the member prior to giving treatment, but insurance coverage information was not obtained and/or was not verified prior to the service(s). This situation is not an extenuating circumstance. The normal prior authorization and/or admission notification practices are to be followed.

Note to Providers: Best practice is verifying that current insurance information is on file, which can help reduce the number of 'Unable to Know Coverage' situations. Each time a patient is seen, providers should obtain comprehensive coverage information from the guarantor/member.

2. Natural disaster prevented the provider or facility from securing a pre-authorization or providing hospital admission notification.

3. Member is unable to communicate (e.g., unconscious) medical insurance coverage. Neither family nor collateral support present can provide coverage information.

Examples:

- Trauma or unresponsive patients: These patients are usually brought in via 911 with no family, no id etc. – may be admitted as Jane/John Doe.

- Psychiatric patients: These patients are admitted through the Emergency Department for clinical conditions related to cognitive impairment.
- Child not attended by parent: These patients are children who need immediate medical attention and are brought in by someone other than their parents, e.g. babysitter, grandparent, etc.
- Non-English speaking patients: These patients don't speak English and a translator cannot be obtained in a timely manner.

4. Compelling evidence the provider attempted to obtain pre-authorization. The evidence shall support the provider followed our policy and that the required information was entered correctly by the provider office into the appropriate system.

Note: A copy of the faxed pre-authorization request showing the information was entered correctly indicating the member health plan information and a fax confirmation from the fax machine showing the fax was successfully sent to the appropriate health plan fax number will be considered compelling evidence.

5. A surgery which requires pre-authorization occurs in an urgent/emergent situation. Services are subject to review post-service for medical necessity

6. A participating provider or facility is unable to anticipate the need for a pre-authorization before or while performing a service or surgery.

These are situations where immediate or very-near-term medical services are required that are typically related to a service already being performed, e.g., diagnostic, office visit, surgery. Prior authorization is not completed prior to service delivery. (Note: These situations are only extenuating circumstances related to a prior authorization and do not prevent a provider from notifying the health plan about an admission within the specified time period, e.g., 24 hours.)

Examples:

- Patient is seen in a physician's office and the physician determines there is an acute and immediate need for diagnostic imaging or a hospital admission.
- Patient is undergoing a procedure which may or may not require pre-authorization. Once the procedure begins, it evolves into a different/additional/more complex procedure or identifies the need for an add-on surgery/procedure, which is often scheduled for the same day or late in the afternoon/evening for the next morning.

This DOES NOT INCLUDE when the provider performs a procedure or provides a service that is considered experimental or investigational where a health plan denial of coverage would result in patient financial responsibility.

An extenuating circumstance DOES NOT APPLY when the service or services occur during an office visit solely for the convenience of the provider.

***7. An enrollee is discharged from a facility and insufficient time exists for institutional or home health care services to receive approval prior to delivery of the service. *NOTE: This criteria is only applicable to plans issued on or after January 1, 2018 by Regence in WA State only excluding Medicare Advantage and FEP.**

Regence

Regence BlueCross BlueShield of Oregon is an Independent Licensee of the Blue Cross and Blue Shield Association

Notifying Regence About an Extenuating Circumstance

Pre-Claim Submission

Please note that if you are submitting an extenuating circumstance request for a member who has discharged from your facility that you submit the request with your claim for processing.

Call the **Provider Contact Center** to notify us of an extenuating circumstance

The following may be requested:

Member name, DOB, ID #

Provider name and ID

Date of Service

Description of extenuating circumstance that was present

Supporting documentation of the extenuating circumstance will be requested to be faxed to (866) 273-1820.

Suggested supporting documentation is outlined below.

Notification of an extenuating circumstance may also be faxed directly to (866) 273-1820 and must include ALL the following:

Member Name, DOB and ID

Provider name and ID

Date of Service

CPT codes

Description of extenuating circumstance that was present

Fax cover sheet should include “Extenuating Circumstance” in subject line:

Return Fax #

Supporting documentation (suggested documentation is outlined below)

Note: Claims submitted prior to receiving a written response from Regence regarding the extenuating circumstance request may be subject to the administrative denial.

Post Claim Administrative Denial

Use the adverse determination appeal form (PDF) to dispute a claim that has denied for no pre-authorization. Please complete the form and follow the instructions outlined in the section that applies to ‘Denials for Pre-authorization not obtained’.

Regence

Regence BlueCross BlueShield of Oregon is an Independent Licensee of the Blue Cross and Blue Shield Association

Please fax the completed form and all extenuating circumstance supporting documentation as applicable to: (866) 273-1820.

Suggested supporting documentation is outlined below.

Extenuating Circumstance Supporting Documentation

Submit the following documentation to support an extenuating circumstance as applicable:

Dated documentation, e.g. admission face sheet, obtained at the time of service indicating: The insurance information provided by the patient/representative or the patient's/representative's inability to provide insurance information or the patient's/representative's reporting self-pay.

Verification of no coverage such as Availity screenshot at the time of inquiry (though eligibility at date of service was later confirmed).

Dated documentation obtained at time of service showing eligibility confirmation from another payer, e.g. web eligibility screen shot or copy of electronic eligibility confirmation, AND/OR that payer's EOB denying the service as not eligible for coverage (e.g. denied due to alternate primary coverage).

Applicable office visit chart notes for either the date of service or the referral along with other clinical documentation (as needed), e.g. diagnosis, H & P, failed alternative treatment(s), or interim/alternative treatment(s) as appropriate, indicating the medical necessity for the procedure and the rationale for providing the procedure at that time without prior authorization, i.e. procedure is time sensitive or emergent.

A copy of the faxed pre-authorization request showing the information was entered correctly indicating the member health plan information and a fax confirmation from the fax machine showing the fax was successfully sent to the appropriate health plan fax number.

Any other documentation felt to support an extenuating circumstance was present.

Note: Submission of the above referenced documentation does not guarantee payment. Even if the Extenuating Circumstance criteria applies, the service is subject to benefit coverage and medical necessity under post service review.

SECTION 4 – DOCUMENTATION SUBMISSION

Submit the following documentation, as appropriate, with this request:

- Signed copy of prescription
- Invoice with pricing

  AND
- Specific clinical documentation as outlined in the associated Regence Medical Policy, Policy Guidelines section

  OR
- Specific clinical information documenting the applicable Medicare, or BCBS FEP medical necessity criteria, **including:**
  - History and physical
  - Lab/Radiology/Testing results
  - Current symptoms and functional impairment
  - Treatment history and any other information such as chart notes that support medical necessity for the request

Any other supporting documents you would like considered, such as letters from outpatient providers, etc.

Medical Policy Manual Genetic Testing, Policy No. 01

Genetic Testing for Alzheimer's Disease

Effective: April 1, 2024

Next Review: February 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genetic testing has been investigated as an aid in the diagnosis of patients presenting with symptoms suggestive of Alzheimer's disease (AD), or as a technique for risk assessment in asymptomatic patients with a family history of AD.

MEDICAL POLICY CRITERIA

I. Genetic testing for variants in presenilin genes (*PSEN*) or amyloid-beta precursor protein gene (*APP*) associated with autosomal dominant Alzheimer's disease may be considered **medically necessary** for an asymptomatic individual when either of the following criteria are met:

   A. Targeted genetic testing for a known familial variant when the individual has a first- or second-degree relative (see Policy Guidelines) with a known familial variant AND the results of testing will be used to inform reproductive decision-making; OR

   B. The individual has a family history of dementia consistent with autosomal dominant Alzheimer's disease (three or more affected members in two generations) for whom the genetic status of the affected family members is unavailable, AND the results of testing will be used to inform reproductive decision-making.

II. Genetic testing for risk assessment or in the evaluation of dementia or Alzheimer's disease is considered **investigational** for all other indications and when Criterion I is not met**.** Genetic testing includes, but is not limited to, testing for the apolipoprotein E (*APOE*) epsilon 4 allele, presenilin (*PSEN*) genes, amyloid precursor protein (*APP*) gene, or triggering receptor expressed on myeloid cells 2 (*TREM2*) gene.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

First-degree relatives are parents, siblings, and children of an individual; second-degree *relatives* are grandparents, aunts, uncles, nieces, nephews, grandchildren.

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
   - History and physical exam including any relevant diagnoses related to the genetic testing
   - Conventional testing and outcomes
   - Conservative treatments, if any

BACKGROUND

Alzheimer's disease (AD) is the most common form of dementia. In 2020, as many as 5.8 million Americans were living with AD, and by 2060 this number is projected to rise to 14 million.[1] Although scientist don't fully understand the cause of AD, it is diagnosed based on a clinical-neuropathologic assessment, and age and a family history are the best known risk factors. The symptoms of AD most commonly appear after the age of 60, known as late-onset AD; however, AD can be found in younger people, known as early-onset AD. Researchers believe genetics may play a role in the development of AD in patients who have a family history, or in the risk assessment or management of asymptomatic patients with a family history of AD.

GENETIC VARIANTS

Individuals with early onset familial AD (i.e., before age 65, but as early as 30 years) form a small subset of AD patients. AD within families of these patients may show an autosomal dominant pattern of inheritance. Pathogenic mutations in three genes have been identified in affected families: amyloid-beta precursor protein gene (*APP*), presenilin 1 (*PSEN1*) gene, and presenilin 2 (*PSEN*2) gene. *APP* and *PSEN1* pathogenic variants have 100% penetrance absent death from other causes, while *PSEN*2 has 95% penetrance. A variety of variants within these genes has been associated with AD; variants in *PSEN1* appear to be the most common. While only 3%–5% of all patients with AD have early onset disease, pathogenic variants have been identified in up to 70% or more of these patients. Identifiable genetic variants are, therefore, rare causes of AD.

Testing for the apolipoprotein E (*APOE*) 4 allele among patients with late-onset AD and for *APP*, *PSEN1*, or *PSEN*2 variants in the rare patient with early onset AD have been investigated as an aid in diagnosis in patients presenting with symptoms suggestive of AD, or a technique for risk assessment in asymptomatic patients with a family history of AD. Pathogenic variants in *PSEN1* and *PSEN*2 are specific for AD; *APP* variants are also found in cerebral hemorrhagic amyloidosis of the Dutch type, a disease in which dementia and brain amyloid plaques are uncommon

The apolipoprotein E (*APOE*) lipoprotein is a carrier of cholesterol produced in the liver and brain glial cells. The *APOE* gene has three alleles—ε2, 3, and 4—with the ε3 allele being the most common. Individuals carry two *APOE* alleles. The presence of at least one ε4 allele is associated with a 1.2- to 3-fold increased risk of AD depending on the ethnic group. The correlation between *APOE* and AD in African-American, Hispanic populations is not as strong as is seen in white populations, despite higher rates of AD than white populations in both groups.[2] Among those homozygous for ε4 (about 2% of the population), the risk of AD is higher than for those heterozygous for ε4. The mean age of onset of AD is about 68 years for ε4 homozygotes, about 77 years for heterozygotes, and about 85 years for those with no ε4 alleles. About half of patients with sporadic AD carry an ε4 allele. However, not all patients with the allele develop AD. The ε4 allele represents a risk factor for AD rather than a disease-causing variant. In the absence of *APOE* testing, first-degree relatives of an individual with sporadic or familial AD are estimated to have a two- to four-fold greater risk of developing AD than the general population.[3] There is evidence of possible interactions between ε4 alleles, other risk factors for AD (e.g., risk factors for cerebrovascular disease such as smoking, hypertension, hypercholesterolemia, and diabetes[4]), and a higher risk of developing AD. However, it is not clear that all risk factors have been taken into account in such studies, including the presence of polymorphisms in other genes that may increase the risk of AD.

Studies have also identified rs75932628-T, a rare functional substitution for R47H of *TREM2*, as a heterozygous risk variant for late-onset AD.[5, 6] On chromosome 6p21.1, at position 47 (R47H), the T allele of rs75932628 encodes a histidine substitute for arginine in the gene that encodes *TREM2*.

TREM2 is highly expressed in the brain and is known to have a role in regulating inflammation and phagocytosis. *TREM2* may serve a protective role in the brain by suppressing inflammation and clearing it of cell debris, amyloids and toxic products. A decrease in the function of *TREM2* would allow inflammation in the brain to increase and may be a factor in the development of AD. The effect size of the *TREM2* variant confers a risk of AD that is similar to the *APOE* ε4 allele, although it occurs less frequently.

Biomarker evidence has been integrated into the diagnostic criteria for probable and possible AD for use in research settings.[7] Other proposed diagnostic tests for AD include cerebrospinal (CSF) fluid levels of Tau protein or beta-amyloid precursor protein. These CSF tests are addressed in a separate medical policy (see Cross References).

REGULATORY STATUS

No U.S. Food and Drug Administration (FDA)-cleared genotyping tests were found. The FDA has not regulated these tests to date. Thus, genotyping is offered as a laboratory-developed test. Clinical laboratories may develop and validate tests in-house ("home-brew") and market them as a laboratory service. Such tests must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). The laboratory offering the service must be licensed by CLIA for high-complexity testing.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[8] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

- The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
- The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
- The clinical utility of the test, which describes how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

This evidence review focuses on clinical validity and utility.

GENETIC TESTING FOR LATE-ONSET ALZHEIMER DISEASE

Clinical Validity

The advances in genetic understanding of AD have been considerable, with associations between late-onset AD and more than 20 non-*APOE* genes suggested.[9]

Naj (2014) published a genome-wide association study of multiple genetic loci in late-onset AD.[10] Genetic data from 9,162 Caucasian participants with AD from the Alzheimer Disease Genetics Consortium were assessed for polymorphisms at 10 loci significantly associated with risk of late-onset AD. Analysis confirmed the association of *APOE* with an earlier age of onset and found significant associations for *CR1*, *BIN1*, and *PICALM*. *APOE* contributed 3.7% of the variation in age of onset and the other nine loci combined contributed 2.2% of the variation. Each additional copy of the *APOE* ε4 allele reduced age of onset by 2.45 years.

Lambert (2013) published a large meta-analysis of GWAS of susceptibility loci for late-onset AD in 17,008 AD cases and 37,154 controls of European ancestry.[11] Nineteen loci had genome-wide significance in addition to the *APOE* locus. The researchers confirmed several genes already reported to be associated with AD (*ABCA7*, *BIN1*, *CD33*, *CLU*, *CR1*, *CD2AP*, *EPHA1*, *MS4A6A–MS4A4E*, *PICALM*). New loci located included *HLA-DRB5–HLA-DRB1*, *PTK2B*, *SORL1*, and *SLC24A4-RIN3*.

Susceptibility Testing at the Apolipoprotein E Gene

Many studies have examined the association between the apolipoprotein ε4 allele (*APOE*E4*) and AD. The Rotterdam and Framingham studies are both examples of large observational studies demonstrating the association. The Rotterdam Study was a prospective cohort study in the city of Rotterdam, the Netherlands, with main objectives of investigating risk factors of cardiovascular, neurologic, ophthalmologic, and endocrine diseases in the elderly.[12] In a sample of 6,852 participants, carriers of a single ε4 allele had a relative risk (RR) of developing AD approximately double that of ε3/ε3 carriers. Carriers of the two ε4 alleles had a relative risk of developing dementia approximately eight times that of ε3/ε3 carriers. The Framingham Heart Study was a longitudinal cohort study initiated in 1948 in Framingham, Massachusetts, to identify common risk factors for cardiovascular disease.[13] In 1,030 participants, the relative risk for developing AD was 3.7 (95% confidence interval [CI] 1.9 to 7.5) for carriers of a single ε4 allele and 30.1 (95% CI 10.7 to 84.4) for carriers with two ε4 alleles compared to those without an ε4 allele. The association of the *APOE* ε4 allele with AD is significant; however, *APOE* genotyping does not have high specificity or sensitivity, and is of little value in the predictive testing of asymptomatic individuals.[14]

The American College of Medical Genetics and Genomics has concluded that *APOE* genotyping for AD risk prediction has limited clinical utility and poor predictive value.[15]

The association of *APOE* genotype with response to AD therapy has been examined. Exploratory analyses of pooled safety data from two phase 3 trials of the FDA-approved amyloid-beta targeting therapy aducanumab indicate that APOE ε4 carrier status is associated with a higher incidence of amyloid-related imaging abnormalities (ARIA).[16-18] Specifically, the incidence of ARIA-edema was 43% versus 20%, in APOE ε4 carriers and non-carriers receiving a 10 mg/kg dose of aducanumab, respectively. The overall incidence of any ARIA ranged from 36-41% in the treatment group compared to 10.3% in the placebo group. The clinical effects of ARIA range from asymptomatic to severe. Although the majority of patients were asymptomatic or had symptoms such as headache, confusion, or dizziness that resolved with temporary stoppage of the drug, 6.2% of participants receiving the high dose of aducanumab discontinued the drug due to ARIA compared to 0.6% in the placebo arm.

The majority of ARIA-edema radiographic events occurred early in treatment (within the first 8 doses), although ARIA can occur at any time. Among patients treated with a planned dose of aducanumab 10 mg/kg who had ARIA-edema, the maximum radiographic severity was mild in 30%, moderate in 58%, and severe in 13% of patients (refer to prescribing label for classification of severity of ARIA). Resolution occurred in 68% of ARIA-edema patients by 12 weeks, 91% by 20 weeks, and 98% overall after detection. Ten percent of all patients who received aducanumab 10 mg/kg had more than 1 episode of ARIA-edema. Radiographic severity and symptomatic status were similar for APOE ε4 carriers and non-carriers.

Aducanumab dosing management decisions in the trials were based on clinical symptom severity and ARIA severity on MRI.[17] After radiographic resolution of ARIA-edema or stabilization of ARIA-hemorrhage and resolution of symptoms (if present), participants could resume dosing at the same dose and titration schedule. Limited follow-up data are available for the safety analysis because the phase 3 trials were stopped prematurely for futility.

The USA-1 Study group found *APOE* genotype did not predict therapeutic response.[19] Rigaud (2002) followed 117 individuals with AD over 36 weeks in an open-label trial of donepezil; 80 (68%) completed the trial.[20] They found no statistically significant effect of *APOE* genotype on change in cognition (assessed by Cognitive subscale of the Alzheimer's Disease Assessment Scale). However, the study was not designed to examine predictive therapeutic response, and there were baseline cognitive differences according to *APOE* genotype. There is currently insufficient information to make treatment decisions based on *APOE* subtype.

Susceptibility Testing at the Triggering Receptor Expressed on Myeloid Cells 2 (*TREM2*) Gene

Korvatska (2015) published results from a retrospective study of genetic and pathologic studies that included 131 families (751 individuals) with late-onset AD (LOAD) between 1985 and 2014.[21] The authors found 12 of the 16 patients with AD in the LOAD123 family carried R47H. Eleven patients with dementia had apolipoprotein ε 4 (*APOE4*) and *R47H* genotypes. R47H carriers demonstrated a shortened disease duration (mean [SD] 6.7 [2.8] vs. 11.1 [6.6] years, two-tailed t test; p =0.04) and more frequent α-synucleinopathy. The panmicroglial marker ionized calcium-binding adapter molecule 1 was decreased in all AD cases and the decrease was most pronounced in *R47H* carriers (mean [SD] in the hilus 0.114 [0.13] for R47H_AD vs. 0.574 [0.26] for control individuals, two-tailed t test p=0.005 and vs. 0.465 [0.32] for AD, p=0.02; in frontal cortex gray matter: 0.006 [0.004] for *R47H*_AD vs. 0.016 [0.01] for AD, p=0.04, and vs. 0.033 [0.013] for control individuals, p<0.001). Major histocompatibility complex class II, a marker of microglial activation, was increased in all patients with AD (AD: 2.5, R47H_AD: 2.7, and control: 1.0, p < 0.01).

Jonsson (2013) evaluated 3,550 subjects with AD and found a genome-wide association with only one marker, the T allele of rs75932628 (excluding the *APOE* locus and the *A673T* variant in *APP*).[5] The frequency of *TREM2* rs75932628 was then tested in a general population of 110,050 Icelanders of all ages and was found to confer a risk of AD of 0.63% (odds ratio [OR] 2.26, 95% confidence interval [CI] 1.71 to 2.98, $p=1.13x10^{-8}$). In the control population of 8,888 patients 85 years of age or older without a diagnosis of AD, *TREM2* frequency was 0.46% (OR 2.92, 95% CI 2.09 to 4.09, $p=3.42x10^{-10}$). In 1,236 cognitively intact controls age 85 or older, the frequency of *TREM2* decreased even further to 0.31% (OR 4.66, 95% CI 2.38 to 9.14, $p=7.39x10^{-6}$). The decrease in *TREM2* frequency in elderly patients who are cognitively intact supports the findings associating *TREM2* with increasing risk of AD.

Guerriero (2013) also found a strong association of the *R47H TREM2* variant with AD (p=0.001).[6] Using three imputed data sets of genome-wide association AD studies, a meta-analysis found a significant association with the variant and disease (p=0.002). The authors further reported direct genotyping of R47H in 1994 AD patients and 4062 controls, and found a highly significant association with AD (OR 5.05, 95% CI 2.77 to 9.16, $p=9.0x10^{-9}$).

Clinical Utility

Chao (2008) published results from the Risk Evaluation and Education for Alzheimer’s Disease (REVEAL) study, which was designed to examine consequences of AD risk assessment by

APOE genotyping.[22] Of 289 eligible participants, 162 were randomized (mean age, 52.8 years; 73% female; average education, 16.7 years) to either risk assessment based on *APOE* testing and family history (n=111) or family history alone (n=51). During a one-year follow-up, those undergoing *APOE* testing with a high-risk genotype were more likely than low-risk or untested individuals to take more vitamins (40% vs. 24% and 30%, respectively), change diet (20% vs. 11% and 7%, respectively), or change exercise behaviors (8% vs. 4% and 5%, respectively). There is insufficient evidence to conclude that these short-term behavioral changes would alter clinical outcomes. Green (2009) examined anxiety, depression, and test-related distress at six weeks, six months, and one year in the 162 participants randomized in REVEAL.[23] There were no significant differences between the group that received the results of *APOE* testing and the group that did not in changes in anxiety or depression overall or in the subgroup of participants with the *APOE* ε4 allele. However, the ε4 negative participants had significantly lower test-related distress than ε4 positive participants (p=0.01).

Christensen (2016) examined disclosing associations between *APOE* genotype and AD risk alone versus AD and coronary artery disease (CAD) risk in an equivalence trial from the REVEAL group.[24] Two hundred ninety participants were randomized to receive AD risk disclosure alone or AD+CAD risk disclosure. The 257 participants who received their genetic information were included in analyses. Mean anxiety, depression, and test-related distress scores were below cutoffs for mood disorders at all time points in both disclosure groups and were similar to baseline levels. At the 12-month follow-up, both anxiety (measured by the Beck Anxiety Index) and depression (measured by the Center for Epidemiologic Studies Depression Scale) fell within the equivalence margin indicating no difference between disclosure groups. Among participants with an ε4 allele, distress (measured by Impact of Event Scale) was lower at 12 months in AD+CAD group than in the AD-only group (difference -4.8, 95% CI -8.6 to -1.0, p=0.031). AD+CAD participants also reported more health behavior changes than AD-alone participants, regardless of APOE genotype.

There is a lack of interventions that can delay or mitigate late-onset AD. There is no evidence that early intervention for asymptomatic variant carriers can delay or mitigate future disease. Furthermore, there are many actions patients may take following knowledge of a pathogenic variant. Changes in lifestyle factors (e.g., diet, exercise) or the incorporation of “brain training” exercises can be made, but there is no evidence that these interventions impact clinical disease.

Section Summary

Both the *APOE* gene and the triggering receptor gene have shown strong statistical associations with AD, thus demonstrating some degree of clinical validity. However, the clinical sensitivity and specificity of *APOE* ε4 is poor, and there is a lack of evidence on the clinical sensitivity and specificity of the triggering receptor gene. Furthermore, no studies were identified that address how the use of the *APOE* or other AD-associated variants might be incorporated into clinical practice, and it is not clear how management of patients with these genes would change in a way that improves outcomes. The REVEAL studies have found short-term changes in behaviors following disclosure of *APOE* genetic testing results in high-risk adults with little increase in anxiety or depression overall, although with possible increase in distress among ε4 allele carriers. It is unclear whether these changes in behaviors would improve clinical outcomes or whether there are long-term effects on psychological outcomes among ε4 carriers. Therefore, clinical utility has not been demonstrated for these tests.

GENETIC TESTING FOR EARLY-ONSET FAMILIAL ALZHEIMER'S DISEASE

Clinical Validity

In the scenario of targeted testing of individuals with a known familial pathogenic variant, due to nearly complete penetrance of pathogenic variants, an identified carrier will almost certainly develop the disease unless dying at an age preceding disease onset. Therefore, the clinical validity is nearly certain.

In the scenario of genetic testing of individuals with a family history consistent with autosomal dominant early-onset AD but in whom a pathogenic variant has not been found, the testing yield is less certain. Genetic testing for presenilin 1 (*PSEN1*) is estimated to detect disease-causing variants in 30% to 60% of individuals with familial early-onset AD,[25, 26] although estimates vary A number of variants scattered throughout the *PSEN1* gene have been reported, requiring sequencing of the entire gene when the first affected member of a family with an autosomal dominant pattern of AD inheritance is tested. Variants in amyloid-beta precursor protein (*APP*) and presenilin 2 (*PSEN2*) genes account for another 10% to 20% of cases.

Genetic yields may vary by population. Giau (2019) reported on 200 patients with clinically diagnosed early-onset AD from Thailand, Malaysia, the Philippines, and Korea who were genetically screened between 2009 and 2018.[27] Thirty-two (16%) patients carried pathogenic *APP* (8/32 [25%]), *PSEN1* (19/32 [59%]), or *PSEN2* (5/32 [16%]) variants. However, this analysis included possible and probable pathogenic variants in addition to those classified as definite. Overall, approximately 84% (p=0.01) of autosomal dominant pedigrees in the tested Asian population were genetically unexplained. Clinical and phenotypic expressivity is variable. A report by Ryan (2016) indicates that individuals with a *PSEN1* variants may have a significantly younger age of onset than individuals with an *APP* variant (mean age [SD] 43.6 years [7.2] vs. 50.4 years [5.2], respectively, p<0.0001).[28] However, the presence of *PSEN1*, *PSEN2*, or *APP* variants is not useful in predicting age of onset (although age of onset is usually similar in affected family members), severity, type of symptoms, or rate of progression in asymptomatic individuals.

A study by Cochran (2019) confirmed a high diagnostic yield in early-onset or atypical dementia.[29] Fifty percent (16/32) of patients tested harbored one or more genetic variants capable of explaining symptoms, including variants in *APP*. Nine of 32 patients (28%) had a variant defined as pathogenic or likely pathogenic whereas six had one or more variants with moderate penetrance. The authors noted this supports a potential oligogenic model for early-onset dementia.

Clinical Utility

The potential clinical utility of testing is in early identification of asymptomatic patients who are at risk for developing early-onset AD. Genetic testing, will in most cases, lead to better risk stratification, distinguishing patients who will develop the disease from those who will not. If early identification of patients at risk leads to interventions to delay or mitigate clinical disease, then clinical utility would be established. Identification of asymptomatic, young adult carriers could impact reproductive planning. And clinical utility may be demonstrated if testing leads to informed reproductive planning that improves outcomes. However, there is no evidence that early intervention for asymptomatic variant carriers can delay or mitigate future disease. There are many actions patients may take following knowledge of a pathogenic variant: changes in

lifestyle factors (e.g., diet, exercise) and incorporation of “brain training” exercises; but there is no evidence that these interventions impact clinical disease.

Alternatively, clinical utility could be demonstrated if knowledge of variant status leads to beneficial changes in psychological outcomes. However, a systematic review on the psychological and behavioral impact of genetic testing for AD found few studies on the impact of testing for early-onset familial AD. The existing studies generally have small sample sizes and retrospective designs, and the research was conducted in different countries, which may limit the generalizability of the findings.[30]

When a known pathogenic variant is identified in a prospective parent, with reasonable certainty, disease will develop and there is a 50% risk of an affected offspring. When a pathogenic variant is detected in a prospective parent, the prospective parent can choose to refrain from having children or choose medically assisted reproduction during which preimplantation testing would allow a choice to avoid an affecting offspring. Identification of a pathogenic variant by genetic testing is more accurate than the alternative of obtaining a family history alone. Therefore, testing in the reproductive setting can improve health outcomes.

Section Summary

For those individuals who do have a family member with early-onset, familial AD, with a known pathogenic familial variant or a family pedigree consistent with autosomal dominant AD, testing a prospective parent when performed in conjunction with genetic counseling provides more accurate information to guide reproductive planning than family history alone. Therefore, the clinical utility for the purposes of reproductive decision making has been demonstrated for these tests. There are currently no known preventive measures or treatments that can mitigate the effect of AD. It is not clear how change in the management of asymptomatic patients with these genes would improve outcomes. Outside the reproductive setting when used for prognosis or prediction, there is insufficient evidence to draw conclusions on the benefits of genetic testing for pathogenic variants.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF MEDICAL GENETICS AND GENOMICS

The American College of Medical Genetics and Genomics lists genetic testing for *APOE* alleles as one of five recommendations in the Choosing Wisely initiative.[15] The recommendation is “Don’t order *APOE* genetic testing as a predictive test for Alzheimer disease.” The stated rationale is that *APOE* is a susceptibility gene for later-onset AD, the most common cause of dementia. These recommendations stated that “The presence of an ε4 allele is neither necessary nor sufficient to cause AD. The relative risk conferred by the ε4 allele is confounded by the presence of other risk alleles, gender, environment and possibly ethnicity, and the *APOE* genotyping for AD risk prediction has limited clinical utility and poor predictive value.”

AMERICAN COLLEGE OF GENETICS AND NATIONAL SOCIETY OF GENETIC COUNSELORS

The American College of Genetics and the National Society of Genetic Counselors issued the following joint practice guidelines in 2011, which were reaffirmed in 2019:[3, 31]

- Pediatric testing for AD should not occur.

- Prenatal testing for AD is not advised if the patient intends to continue a pregnancy with a mutation.
- Genetic testing for AD should only occur in the context of genetic counseling (in person or through videoconference) and support by someone with expertise in this area.
    - Symptomatic patients: Genetic counseling for symptomatic patients should be performed in the presence of the individual's legal guardian or family member.
    - Asymptomatic patients: A protocol based on the International Huntington Association and World Federation of Neurology Research Group on Huntington's Chorea Guidelines is recommended.
- Direct-to-consumer *APOE* testing is not advised.
- A ≥3-generation family history should be obtained, with specific attention to the age of onset of any neurologic and/or psychiatric symptoms, type of dementia and method of diagnosis, current ages, or ages at death (especially unaffected relatives), and causes of death. Medical records should be used to confirm AD diagnosis when feasible. The history of additional relatives may prove useful, especially in small families or those with a preponderance of early death that may mask a history of dementia.
- A risk assessment should be performed by pedigree analysis to determine whether the family history is consistent with EOAD [early-onset AD] or LOAD [late-onset AD] and with autosomal dominant (with or without complete penetrance), familial, or sporadic inheritance.
- Patients should be informed that currently there are no proven pharmacologic or lifestyle choices that reduce the risk of developing AD or stop its progression.
- The following potential genetic contributions to AD should be reviewed:
    - The lifetime risk of AD in the general population is approximately 10–12% in a 75–80 year lifespan.
    - The effect(s) of ethnicity on risk is still unclear.
    - Although some genes are known, there are very likely others (susceptibility, deterministic, and protective) whose presence and effects are currently unknown.

For families in which an autosomal dominant AD gene mutation is a possibility:

- Discuss the risk of inheriting a mutation from a parent affected with autosomal dominant AD is 50%. In the absence of identifying a mutation in apparent autosomal dominant families, risk to offspring could be as high as 50% but may be less.
- Testing for genes associated with early onset autosomal dominant AD should be offered in the following situations:
    - A symptomatic individual with EOAD in the setting of a family history of dementia or in the setting of an unknown family history (e.g., adoption).
    - Autosomal dominant family history of dementia with one or more cases of EOAD.
    - A relative with a mutation consistent with EOAD (currently *PSEN1*/2 or *APP*).
- The Alzheimer Disease & Frontotemporal Dementia Mutation Database should be consulted (available online at: www.molgen.ua.ac.be/ADMutations/) before disclosure of genetic test results, and specific genotypes should not be used to predict the phenotype in diagnostic or predictive testing.
    - Discuss the likelihood of identifying a mutation in *PSEN1*, *PSEN*2, or *APP*, noting that current experience indicates that this likelihood decreases with lower proportions of affected family members and/or older ages of onset.
    - Ideally, an affected family member should be tested first. If no affected family member is available for testing and an asymptomatic individual remains

interested in testing despite counseling about the low likelihood of an informative result (a positive result for a pathogenic mutation), he/she should be counseled according to the recommended protocol. If the affected relative, or their next of kin, is uninterested in pursuing testing, the option of DNA banking should be discussed.

SUMMARY

There is enough research to show that *PSEN* and *APP* genetic testing for autosomal dominant Alzheimer's disease can help individuals at risk for this disorder to make reproductive decisions. Therefore, this genetic testing may be considered medically necessary when policy criteria are met.

There is not enough research to show that genetic testing for late- or early-onset Alzheimer's disease can improve health outcomes, including for those with a family history of Alzheimer's disease. Therefore, genetic testing when policy criteria are not met, including risk assessment or to aid in the diagnosis of Alzheimer's disease, is considered investigational.

Genetic Testing for Hereditary Breast and Ovarian Cancer and Li-Fraumeni Syndrome

Effective: January 1, 2025

Next Review: February 2025
Last Review: December 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Familial cancer syndromes, including hereditary breast and ovarian cancer (HBOC) syndrome are related to variants in the *BRCA* genes (*BRCA1* and *BRCA2*). Variants in several other genes, including *PALB2* and *STK11*, are also associated with increased risk of breast, ovarian, and other cancers. Li-Fraumeni syndrome (LFS) is a cancer predisposition syndrome associated a high lifetime cumulative risk of cancer and a tendency for multiple cancers in affected individuals. LFS is related to variants in the *TP53* gene. Identification of patients with variants in *BRCA1/2, TP53,* or other genes may lead to enhanced screening and/or surveillance that could lead to improved outcomes.

MEDICAL POLICY CRITERIA

Note: Both maternal and paternal family histories are important in identifying families with a high risk of genetic variant and therefore, each lineage must be considered separately. For PTEN single-gene testing, see Cross References below.

I. **Family with a Known Pathogenic Variant**: Genetic testing for a known familial pathogenic variant in *BRCA1*, *BRCA2, BRIP1*, *CDH1*, *PALB2, PTEN, RAD51C*, *RAD51D, STK11* or *TP53* may be considered **medically necessary**.

II. **Individuals with Active Cancer or a Personal History of Cancer**: Genetic testing (including panel testing) for *BRCA1*, *BRCA2, CDH1*, *PALB2, PTEN, STK11* and/or *TP53* variants in cancer-affected individuals may be considered **medically necessary** when one or more of the following criteria are met:

A. Personal history of breast, pancreatic, ovarian (See Policy Guidelines), fallopian tube, and/or peritoneal cancer; or

B. Personal history of prostate cancer (Gleason score ≥ 7) *and* one or more of the following:

1. Metastatic prostate cancer; or
2. High-risk prostate cancer, defined as any of the following:
    a. Gleason score ≥ 8; or
    b. T stage of T3a, T3b, or T4; or
    c. PSA > 20 ng/mL; or
    d. Gleason pattern 5 histology
3. Intraductal/cribriform histology; or
4. Ashkenazi Jewish ancestry; or
5. One or more close blood relatives with any of the following: breast, ovarian, fallopian tube, peritoneal, pancreatic, and/or prostate cancer (Gleason score ≥ 7) (see Policy Guidelines).

C. *BRCA1* and *BRCA2* germline (blood-based) testing when tumor genetic testing has been performed and the results indicate that a *BRCA1* or *BRCA2* variant is present in tumor tissue.

D. The treating provider has documented that the individual is at increased risk for a *BRCA* variant based on one of the following seven risk-stratification tools endorsed by the USPSTF (See Policy Guidelines) and the documentation indicates which tool was used: the Ontario Family History Assessment Tool, Manchester Scoring System, Referral Screening Tool, Pedigree Assessment Tool, Family History Screen 7 (FHS-7), International Breast Cancer Intervention Study instrument (Tyrer-Cuzick), BRCAPro (brief versions).

III. **Individuals without Active Cancer and Without History of Cancer**: Genetic testing (including panel testing) for *BRCA1*, *BRCA2, CDH1*, *PALB2, PTEN, STK11,* and/or *TP53* variants in cancer-unaffected individuals (no personal history of the following: breast cancer, ovarian cancer, fallopian tube, peritoneal cancer, pancreatic cancer, or prostate cancer [Gleason score ≥ 7]) with unknown variant status, may be considered **medically necessary** when one or more of the following criteria are met:

A. Individual is at increased risk when one or more of the following family history criteria are met:

1. A first-degree relative has been diagnosed with breast or ovarian cancer; or
2. Two or more close blood relatives (see Policy Guidelines) have been diagnosed with breast cancer, ovarian cancer, pancreatic cancer, prostate cancer, diffuse gastric cancer, and/or colorectal cancer; or

3. A close blood relative (see Policy Guidelines) has been diagnosed with any of the following:
    a. Bilateral breast cancer; or
    b. Male breast cancer; or
    c. Breast cancer before age 50; or
    d. Both breast and ovarian cancer.

B. The treating provider has documented that the individual is at increased risk for a *BRCA* variant based on one of the following seven risk-stratification tools endorsed by the USPSTF (See Policy Guidelines) and the documentation indicates which tool was used: the Ontario Family History Assessment Tool, Manchester Scoring System, Referral Screening Tool, Pedigree Assessment Tool, Family History Screen 7 (FHS-7), International Breast Cancer Intervention Study instrument (Tyrer-Cuzick), BRCAPro (brief versions); or

C. Confirmatory *BRCA1* or *BRCA2* testing when the treating provider has documented that direct-to-consumer DNA testing (such as ancestry testing) indicates a pathogenic or likely pathogenic *BRCA1* or *BRCA2* variant.

IV. Genetic testing for *TP53* may be considered **medically necessary** when the treating provider has documented a concern that the patient is at increased risk for a *TP53* variant, including in the evaluation of possible Li-Fraumeni syndrome.

V. Genetic testing for *BRIP1*, *RAD51C*, and/or *RAD51D* may be considered **medically necessary** when any of the following criteria are met:

A. Personal history of ovarian cancer; or

B. A first- or second-degree blood relative with ovarian cancer.

VI. Genetic testing for *BRCA1*, *BRCA2, BRIP1*, *CDH1*, *PALB2, PTEN, RAD51C*, *RAD51D, STK11* and/or *TP53* variants for hereditary breast/ovarian cancer risk is considered **investigational** in patients who do not meet Criteria I., II., III., IV., or V.

VII. Single gene or panel testing for any other gene not listed in the criteria above (including but not limited to *ATM*, *BARD1*, and *CHEK2*) is considered **investigational** for hereditary breast and/or ovarian cancer.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

DEFINITIONS

Close blood relatives include 1st-, 2nd-, and 3rd-degree relatives from the same lineage as follows:

- *1st-degree relatives* are parents, siblings, and children of an individual;
- *2nd-degree relatives* are grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings (siblings with one shared biological parent) of an individual; and
- *3rd-degree relatives* are great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins.

Ovarian cancer is a type of cancer that starts in the ovaries and can spread into the pelvis and abdomen. For the purposes of this policy, fallopian tube and peritoneal cancers are also included in the definition of ovarian cancer.

Invasive and stage 0 (including ductal and lobular carcinoma in situ) are considered breast cancer for the purposes of this policy.

RISK STRATIFICATION TOOLS FOR IDENTIFYING AN INCREASED RISK OF *BRCA* VARIANTS

The thresholds for referral for genetic counseling for the USPSTF-endorsed screening tools are listed below. Most of these tools are accessible from the USPSTF website at: https://www.uspreventiveservicestaskforce.org/uspstf/recommendation/brca-related-cancer-risk-assessment-genetic-counseling-and-genetic-testing

- Ontario Family History Assessment Tool (FHAT): Score of ≥ 10
- Manchester Scoring System: Score of 10 in either column or combined score of 15 for both columns
- Referral Screening Tool (RST): Presence of ≥ 2 items
- Pedigree Assessment Tool (PAT): Score of ≥ 8
- Family History Screen 7 (FHS-7): ≥ 1 positive response
- International Breast Cancer Intervention Study instrument (Tyrer-Cuzick): risk level ≥ 10%
- BRCAPro (brief versions): risk level ≥ 10%

TESTING AFFECTED FAMILY MEMBERS

Initial testing of an affected family member is strongly recommended whenever possible. Should a *BRCA* variant be found in the affected family member(s), unaffected family member DNA can be tested specifically for the same variant without having to sequence the entire gene.

BRCA TESTING FOR TREATMENT WITH LYNPARZA™ (OLAPARIB)

For individuals who have had a previous *BRCA* test other than BRACAnalysis CDx (Myriad Genetics), repeat *BRCA* variant testing with BRACAnalysis CDx may be necessary when treatment with Lynparza™ (olaparib) is being considered.

BRCA TESTING FOR TREATMENT WITH RUBRACA™ (RUCAPARIB)

For individuals who have had a previous *BRCA* test other than FoundationFocus CDxBRCA (Foundation Medicine), repeat *BRCA* variant testing with FoundationFocus CDxBRCA may be necessary when treatment with Rubraca™ (rucaparib) is being considered.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF GENETIC TESTING DOCUMENTATION

All of the following information must be submitted for review prior to the genetic testing:

1. Name of genetic test(s) and/or panel test
2. The exact gene(s) and/or variants being tested

3. Name of performing laboratory and/or genetic testing organization (more than one may be listed)
4. Relevant billing codes
5. Date of sample collection/blood draw
6. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence of testing
7. Clinical documentation by the provider (e.g., primary care physician, family practitioner, gynecologist) of family history and supporting rationale for the requested test(s)

BACKGROUND

BRCA1 AND *BRCA2*

Several genetic syndromes with an autosomal dominant pattern of inheritance that feature breast cancer have been identified. Of these, hereditary breast and ovarian cancer (HBOC), and some cases of hereditary site-specific breast cancer have causative variants in *BRCA* genes in common. Families suspected of having HBOC syndrome are characterized by an increased susceptibility to breast cancer occurring at a young age, bilateral breast cancer, male breast cancer, ovarian cancer at any age, as well as cancer of the fallopian tube and primary peritoneal cancer. Other cancers, such as prostate cancer, pancreatic cancer, gastrointestinal cancers, melanoma, laryngeal cancer, occur more frequently in HBOC families. Hereditary site-specific breast cancer families are characterized by early onset breast cancer, but without ovarian cancer. For this policy, both will be referred to collectively as hereditary breast and/or ovarian cancer.

Germline variants in the *BRCA1* and *BRCA2* genes are responsible for cancer susceptibility in the majority of HBOC families, especially if ovarian cancer is a feature. However, in site-specific breast cancer, *BRCA* variants are responsible for only a proportion of affected families, and research to date has not yet identified other moderate or high-penetrance gene variants that account for disease in these families. *BRCA* gene variants are inherited in an autosomal dominant fashion through either the maternal or paternal lineage (each lineage must be considered separately). It is possible to test for abnormalities in *BRCA1* and *BRCA2* genes to identify the specific variant in cancer cases, and to identify family members with increased cancer risk. Family members without existing cancer who are found to have *BRCA* variants can consider preventive interventions for reducing risk and mortality. Genetic counseling is highly recommended when genetic testing is offered and when the genetic test results are disclosed. Please see Appendix 1 for a recommended testing strategy.

BRIP1

BRIP1 (BRCA1 interacting protein C-terminal helicase 1) encodes a protein that interacts with BRCA1 to function in DNA repair. Heterozygous pathogenic *BRIP1* variants increase the risk

of ovarian cancer, while homozygous pathogenic *BRIP1* variants are associated with Fanconi anemia. The prevalence of *BRIP1* variants in women with ovarian cancer appears to be approximately 1% and the lifetime risk associated with a pathogenic variant is estimated to be 5.8%.[1]

PALB2

PALB2 (partner and localizer of BRCA2) encodes a protein that assists BRCA2 in DNA repair and tumor suppression. Heterozygous pathogenic *PALB2* variants increase the risk of developing breast and pancreatic cancers; homozygous variants are found in Fanconi anemia. Pathogenic *PALB2* variants are uncommon in unselected populations and prevalence varies by ethnicity and family history. Women with a pathogenic *PALB2* variant have a 14% lifetime risk of breast cancer by age 50, which increases to 35% by age 70.[2]

PTEN

PTEN (phosphatase and tensin homolog) encodes a tumor suppressor that antagonizes the PI3K signaling pathway through its lipid phosphatase activity and negatively regulates the MAPK pathway through its protein phosphatase activity.[3] *PTEN* variants are inherited in an autosomal dominant manner. There is a spectrum is disorders that result from germline variants in *PTEN* referred to as *PTEN* hamartoma tumor syndrome / Cowden syndrome. These syndromes are associated with multiple tumors, including a lifetime risk of breast cancer of up to 50%.[1]

STK11

STK11 (serine/threonine kinase 11) encodes a tumor suppressor that controls the activity of AMP-activated protein kinase (AMPK) family members, thereby playing a role in cell metabolism, apoptosis and DNA damage response. *STK11* variants are associated with Peutz-Jeghers syndrome, an autosomal dominant syndrome characterized by the gastrointestinal polyps, breast cancer, non-epithelial ovarian cancer, and other neoplasms.[1]

RAD51C and *RAD51D*

RAD51 genes encode tumor suppressors that are involved in DNA repair. Heterozygous pathogenic variants in these genes are associated with ovarian cancer. The cumulative risk of ovarian cancer for an individual with such a variant approaches 2.6% (the risk for women with a family history of ovarian cancer without a BRCA variant) between the ages of 50 to 54 for *RAD51D* and 60 to 64 for *RAD51C*.[1]

TP53

The *TP53* gene contains the genetic instructions for the production of tumor protein p53 (or p53). The p53 protein is a tumor suppressor that functions as a cell cycle regulator to prevent cells from uncontrolled growth and division when there is DNA damage. Somatic (acquired) pathogenic variants are one of the most frequent alterations found in human cancers. Germline (inherited) pathogenic variants in *TP53* are associated with Li-Fraumeni syndrome (LFS).

ATM

ATM (ataxia-telangiectasia mutated), located on chromosome 11q22.3, is associated with the autosomal recessive condition ataxia-telangiectasia syndrome. This condition is characterized

by progressive cerebellar ataxia with onset between the ages of 1 and 4 years, telangiectasias of the conjunctivae, oculomotor apraxia, immune defects, and cancer predisposition. Females with a heterozygous *ATM* variant have a risk of breast cancer about twice as high as that of the general population; however, they do not appear to have an elevated ovarian cancer risk.

BARD1

The *BARD1* (BRCA1-associated RING domain) gene is located on chromosome 2 (sequence 2q34-q35). *BARD1* encodes a protein which interacts with the N-terminal region of *BRCA1*, and *BARD1* and *BRCA1* can form a heterodimer by their N-terminal RING finger domains which form a stable complex.[4] *BARD1* variants have been associated with an increased risk of estrogen-receptor (ER) negative breast cancer, triple-negative breast cancer, and with breast cancer at a younger age (under age 50 years) in some studies, but do not appear to increase risk of ovarian cancer.[5, 6]

CHEK2

CHEK2 (cell cycle checkpoint kinase 2) is involved with DNA repair and human cancer predisposition like BRCA1 and BRCA2. CHEK2 is normally activated in response to DNA double-stranded breaks. CHEK2 regulates the function of BRCA1 protein in DNA repair and also exerts critical roles in cell cycle control and apoptosis. The *CHEK2* variant, *1100delC* in exon 10 has been associated with familial breast cancers.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[7] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

The clinical utility of testing for variants in the *BRCA1* and *BRCA2* genes to inform surveillance, prognosis and treatment of patients with hereditary breast cancer has been unequivocally demonstrated. Therefore, the scientific evidence will no longer be reviewed for the clinical utility of *BRCA1* and *BRCA2* testing, as they may be considered medically necessary.

In addition, there are several genes: *PTEN, STK11*, *CDH1*, and *TP53*; which are the causative factors in rare, but highly penetrant cancer syndromes that substantially increase the risk of breast cancer. Although rare, when taken together, variants in these genes are thought to account for at least 5% to 10% of breast cancer diagnoses. Since the clinical utility of testing for variants in these genes to inform surveillance, prognosis and treatment of patients with hereditary breast cancer has been demonstrated, they will not be reviewed extensively in the evidence section below.

The focus of the scientific evidence review below is on the investigational indications only, such as *CHEK2* testing. The evidence review is related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and

- Improve health outcomes as a result of those decisions.

CHEK2 TESTING

Systematic Reviews on Breast Cancer Association

A number of systematic reviews have described the association of cell cycle checkpoint kinase 2 (*CHEK2*) variants with hereditary breast cancer. The prevalence of this finding varies greatly by geographic region, being most common in Northern and Eastern Europe. In the US, *CHEK2* variants are much less common than *BRCA* variants and *BRCA* rearrangements. For example, in the study by Walsh (2006), 14 (4.7%) of the 300 patients with a positive family history of breast cancer (four affected relatives) who were negative by standard *BRCA* testing, were positive for *CHEK2* variants.[8]

A systematic review and meta-analysis by Suszynska (2019) included association estimates for *CHEK2* variants.[9] The systematic review included studies published through July 2017 reporting on genetic test results of breast and ovarian cancer patients who were referred for evaluation by a multi-gene panel. The studies of panel results were used to calculate variant frequencies by the gene. As a control, population variant frequencies were extracted from the Genome Aggregation Database. In the 43 breast cancer studies included in the review, 94,845 patients contributed to the meta-analysis of *CHEK2* in breast cancer patients. The odds ratio (OR) of breast cancer for *CHEK2* variants including variants c.470T>C and c.1283C>T was 0.96 (95% confidence interval [CI] 0.90 to 1.03); after excluding variants c.470T>C and c.1283C>T, the remaining *CHEK2* variants had an OR for breast cancer of 1.73 (95% 1.58 to 1.89).

Liang (2018) conducted a meta-analysis to investigate the link between *CHEK2* and breast cancer.[10] Two researchers independently searched seven online databases and selected for analysis 26 published studies representing a pooled sample of 118,735 cancer patients and 195,807 controls, all case-control studies conducted in Europe or the Americas. Meta-analysis revealed that *CHEK2* variants are more common in patients with breast cancer (OR 2.89; 95% CI 2.63 to 3.16), with variants 5.9% more likely in female patients with breast cancer than in male patients with breast cancer. Limitations of the study included a study population that might not represent the general population, inaccurate control sampling methods in some original studies, selection biases, and unclear criteria for breast-cancer diagnoses.

A meta-analysis by Schmidt (2016) evaluated data on *CHEK2* variant status and breast cancer risk from the Breast Cancer Association Consortium.[11] The analysis included 44,777 breast cancer patients and 42,997 controls from 33 studies in which individuals were genotyped for *CHEK2* variants. The estimated odds for invasive breast cancer in patients with and without the *CHEK2 1100delC* variant was 2.26 (95% CI 1.90 to 3.10).

In a meta-analysis by Yang (2012), the link between *CHEK2 1100delC* heterozygote and breast cancer risk was investigated.[12] A total of 29,154 cases and 37,064 controls from 25 case-control studies were identified in this meta-analysis. A significant association was found between *CHEK2 1100delC* heterozygote and breast cancer risk. Authors concluded that the *CHEK2 1100delC* variant could be a potential factor for increased breast cancer risk in Caucasians; however, they suggested that more consideration is needed in order to apply it to allele screening or other clinical work.

In a systematic review and meta-analysis by Liu (2012), authors identified fifteen case-control studies with 19,621 cases and 27,001 controls that were included in their analysis.[13] Authors reported a significant association found between the *CHEK2 I157T* variant and increased risk of unselected breast cancer, and early-onset breast cancer. In addition, an even stronger significant association was found between the *CHEK2 I157T* variant and increased risk of lobular type breast tumors. Authors concluded the *CHEK2 I157T* variant may be another important genetic variant which increases risk of breast cancer, especially the lobular type. The methodological quality of this review was limited; the evidence was not quality appraised for risk of bias.

A meta-analysis by Han (2013) investigated the relationship of the *CHEK2 I157T* variant and the incidence of cancer.[14] In total, 26,336 cases and 44,219 controls from 18 case-control studies were used in the meta-analysis. Authors concluded that the *CHEK2 I157T* variant was an important cancer gene, which increases cancer risk, especially for breast and colorectal cancer.

Zhang (2011) performed a systematic review of candidate-gene association studies of breast cancer risk, identifying more than 1,000 published articles. Meta-analysis was performed for a total of 279 genetic variants in 128 genes that were identified by at least three different researchers. Significant associations with the risk of breast cancer were found for 29 variants in 20 genes. The association was strong for ten variants in six genes, four of which were located in the *CHEK2* gene.[15]

Peng (2011) identified 87 meta-analyses and pooled analyses which examined the association of 145 candidate gene variants and breast cancer. They found significant association for 46 variants, with ORs ranging from 0.66 to 3.13. The further analysis of ORs (using the method of false-positive report probability) identified ten noteworthy associations, including *CHEK2* (**1100delC*).[16]

Weischer (2008) performed a meta-analysis of studies on *CHEK2 1100delC* heterozygosity and the risk of breast cancer among patients with unselected (including the general population), early-onset (<51 years of age) and familial breast cancer.[17] The analysis identified prospective cohort and case-control studies on *CHEK2* 1100delC and the risk of breast cancer published before March 2007. Inclusion criteria were women with unilateral breast cancer who did not have a known multicancer syndrome, Northern or Eastern European descent, availability for *CHEK2* genotyping, *BRCA1* and *BRCA2* variant-negative or unknown status, and breast cancer-free women as controls. The meta-analysis included 16 studies with 26,488 patient cases and 27,402 controls. Using fixed-effect models, for *CHEK2 1100delC* heterozygotes versus those without a variant, the aggregated OR for breast cancer was 2.7 (95% CI 2.1 to 3.4) and 2.4 (95% CI 1.8 to 3.2), respectively, for *CHEK2 1100delC* heterozygotes versus those without a variant in studies of patients with unselected breast cancer, 2.6% (95% CI 1.3 to 5.5) versus 2.7 (95% CI 1.3 to 5.6), respectively, for early-onset breast cancer, and 4.8 (95% CI 3.3 to 7.2) versus 4.6 (95% CI 3.1 to 6.8), respectively, for familial breast cancer. The cumulative risk at age 70 years for *CHEK2*1100delC* variant was 37% (confidence interval 26% to 56%). This risk is lower than cumulative risk at age 70 of 57% for *BRCA1* and 49% for *BRCA2*.

CHEK2 and Breast Cancer Prognosis

A study by Huzarski (2014) estimated the 10-year survival rate for patients with early-onset breast cancer, with and without *CHEK2* variants.[18] Patients were consecutively identified

women with invasive breast cancer diagnosed at or below the age of 50, between 1996 and 2007, in 17 hospitals throughout Poland. Patients were tested for four founder variants in the *CHEK2* gene after diagnosis, and their medical records were used to retrieve tumor characteristics and treatments received. Dates of death were retrieved from a national registry. A total of 3,592 women were eligible for the study, of whom 487 (13.6%) carried a *CHEK2* variant (140 with truncating variants, 347 with missense variants). Mean follow-up was 8.9 years. Ten-year survival for individuals with a *CHEK2* variant was similar to that of individuals without a variant, at 78.8% (95% CI 74.6% to 83.2%) and 80.1% (95% CI 78.5% to 81.8%), respectively. After adjusting for other prognostic features, the hazard ratio comparing those with and without the missense variant was similar, as for those with and without a truncating variant.

A study by Kriege (2014) compared breast cancer outcomes in patients with and without *CHEK2* variants.[19] Different study cohorts were combined to compare 193 individuals with *CHEK2* variants with 4,529 controls. Distant disease-free survival and breast cancer-specific survival were similar in the first six years after diagnosis. After six years, both distant disease-free survival (multivariate HR 2.65, 95% CI 1.79 to 3.93) and breast cancer-specific survival (multivariate HR 2.05, 95% C, 1.41 to 2.99) were worse in those *CHEK2* variants. No interaction between *CHEK2* status and adjuvant chemotherapy was observed.

Weischer (2012) reported on breast cancer associated with early death, breast cancer–specific death, and the increased risk of a second breast cancer (defined as a contralateral tumor) in patients with and without a *CHEK2* variant.[20] The study included 25,571 white women of Northern and Eastern European descent who had invasive breast cancer, with data from 22 studies participating in the Breast Cancer Association Consortium conducted in 12 countries. The 22 studies included 30,056 controls. Data were reported on early death in 25,571 women, breast cancer–specific death in 24,345 and a diagnosis of a second breast cancer in 25,094. Of the 25,571 women, 459 (1.8%) were *CHEK2 1100delC* heterozygous and 25,112 (98.2%) did not have a *CHEK2* variant. Median follow-up was 6.6 years, over which time 124 (27%) deaths, 100 (22%) breast cancer–specific deaths, and 40 (9%) second breast cancers among those with a *CHEK2 1100delC* variant were observed. Corresponding numbers among those without this variant were 4,864 (19%), 2,732 (11%), and 607 (2%), respectively. At the time of diagnosis, those with a *CHEK2* variant versus those without were on average four years younger ($p<0.001$) and more often had a positive family history ($p<0.001$).

CHEK2 Evidence Summary

The evidence for testing for *CHEK2* variants in individuals who are undergoing risk assessment for breast cancer includes population and family-based case control studies. Relevant outcomes are overall survival, test accuracy, test validity, morbid events, resource utilization, and treatment-related morbidity. Studies have shown that a *CHEK2* variant is of moderate penetrance and confers a risk of breast cancer of two to four times that of the general population; this risk appears to be higher in patients who also have a strong family history of breast cancer, however, risk estimates are subject to bias and overestimation. Several studies have suggested that individuals with *CHEK2* variants with breast cancer may have worse breast cancer-specific survival and distant-recurrence free survival, with about twice the risk of early death.

Further studies are needed to determine whether some patients with a *CHEK2* variant have a risk that is similar to the risk with a high-penetrance variant and identify those that would be

best managed according to the well-established guidelines for high-risk patients. Clinical management recommendations for inherited conditions associated with moderate penetrance variants, such as *CHEK2*, are not standardized, nor is it known if testing for *CHEK2* variants will lead to changes in patient management or improved health outcomes. Therefore, the evidence is insufficient to determine the effects of the technology on health outcomes.

ATM TESTING

Systematic Reviews on Breast Cancer Association

A systematic review conducted by Moslemi (2021) included 24 cross-sectional studies reporting on the prevalence of *ATM* variants in individuals with breast cancer.[21] The review found a pooled prevalence of 7% (95% CI 6% to 9%) based on 21 studies included in the meta-analysis with high heterogeneity (I^2=93%). In individuals with and *ATM* and *BRCA1* or *BRCA2* variant, prevalence was 11% (95% CI 7% to 11%, I^2=99%), in those with an ATM variant but without a *BRCA1/2* variant, the prevalence was 3% (95% CI 2% to 4%, I^2=85%). Meta-regression found age did not have a significant effect on prevalence of ATM in individuals with breast cancer, and Egger's test did not reveal evidence of publication bias (p=0.98).

The Suszynska (2019) systematic review described previously also included association estimates for *ATM* variants.[9] In the 43 breast cancer studies included in the review, 94,787 patients contributed to the meta-analysis of *ATM* in breast cancer patients. The OR of breast cancer for *ATM* variants was 2.42 (95% CI 2.16 to 2.71).

Marabelli (2016) reported on a meta-analysis of the penetrance of *ATM* variants in breast cancer, which used a model allowing the integration of different types of cancer risk estimates to generate a single estimate associated with heterozygous *ATM* gene variants.[22] The meta-analysis included 19 studies, which were heterogeneous in terms of population, study designs, and baseline breast cancer risk. The estimated cumulative absolute risk of breast cancer in those with a heterozygous *ATM* variant was 6.02% by age 50 (95% credible interval 4.58% to 7.42%) and 32.83% by age 80 (95% credible interval 24.55% to 40.43%).

ATM Evidence Summary

For individuals with risk of HBOC who receive genetic testing for an *ATM* variant, the evidence includes studies of variant prevalence and studies of breast cancer risk. Relevant outcomes are OS, disease-specific survival, and test validity. The available studies on clinical validity have demonstrated that *ATM* variants are of moderate penetrance; moreover, *ATM* variants confer a risk of breast cancer two to four times that of the general population. Direct evidence for the clinical utility of genetic testing for *ATM* variants in individuals with risk of HBOC was not identified. It is unclear that the RR associated with the moderate penetrance variants would increase risk enough beyond that already conferred by familial risk to change screening behavior. In contrast to high-penetrance variants, there is unlikely to be a similar benefit-to-risk calculus for preventive interventions in women with a moderate penetrance variant such as *ATM*. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

BARD1 TESTING

Systematic Reviews on Breast Cancer Association

Two systematic reviews conducted by Suszynska (2019)[9] and (2020)[23] reported estimates on the association of *BARD1* variants with risk of breast cancer. The prevalence of *BARD1* variants was 0.22% to 0.25% in individuals with breast cancer; prevalence in controls was about 0.09%. The reviews found presence of a *BARD1* variant was associated with approximately a two- to three-fold increased risk of breast cancer. The 2020 review identified 60 distinct pathogenic variants among individuals with breast cancer, 21 of which were present in controls. In individuals with a recurrent pathogenic variant (defined as occurring in three or more cases), risk was elevated among those with the c.334C>T (R112*), c.1652C>G (S551*), c.1690C>T (Q564*) variants, but prevalence was very low (≤0.03% among cases and ≤0.004% among controls) and these estimates were imprecise.

BARD1 Evidence Summary

For individuals with risk of HBOC who receive genetic testing for a *BARD1* variant, the evidence includes studies of variant prevalence and studies of breast cancer risk. Relevant outcomes are OS, disease-specific survival, and test validity. The available studies on clinical validity have demonstrated that *BARD1* variants are of low to moderate penetrance; *BARD1* variants confer a risk of breast cancer about two to three times that of the general population. Direct evidence for the clinical utility of genetic testing for *BARD1* variants in individuals with risk of HBOC was not identified. It is unclear that the relative risk associated with the low- to moderate-penetrance variants would increase risk enough beyond that already conferred by familial risk to change screening behavior. In contrast to high-penetrance variants, there is unlikely to be a similar benefit-to-risk calculus for preventive interventions in women with a low- to moderate-penetrance variant such as *BARD1*. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK GUIDELINES (NCCN)

Genetic/Familial High-Risk Assessment for Breast, Ovarian, and Pancreatic Cancer[1]

High-Penetrance Genes: *BRCA1*, *BRCA2*, *CDH1*, *PALB2*, *PTEN*, and *TP53*

- The NCCN Guidelines for Genetic/Familial High-Risk Assessment for Breast and Ovarian Cancer (v.3.2024) recommend testing for high-penetrance breast and/or ovarian cancer susceptibility genes, including *BRCA1/2*, *CDH1*, *PALB2*, *PTEN*, and *TP53* testing, in select individuals.
- In patients with a known familial pathogenic or likely-pathogenic variant, targeted testing for the specific variant is recommended.
- In patients with no known familial variant, multi-gene testing of the patient or, if the patient is unaffected, testing of the family member with the highest likelihood of a pathogenic/likely pathogenic variant is recommended prior to testing the patient, if possible; if the affected individual is of Ashkenazi Jewish descent, testing for the three known founder variants is recommended.

Additional Genes

The NCCN guidelines include a table listing *BRCA1*, *BRCA2*, *TP53* and a number of other genes associated with increased risks of breast, ovarian, and/or pancreatic cancer, along with cancer risk management for these genes. The authors note that the inclusion of a gene in the

table “does not imply the endorsement either for or against multi-gene testing for moderate-penetrance genes.”

Regarding moderate penetrance genes and multigene testing, the guidelines state:

> “Multi-gene testing can include “intermediate” penetrant (moderate-risk) genes. For many of the genes, there are limited data on the degree of cancer risk, and there may currently be no clear guidelines on risk management for carriers of P/LP [pathogenic/likely pathogenic] variants. Not all genes included on available multi-gene tests will change risk management compared to that based on other risk factors such as family history.”

Prostate Cancer[24]

The NCCN guidelines for prostate cancer (v.2.2024) include recommendations for germline testing for genes related to hereditary breast and ovarian cancers in patients with prostate cancer, including *BRCA1* and *BRCA2*. Germline testing is recommended for patients with high-risk, very-high-risk, regional, or metastatic prostate cancer prostate cancer patients and those with any of the following:

- Ashkenazi Jewish ancestry
- A family history of a familial cancer risk mutation
- A positive family history of certain types of cancer
- A personal history of breast cancer

US PREVENTIVE SERVICES TASK FORCE (USPSTF)

The 2019 USPSTF guideline titled *Risk Assessment, Genetic Counseing, and Genetic Testing for BRCA-Related Cancer* recommends the following:[25]

- The USPSTF recommends that primary care clinicians assess women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or who have an ancestry associated with BRCA1/2 gene mutations with an appropriate brief familial risk assessment tool. Women with a positive result on the risk assessment tool should receive genetic counseling and, if indicated after counseling, genetic testing (Grade B recommendation).
- The USPSTF recommends against routine risk assessment, genetic counseling or genetic testing for women whose personal or family history or ancestry is not associated with potentially harmful BRCA1/2 gene mutations (Grade D recommendation).

SOCIETY OF GYNECOLOGIC ONCOLOGY (SGO)

In 2014, the SGO[26] published a consensus statement that was evidence informed for inherited gynecologic cancer. SGO recommends genetic assessment (counseling with or without testing) for patients genetically predisposed to breast or ovarian cancer. The SGO and NCCN guidelines generally align with some slight variations. Specifically, SGO recommends that other individuals may benefit from genetic assessment (e.g., unaffected women with a male relative with breast cancer, few female relatives, hysterectomy or oophorectomy at a young age in multiple family members, or adoption in the lineage).

THE AMERICAN SOCIETY OF CLINICAL ONCOLOGY

The American Society of Clinical Oncology (ASCO) 2015 policy statement update on genetic and genomic testing for cancer susceptibility states that testing for high-penetrance variants in appropriate populations has clinical utility in that the variants inform clinical decision making and facilitate the prevention or amelioration of adverse health outcomes.[27] Regarding moderate-penetrance genes, the update stated, “Clinical utility remains the fundamental issue with respect to testing for mutations in moderate-penetrance genes. It is not yet clear whether the management of an individual patient or his or her family should change based on the presence or absence of a mutation. There is insufficient evidence at the present time to conclusively demonstrate the clinical utility of testing for moderate penetrance variants, and no guidelines exist to assist oncology providers."

THE AMERICAN SOCIETY OF CLINICAL ONCOLOGY, AMERICAN SOCIETY FOR RADIATION ONCOLOGY, AND SOCIETY OF SURGICAL ONCOLOGY

ASCO and the Society of Surgical Oncology (SSO) published consensus guidelines for germline testing in patients with breast cancer in 2024, which included the following recommendations:[28]

- “All patients newly diagnosed with breast cancer with stage I-III or de novo stage IV/metastatic disease who are 65 years or younger at diagnosis should be offered *BRCA1*/*2* testing.
- All patients newly diagnosed with breast cancer with stage I-III or de novo stage IV/metastatic disease who are older than age 65 should be offered *BRCA1*/*2* testing if:
    - they are candidates for poly(ADP–ribose) polymerase (PARP) inhibitor therapy for early-stage or metastatic disease,
    - they have triple-negative breast cancer,
    - their personal or family history suggests the possibility of a pathogenic variant,
    - they were assigned male sex at birth,
    - they are of Ashkenazi Jewish ancestry or are members of a population with an increased prevalence of founder mutations.
- Patients undergoing *BRCA1/2* testing should also be offered testing for other cancer predisposition genes as suggested by their personal or family history. Consultation with a provider experienced in clinical cancer genetics can help guide this decision-making and should be made available to patients when possible.
- All patients with recurrent breast cancer (local or metastatic) who are candidates for PARP inhibitor therapy should be offered *BRCA1/2* testing regardless of family history.
- *BRCA1/2* testing should be offered to patients with a second primary cancer either in the contralateral or ipsilateral breast.
- All patients with a personal history of breast cancer diagnosed ≤65 years who are without active disease should be offered *BRCA1/2* testing if the result will inform personal risk management or family risk assessment.
- All patients with a personal history of breast cancer diagnosed over age 65 with no active disease, who meet one of the following criteria, should be

offered *BRCA1*/*2* testing if the result will inform personal risk management or family risk assessment:

  - their personal or family history suggests the possibility of a pathogenic variant,
  - they were assigned male sex at birth,
  - they had triple-negative breast cancer,
  - they are of Ashkenazi Jewish ancestry or are members of a population with an increased prevalence of founder mutations.

- Testing for high penetrance genes beyond *BRCA1*/*2*, including *PALB2*, *TP53*, *PTEN*, *STK11*, and *CDH1*, could inform medical therapy, influence surgical decision making, refine estimates of risks of second primary cancer, and inform family risk assessment, and thus should be offered to appropriate patients.

- Testing for moderate penetrance breast cancer genes currently offers no benefits for treatment of the index breast cancer but may inform risks of second primary cancer or family risk assessment, and thus may be offered to appropriate patients who are undergoing *BRCA1/2* testing.

- If a multi-gene panel is ordered, the specific panel chosen should take into account the patient's personal and family history. Consultation with a provider experienced in clinical cancer genetics can be helpful in selecting a specific multi-gene panel or interpreting its results and should be made available to patients when possible."

Consensus guidelines for the management of hereditary breast cancer published in 2020 by the ASCO, the SSO, and the American Society for Radiation Oncology include a number of recommendations related to surgery, radiation, and therapy, including the following:[29]

- "Germline *BRCA* status should not preclude a patient with newly diagnosed breast cancer otherwise eligible for breast-conserving therapy (BCT) from receiving BCT. (Type: Formal consensus; Evidence quality: Intermediate; Strength of recommendation: Moderate)

- Surgical management of the index malignancy (BCT v ipsilateral therapeutic and contralateral risk-reducing mastectomy [CRRM]) in *BRCA1/2* mutation carriers should be discussed, considering the increased risk of CBC and possible increased risk of an ipsilateral new primary breast cancer compared with noncarriers. (Type: Formal consensus; Evidence quality: Intermediate; Strength of recommendation: Strong)

- The following factors should be considered for assessing risk of CBC and role of risk-reducing mastectomy in *BRCA1/2* mutation carriers: age at diagnosis (the strongest predictor of future CBC; refer to Table 1 in the original guideline), family history of breast cancer, overall prognosis from this or other cancers (e.g., ovarian), ability of patient to undergo appropriate breast surveillance (magnetic resonance imaging [MRI]), comorbidities, and life expectancy. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)

- *BRCA1/2* mutation carriers who do not have bilateral mastectomy should undergo high-risk breast screening of remaining breast tissue with annual mammogram and MRI. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)

- For women with newly diagnosed breast cancer who have a mutation in a moderate-penetrance breast cancer susceptibility gene, mutation status alone should not determine local therapy decisions for the index tumor or CRRM. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)
- In patients with breast cancer with a mutation in a moderate-penetrance breast cancer susceptibility gene, BCT should be offered to those for whom BCT is an appropriate treatment option. There is a lack of data regarding ipsilateral breast cancer events after BCT among patients with moderate-risk mutations. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)
- The evidence regarding CBC risk is limited for mutations in moderate-penetrance breast cancer genes, aside from some data on *CHEK2* 1100delC. Information about the specific gene and what is known about the risk of CBC should be discussed in the context of shared decision making. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)
- Patients with mutations in moderate-penetrance genes who do not have bilateral mastectomy should undergo high-risk breast screening of remaining breast tissue with annual mammogram and MRI. (Type: Formal consensus; Evidence quality: Low; Strength of recommendation: Moderate)"

SUMMARY

BRCA1, BRCA2, TP53, PALB2*, *PTEN*, *STK11,* and/or *CDH1

There is enough research to show that testing for variants in certain genes can guide treatment decisions and improve health outcomes for people suspected of having hereditary breast or ovarian cancer. In addition, clinical guidelines based on research from the National Comprehensive Cancer Network (NCCN) recommend genetic testing of these genes for certain people. Therefore, testing for variants in *BRCA1, BRCA2, TP53, PALB2, PTEN, STK11, and/or CDH1* may be considered medically necessary when criteria are met.

There is not enough research to show that testing for variants in *BRCA1, BRCA2, TP53, PALB2, PTEN, STK11, and/or CDH1* can improve health outcomes for individuals who do not meet the policy criteria. Therefore, this testing is considered investigational.

Other Genes

There is not enough research to show that testing for genes other than *BRCA1*, *BRCA2*, *BRIP1, RAD51C, RAD51D, PALB2*, *PTEN*, *STK11, CDH1,* and/or *TP53*, including but not limited to *ATM, BARD1,* and *CHEK2* testing, can improve health outcomes for people suspected of having a hereditary breast and ovarian cancer syndrome. While there are a number of genes that are associated with increased risk of breast and/or ovarian cancer, it is not clear that changing patient management based on the results of testing these moderate-penetrance genes will lead to better health outcomes compared to management based on other risk factors such as family history. Therefore, testing for any other genes, including panel testing of *BRCA1*, *BRCA2*, *BRIP1, RAD51C, RAD51D, PALB2*, *PTEN*, *STK11, CDH1,*

and/or *TP53* done in combination with other genes, is considered investigational for determining risk of hereditary breast or ovarian cancer.

CODES

Codes	Number	Description
		Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated
	0103U	Hereditary ovarian cancer (eg, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated [24 genes (sequencing and deletion/duplication); EPCAM (deletion/duplication only)]
	0129U	Hereditary breast cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), genomic sequence analysis and deletion/duplication analysis panel (ATM, BRCA1, BRCA2, CDH1, CHEK2, PALB2, PTEN, and TP53)
	0131U	Hereditary breast cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), targeted mRNA sequence analysis panel (13 genes) (List separately in addition to code for primary procedure) (Use 0131U in conjunction with 81162, 81432, 0102U)
	0132U	Hereditary ovarian cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), targeted mRNA sequence analysis panel (17 genes) (List separately in addition to code for primary procedure) (Use 0132U in conjunction with 81162, 81432, 0103U)
	0235U	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions
	81162	BRCA1, (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis and full duplication/deletion analysis (ie, detection of large gene rearrangement)
	81163	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
	81164	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (ie, detection of large gene rearrangements)
	81165	BRCA1 (BRCA1, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
	81166	BRCA1 (BRCA1, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (ie, detection of large gene rearrangements)
	81167	BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (ie, detection of large gene rearrangements)
	81212	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; 185delAG, 5385insC, 6174delT variants

Codes	Number	Description
	81215	BRCA1 (BRCA1, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; known familial variant
	81216	BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
	81217	BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; known familial variant
	81307	PALB2 (partner and localizer of BRCA2) (eg, breast and pancreatic cancer) gene analysis; full gene sequence
	81308	PALB2 (partner and localizer of BRCA2) (eg, breast and pancreatic cancer) gene analysis; known familial variant
	81321	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; full sequence analysis
	81322	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; known familial variant
	81323	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; duplication/deletion variant
	81351	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; full gene sequence
	81352	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; targeted sequence analysis (eg, 4 oncology)
	81353	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; known familial variant
	81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
	81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
	81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
	81432	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer, hereditary pancreatic cancer, hereditary prostate cancer), genomic sequence analysis panel, 5 or more genes, interrogation for sequence variants and copy number variants; genomic sequence analysis panel, must include sequencing of at least 10 genes, always including BRCA1, BRCA2, CDH1, MLH1, MSH2, MSH6, PALB2, PTEN, STK11, and TP53
	~~81433~~	~~Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); duplication/deletion analysis panel, must include analyses for BRCA1, BRCA2, MLH1, MSH2, and STK11~~ (Deleted 01/01/2025)
	81479	Unlisted molecular pathology procedure
HCPCS	None	

Appendix 1 Recommended Testing Strategy

- Individuals meeting the criteria above should be tested for *BRCA1* and *BRCA2* variants
- Individuals with a known familial BRCA variant
    - Targeted testing for the specific variant is recommended

Appendix 1 Recommended Testing Strategy

- Individuals with unknown familial BRCA variant
  - Non-Ashkenazi Jewish descent
    - If no familial variant can be identified, two possible testing strategies are:
      - Full sequencing followed by testing for common large genomic rearrangements (deletions/duplications) only if sequencing detects no variant (negative result).
      - Alternatively, simultaneous full sequencing and testing for common large genomic rearrangements (also known as comprehensive BRCA testing) may be performed.
    - If comprehensive BRCA testing is negative, testing for uncommon large genomic rearrangements (e.g., BART) may be done.
      - Testing for uncommon large rearrangements should not be done unless both sequencing and testing for common large rearrangements have been performed and are negative.
  - Ashkenazi Jewish descent
    - NCCN recommends testing for the three known founder variants first (i.e., 185delAG and 5182insC in *BRCA1*; 6174delT in *BRCA2*).
    - If testing is negative for the founder variants, comprehensive genetic testing may be considered.

Comprehensive Variant Analysis

Comprehensive variant analysis currently includes sequencing the coding regions and intron/exon splice sites, as well as tests to detect common large deletions and rearrangements that can be missed with sequence analysis alone. Prior to August 2006, testing for large deletions and rearrangements was not performed, thus some patients with familial breast cancer who had negative BRCA testing before this time may consider repeat testing for the rearrangements.

Medical Policy Manual Genetic Testing, Policy No. 05

Apolipoprotein E for Risk Assessment and Management of Cardiovascular Disease

Effective: March 1, 2025

Next Review: December 2025
Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Apolipoprotein E (apo E) genotype has been associated with risk for coronary artery disease (CAD) and may affect responses to lipid-lowering medications. Genetic testing of apo E has been proposed for individual CAD risk assessment and to predict the response to statin therapy.

MEDICAL POLICY CRITERIA

Apolipoprotein E genetic testing is considered **investigational** for the risk assessment and management of cardiovascular disease.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

CROSS REFERENCES

1. Measurement of Lipoprotein-Associated Phospholipase A2 (Lp-PLA2) in the Assessment of Cardiovascular Risk, Laboratory, No. 63

BACKGROUND

Numerous lipid and nonlipid biomarkers have been proposed as potential risk markers for cardiovascular disease. Low-density lipoproteins (LDL) have been identified as the major atherogenic lipoproteins and have long been identified by the National Cholesterol Education Project (NCEP) as the primary target of cholesterol-lowering therapy. LDL particles consist of a surface coat composed of phospholipids, free cholesterol, and apolipoproteins surrounding an inner lipid core composed of cholesterol ester and triglycerides. Traditional lipid risk factors such as LDL-cholesterol (LDL-C), while predictive on a population basis, are weaker markers of risk on an individual basis. Only a minority of subjects with elevated LDL and cholesterol levels will develop clinical disease, and up to 50% of cases of coronary artery disease (CAD) occur in subjects with 'normal' levels of total and LDL-C. Thus, there is considerable potential to improve the accuracy of current cardiovascular risk prediction models.

Apolipoprotein E (apo E) is the primary apolipoprotein found in very-low-density lipoproteins (VLDLs) and chylomicrons. Apo E is the primary binding protein for LDL receptors in the liver and is thought to play an important role in lipid metabolism. The apo E gene is polymorphic, consisting of three alleles (e2, e3, and e4) that code for three protein isoforms, known as E2, E3, and E4, which differ from one another by one amino acid. These molecules mediate lipid metabolism through their different interactions with the LDL receptors. The genotype of apo E alleles can be assessed by gene amplification techniques, or the apo E phenotype can be assessed by measuring plasma levels of apo E.

It has been proposed that various apo E genotypes are more atherogenic than others and that apo E measurement may provide information on risk of CAD above traditional risk factor measurement. It has also been proposed that the apo E genotype may be useful in the selection of specific components of lipid-lowering therapy such as drug selection. In the major lipid-lowering intervention trials, including trials of statin therapy, there is considerable variability in response to therapy that cannot be explained by factors such as compliance. Apo E genotype may be one factor that determines an individual's degree of response to interventions such as statin therapy.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[1] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

A 2002 BlueCross BlueShield Association Technology Evaluation Center (TEC) Assessment[2] summarized the steps necessary to determine utility of a novel cardiac risk factor. Three steps were required:

- Standardization of the measurement of the risk factor.
- Determination of its contribution to risk assessment. As a risk factor, it is important to determine whether the novel risk factor […] independently contributes to risk assessment compared to established risk factors.

- Determination of how the novel risk assessment will be used in the management of the patient, compared to standard methods of assessing risk, and whether any subsequent changes in patient management result in an improvement in patient outcome.

Similarly, the Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III; ATP III) noted that emerging risk factors should be evaluated against the following criteria in order to determine their clinical significance:[3]

- Significant predictive power that is independent of other major risk factors
- A relatively high prevalence in the population (justifying routine measurement in risk assessment)
- Laboratory or clinical measurement must be widely available, well standardized, inexpensive, have accepted population reference values, and be relatively stable biologically
- Preferable, but not necessarily, modification of the risk factor in clinical trials will have shown reduction in risk.

The focus of the following literature appraisal is on evidence related to the clinical utility of testing or the ability of apo E testing to:

- Provide clinically relevant information beyond that provided by traditional lipid measures, and
- Improve health outcomes as a result of patient management decisions that would not otherwise have been made in the absence of apo E testing.

APO E AS A PREDICTOR OF CARDIOVASCULAR DISEASE

A large body of research has established a correlation between lipid levels and the underlying apo E genotype. Numerous studies have focused on the relationship between genotype and physiologic markers of atherosclerotic disease. A number of small- to medium-sized cross-sectional and case-control studies have correlated apo E with surrogate outcomes such as cholesterol levels, markers of inflammation, or carotid intima-media thickness.[4-10] These studies have generally shown a relationship between apo E and these surrogate outcomes. For example, in population studies, the presence of an apo e2 allele was associated with the lowest cholesterol levels and the apo e4 allele was associated with the highest levels.[11, 12] Other studies have suggested that carriers of apo e4 are more likely to develop signs of atherosclerosis independent of total and LDL-cholesterol levels.[13-16]

Some larger observational studies have correlated apo E genotype with clinical disease. For example, the Atherosclerosis Risk in Communities (ARIC) study followed 12,000 middle-aged individuals free of coronary artery disease (CAD) at baseline for 10 years.[17] This study reported that the e3/2 genotype was associated with carotid artery atherosclerosis after controlling for other atherosclerotic risk factors. Volcik (2006) reported that apo E polymorphisms were associated with LDL levels and carotid intima-media thickness but were not predictive of incident CAD.[18] A British birth cohort study found apo e2 genotypes to be associated with both deep and lobar intracerebral hemorrhage (ICH). APO e4 and apo e2/4 genotypes had selective associations with ICH in case-control and age-adjusted analyses.[19] However, Ajnakina (2023) published a study using data from the English Longitudinal Study of Aging (ELSA) that did not find an association between *APO-ε4* status and cardiovascular disease deaths in 7,131 adults aged ≥50 years with 10 years of follow-up.[20]

Shao (2022) conducted a meta-analysis of 32 studies to analyze the correlation between APOE polymorphisms and risk of myocardial infarction (MI).[21] The studies included 13,706 cases of MI and 14,817 controls. Pooled analysis using the random-effects model found the apo e4 genotypes were associated with the highest risk of MI (OR 1.24, 95% CI 1.09-1.42) and MI frequency was lowest in people with apo e2 genotypes (OR 0.74, 95% CI 0.64-0.86).

Sofat (2016) published a meta-analysis of three studies of circulating apo E and CVD events.[22] The method for selecting the studies was not described. The three studies included 9,587 participants and 1,413 CVD events. In the pooled analysis, there was no association of apo E with CVD events. The unadjusted odds ratio (OR) for CVD events for a standard deviation increase in apo E concentration was 1.02 (95% CI, 0.96 to 1.09). After adjustment for other cardiovascular risk factors, the OR for CVD for a standard deviation increase in apo E concentration was 0.97 (95% CI 0.82 to 1.15).

A systematic review by Zhao (2017) assessed the link between apo E polymorphisms and premature CAD.[23] Premature CAD (PAD) was defined as CAD in males below age 55 and females below age 65. The review included 18 research reports with a low to moderate risk of bias, for a total of 2,361 cases of PCAD and 2,811 controls. Overall, the e2 allele was not significantly associated with PCAD. However, when results were stratified by race, the e2 allele appeared to increase the risk of PCAD in Asians (OR 1.54, 95% CI 1.09 to 2.17, as compared to the e3 allele), while a protective effect was seen in Caucasians (OR 0.77, 95% CI 0.62 to 0.95, as compared to the e3 allele). Subgroup analysis showed a decreased risk of myocardial infarction associated with e2 compared to e3 (OR 0.70, 95% CI 0.49 to 0.98). Overall, the e4 allele was associated with greater risk of PCAD (OR 1.62, 95% CI 1.27 to 2.06). This increased risk was seen for all racial groups.

An earlier meta-analysis published by Bennet (2007) summarized the evidence from 147 studies on the association of apo E genotypes with lipid levels and cardiac risk.[24] Eighty-two studies included data on the association of apo E with lipid levels, and 121 studies reported the association with clinical outcomes. The authors reported that patients with the apo e2 allele had LDL levels that were approximately 31% less compared with patients with the apo e4 allele. Patients with the apo e3 allele had an approximately 20% decreased risk for coronary events compared with patients with apo e2 (OR 0.80, 95% CI 0.70 to 0.90), and patients with the apo e4 had an estimated 6% higher risk of coronary events that was not statistically significant (OR 1.06, 95% CI 0.99 to 1.13).

No studies were identified that compared the health outcomes of patient management based on apo E genotypes compared with patient management based on conventional risk assessment measures such as LDL. Therefore, it is unclear how the associations reported above can be used to improve health outcomes over current patient management procedures.

APO E AS A PREDICTOR OF RESPONSE TO THERAPY

Apo E has been investigated as a predictor of response to therapy by examining apo E alleles in the intervention arm(s) of lipid-lowering trials. Some data have suggested that patients with an apo e4 allele may respond better to diet-modification strategies.[25-27] King (2022) found that people who were given nutritional advice tailored to their apo e4 genotype modified their diet.[28] Subjects with apo e4 genotypes associated with increased CVD risk who ate higher than recommended levels of saturated fat reduced their fat intake (p=0.012) to recommended levels after hearing genotype-specific dietary advice (p=0.409). Participants with non-risk apo e4 genotypes who ate higher than recommended levels of saturated fat also reduced their fat

intake (p=0.001) after nutritional advice but continued to consume significantly higher than recommended levels of saturated fat (p=0.007). However, the number of participants who had both the risk-associated genotype and the risk-associated diet at baseline was small (n=9). Other studies have suggested that response to statin therapy may vary with apo E genotype and that the e2 allele indicates greater responsiveness to statins.[25, 27, 29-32] There is also evidence that apo e2 correlates with superior response to long-term aspirin therapy in people with existing cardiovascular disease.[33]

No studies were identified that directly compared the health outcomes of patient management that was based on apo E status with those based on conventional measures.

PRACTICE GUIDELINE SUMMARY

No clinical practice guidelines or position statements from U.S. professional associations were identified that recommended the use of apo E in cardiovascular risk assessment, including but not limited to the following:

- The 2021 National Lipid Association (NLA) scientific statement on lipid measurements in cardiovascular disease.[34]
- The 2020 National Lipid Association (NLA) scientific statement on genetic testing in dyslipidemia[35]
- The 2013 American College of Cardiology/American Heart Association guidelines for the assessment of cardiovascular risk in asymptomatic patients.[36]
- The 2019 U.S. Preventive Services Task Force (USPSTF) recommendations on the use of nontraditional risk factors for the assessment of coronary heart disease.
- The American Diabetes Association and the American College of Cardiology Foundation consensus conference publication.[37]

SUMMARY

APO E AS A PREDICTOR OF CARDIOVASCULAR DISEASE

There is some research that shows that apolipoprotein E (apo E) genotype may have an effect on cholesterol levels and risk for coronary artery disease (CAD). However, there is not enough research to show that testing for apo E genotype helps to improve health outcomes for people at risk for CAD. There are no clinical guidelines based on research that recommend testing apo E genotype for cardiovascular risk. Therefore, the use of apo E measurements in the risk assessment and management of cardiovascular disease is considered investigational.

APO E AS A PREDICTOR OF RESPONSE TO THERAPY

There is not enough research to show that genetic testing of apolipoprotein E (apo E) can improve health outcomes for people that are considering starting a statin medication to reduce their cardiovascular risk. Therefore, apo E testing to predict response to lipid-lowering therapy is considered investigational.

Genetic Testing for Lynch Syndrome and APC-associated and MUTYH-associated Polyposis Syndromes

Effective: January 1, 2025

Next Review: October 2025
Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

There are hereditary conditions that predispose affected individuals to colorectal cancer (CRC), including MUTYH-associated polyposis (MAP), familial adenomatous polyposis (FAP) with associated variants (collectively referred to as APC-associated polyposis), and Lynch syndrome (formerly known as hereditary nonpolyposis colorectal cancer, or HNPCC).

MEDICAL POLICY CRITERIA

Note: This policy only addresses testing for Lynch syndrome and APC-associated and MUTYH-associated polyposis syndromes.

I. Genetic testing for *APC*, *MUTYH*, mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*) and/or *EPCAM* gene variants may be considered **medically necessary** when any one of the following criteria is met:

   A. At-risk relatives (see Policy Guidelines) of patients with either of the following:

      1. Familial adenomatous polyposis (FAP); or

      2. A known *APC*, *MUTYH*, *MLH1*, *MSH2*, *MSH6*, *PMS2* and/or *EPCAM* disease-

associated variant.

B. Patients with a differential diagnosis of attenuated FAP vs. MUTYH-associated polyposis vs. Lynch syndrome

C. Lynch syndrome is suspected in patients with colorectal cancer or endometrial cancer

D. Lynch syndrome is suspected in patients *without* colorectal or endometrial cancer (including both cancer-free individuals and individuals with a Lynch-associated cancer other than colorectal or endometrial cancer, see below), when no affected family members have been tested for MMR or *EPCAM* variants, and one or more of the following is met:

1. A first-degree relative with a colorectal or endometrial cancer diagnosed before age 50
2. A first-degree relative with both of the following (a. and b.):
   a. Colorectal or endometrial cancer; and
   b. A second Lynch syndrome-associated cancer (cancer of the colon/rectum, endometrium, stomach, ovary, pancreas, bladder, ureter, renal pelvis, biliary tract, brain [usually glioblastomas], or small intestine, or a sebaceous adenoma, sebaceous carcinoma, or keratoacanthomas)
3. Two or more first- or second-degree relatives (from the same side of the family) with Lynch syndrome-associated cancers, including one diagnosed before age 50
4. Three or more first- or second-degree relatives (from the same side of the family) with Lynch syndrome-associated cancers
5. Two colorectal cancers in first-degree relatives involving at least two generations, with at least one individual diagnosed by age 55
6. Documentation of 5% or higher predicted risk of the syndrome on a risk prediction model, such as MMRpro, PREMM5, or MMRpredict

II. Genetic testing for *BRAF* variants or *MLH1* promoter methylation may be considered **medically necessary** to exclude a diagnosis of Lynch syndrome when MLH1 protein is not expressed on immunohistochemical (IHC) analysis.

III. Genetic testing for Lynch, APC-associated, and MUTYH-associated polyposis syndromes that does not meet the medical necessity criteria (I or II) is considered **investigational**, including but not limited to panel tests that include genes other than *APC*, *MUTYH*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, and/or *EPCAM*.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Genes Associated with Lynch and Polyposis Syndromes: Genes associated with Lynch and polyposis syndromes include the following: *APC, MUTYH, MLH1, MSH2, MSH6, PMS2* and *EPCAM* genes.

Definition of At-risk Relatives: *At-risk relatives* refers to first- and second-degree relatives of the patient. First-degree relatives include an individual's parents, siblings, and children.

Lynch-Associated Cancers: Lynch-associated cancers include cancers of the colon/rectum, endometrium, stomach, ovary, pancreas, bladder, ureter, renal pelvis, biliary tract, brain (usually glioblastomas), and small intestine, as well as sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas.

Patients with Colorectal or Endometrial Cancer: When tumor tissue is available for testing either the microsatellite instability (MSI) test or the immunohistochemistry (IHC) test with or without *BRAF* gene variant testing should be used as an initial evaluation of tumor tissue prior to MMR gene analysis.

Risk Prediction Models: Multiple risk prediction models that provide quantitative estimates of the likelihood of an MMR variant are available, such as MMRpro[1], PREMM$_5$[2], or MMRpredict[3].

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing?
6. Medical records related to this genetic test
   - o History and physical exam
   - o Conventional testing and outcomes
   - o Conservative treatment provided, if any

BACKGROUND

APC-ASSOCIATED POLYPOSIS

Recommendations for patient surveillance and cancer prevention vary according to the syndrome, therefore it is important to distinguish among classical FAP, attenuated FAP, and MUTYH-associated polyposis (MAP [mono- or biallelic]) by genetic analysis.

Familial Adenomatous Polyposis (FAP) (also known as Classical FAP)

FAP is characterized by the presence of hundreds to thousands of precancerous colon polyps, appearing on average at 16 years of age. If left untreated, all affected individuals eventually develop CRC. The mean age of CRC diagnosis in untreated individuals is 39 years.

Germline variants in the adenomatous polyposis coli (*APC*) gene, located on chromosome five, are responsible for FAP and are inherited in an autosomal dominant manner.

Gardner Syndrome

FAP may also be associated with osteomas of the jaw, skull, and limbs; sebaceous cysts; and pigmented spots on the retina referred to as congenital hypertrophy of the retinal pigment epithelium (CHRPE). These collective extraintestinal manifestations of FAP are referred to as Gardner Syndrome.

Turcot Syndrome

When associated with central nervous system (CNS) tumors, FAP is referred to as Turcot syndrome.

Attenuated FAP (AFAP)

Like FAP, AFAP is characterized by a significant risk for CRC as well, but there are fewer precancerous colonic polyps (10-99, 30 on average). The average age of CRC diagnosis in AFAP patients is 50-55 years. The disorder is associated with fewer extraintestinal cancers than FAP but with a significantly higher risk compared to the general population. The lifetime risk of CRC in individuals with AFAP is about 70% by the age of 80.

AFAP is inherited in an autosomal dominant manner and explained by germline variants in the *APC* gene as well. However, fewer than 30% of AFAP patients have *APC* variants and may have variants in the MUTYH gene instead (see below).

MUTYH-Associated Polyposis (MAP) (formerly MYH-associated polyposis)

MAP occurs with a similar frequency to FAP. While MAP also has clinical features similar to FAP or AFAP, a strong multigenerational family history of polyposis is absent. In contrast to FAP and AFAP, MAP is explained by variants in the *MUTYH* gene and is inherited in an autosomal recessive manner. Biallelic *MUTYH* variants are associated with a cumulative CRC risk of about 80% by age 70. Monoallelic *MUTYH* variant-associated risk of CRC appears to be relatively minimal, although the risk is still under debate.

LYNCH SYNDROME

Lynch syndrome (formerly known as hereditary nonpolyposis colorectal cancer or HNPCC) is a hereditary disorder characterized by a high predisposition to colon cancer (27-45% for men and 22-38% for women by age 70) and cancers of the endometrium, stomach, ovary, pancreas, ureter, renal pelvis, biliary tract, brain (usually glioblastomas), sebaceous gland adenomas and keratoacanthomas, and small intestine.[4, 5] These cancers are sometimes

collectively referred to as HNPCC- or Lynch syndrome-associated cancers. The syndrome is estimated to account for approximately 3% of colorectal and endometrial cancers.[6] Lynch syndrome is also estimated to account for 2% of all endometrial cancers in women and 10% of endometrial cancer in women under 50 years of age. Female carriers of the germline variants *MLH1*, *MSH2*, *MSH6* and *PMS2* have an estimated 40%-62% lifetime risk of developing endometrial cancer, as well as a 4%-12% lifetime risk of ovarian cancer.

Lynch Syndrome and Variants in Mismatch Repair (MMR) Genes

Lynch syndrome is inherited in an autosomal dominant manner and may be caused by any of a large number of possible variants in one of the several mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*, and rarely *MLH3*, *PSM1* and *EXO1*). Variants in MMR genes prevent normal DNA repair in the repetitive DNA sequences called microsatellites. This results in microsatellite instability (MSI) and ultimately leads to an increased risk for malignancy.

A majority (70%) of Lynch syndrome patients have variants in either *MLH1* or *MSH2*, and testing for MMR gene variants is often limited to these two genes. If results are negative, *MSH6* and *PMS2* genes may be tested for variants next. Large gene sizes and the difficulty of detecting variants in these genes make direct sequencing a time- and cost- consuming process. Therefore, additional indirect screening methods are needed to determine which patients should proceed to direct sequencing for MMR gene variants. Available tumor screening methods include MSI testing and immunohistochemical (IHC) testing.

BRAF V600E testing is an optional screening method that may be used in conjunction with IHC testing for *MLH1* to improve efficiency. A methylation analysis of the *MLH1* gene can largely substitute for *BRAF* testing or be used in combination to slightly improve efficiency. *MLH1* gene methylation largely correlates with the presence of *BRAF*-V600E and in combination with BRAF testing can accurately separate Lynch from sporadic CRC in IHC *MLH1*-negative cases.[7] Therefore, *BRAF*-positive samples need not be further tested by MLH1 sequencing.

Lynch Syndrome and Variants in Non-Mismatch Repair (non-MMR) Genes

Deletions in the non-MMR *EPCAM* (epithelial cell adhesion molecule) gene may result in inactivation of the non-mutated *MSH2* gene, thereby causing Lynch syndrome. *EPCAM* testing has been added to many Lynch syndrome profiles and is conducted only when tumor tissue screening results are MSI-high, and IHC shows a lack of *MSH2* expression, but no *MSH2* variant is found by sequencing.

AMSTERDAM AND BETHESDA CRITERIA

The objective of the Amsterdam I and revised Amsterdam II criteria is to define families that are very likely to have Lynch syndrome.[6] In another words, these criteria aim to “establish the diagnosis of Lynch syndrome based upon familial clustering of HNPCC-related tumors.”[8] The revised Amsterdam II criteria are broader than Amsterdam I as they consider both colorectal *and* HNPCC-associated cancers in the assessment.[6] The Amsterdam criteria were originally developed by the International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer (ICG-HNPCC) in order to standardize family selection criteria for collaborative research on Lynch syndrome. Consequently, these criteria are not without limitations when applied to clinical diagnosis. In recent years, “family history is considered less useful as the first step in identifying Lynch syndrome in individuals *with* newly diagnosed CRC than strategies involving

the analysis of tumor samples (e.g., MSI, IHC)."[9, 10] However, family history is still considered "an important component of cancer risk assessment in the general population"[10]

The Bethesda criteria were developed with a different purpose than the Amsterdam criteria.[4, 11] They were designed to "help predict which patients *with* colorectal cancer are likely to have a mismatch-repair variant and should thus undergo further testing."[8]

REGULATORY STATUS

The majority of genetic tests are laboratory derived tests that are not subject to U.S. Food and Drug Administration (FDA) approval. Labs are subject to Clinical Laboratory Improvement Amendment (CLIA) regulations that monitor high-complexity testing.

Genetic Testing Panels

Sequencing of FAP, AFAP, MUTYH or Lynch syndrome variants may be offered in combination with other gene or chromosomal microarray tests that are not associated with Lynch syndrome or FAP. Medical necessity must be established for each genetic test included in a panel. When FAP, AFAP, MUTYH or Lynch syndrome analysis is bundled with any other genetic test, additional Medical Policies may apply.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[12] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

FAP GENETIC TESTING

The initial policy evidence for FAP genetic testing was based on a 1998 TEC Assessment[13], which offered the following conclusions:

- Genetic testing for familial adenomatous polyposis (FAP) may improve health outcomes by identifying which currently unaffected at-risk family members require intense surveillance or prophylactic colectomy.
- At-risk subjects are considered to be those with greater than 10 adenomatous polyps; or close relatives of patients with clinically diagnosed FAP or of patients with an identified *APC* variant.
- The optimal testing strategy is to define the specific genetic variant in an affected family member and then test the unaffected family members to see if they have inherited the same variant.

The additional policy information on attenuated FAP and on MUTYH-associated polyposis diagnostic criteria and genetic testing is based on information from GeneReviews[14] and from several publications[15-19] that build on prior, cited research.

LYNCH SYNDROME AND COLORECTAL CANCER GENETIC TESTING

MISMATCH REPAIR (MMR) GENETIC TESTING

Agency for Healthcare Research and Quality (AHRQ) / Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Evidence Assessment

The policy evidence for Lynch syndrome genetic testing in CRC patients was initially based on an evidence report published by the AHRQ[20], a supplemental assessment to that report contracted by the EGAPP Working Group[9], and an EGAPP recommendation for genetic testing in CRC.[10] Based on the AHRQ report and supplemental assessment, the EGAPP report came to the following conclusions regarding genetic testing for MMR variants in patients already diagnosed with CRC:

- Family history, while important information to elicit and consider in each case, has poor sensitivity and specificity as a screening test to determine who should be considered for MMR mutation testing and should not be used as a sole determinant or screening test.
- MSI and IHC screening tests for MMR mutations have similar sensitivity and specificity. MSI screening has a sensitivity of about 89% for *MLH1* and *MSH2* and 77% for *MSH6*, and a specificity of about 90% for all. It is likely that, using high quality MSI testing methods, these parameters can be improved. IHC screening has a sensitivity for *MLH1*, *MSH2*, and *MSH6* of about 83% and a specificity of about 90% for all.
- Optional BRAF testing can be used to reduce the number of patients, who are negative for *MLH1* expression by IHC, needing *MLH1* gene sequencing, thus improving efficiency without reducing sensitivity for MMR mutations.
- A chain of indirect evidence can be constructed for the clinical utility of testing all patients with CRC for MMR mutations.
    - The chain of indirect evidence from well-designed experimental nonrandomized studies (as noted below) is adequate to demonstrate the clinical utility of testing unaffected (without cancer) first- and second-degree relatives of patients with Lynch syndrome who have a known MMR mutation.
    - Seven studies examined how counseling affected testing and surveillance choices among unaffected family members of Lynch syndrome patients. About half of relatives received counseling, and 95% of these chose MMR gene mutation testing. Among those positive for MMR gene mutations, uptake of colonoscopic surveillance beginning at age 20 to 25 years was high at 53% to 100%.
        - One long-term, nonrandomized controlled study and one cohort study of Lynch syndrome family members found significant reductions in CRC among those who followed recommended colonic surveillance vs. those who did not.
        - Surveillance, prevention for other Lynch syndrome cancers (for detail, refer to last outline bullet)
    - The chain of evidence from descriptive studies and expert opinion (as noted below) is inadequate (inconclusive) to demonstrate the clinical utility of testing the probands with Lynch syndrome (i.e., cancer index patient).
        - Subtotal colectomy is recommended as an alternative to segmental resection, but has not been shown superior in follow-up studies
        - Although a small body of evidence suggests that MSI-positive tumors are resistant to 5-fluorouracil and more sensitive to irinotecan than MSI-negative tumors, no alteration in therapy according to MSI status has yet been recommended.

- Surveillance, prevention for other Lynch syndrome cancers:
  - While invasive and not recommended, women may choose hysterectomy with salpingo-oophorectomy to prevent gynecologic cancer. In one retrospective study, women who chose this option had no gynecologic cancer over 10 years whereas about one-third of women who did not have surgery developed endometrial cancer, and 5.5% developed ovarian cancer
  - In one study, surveillance endometrial biopsy detected endometrial cancer and potentially precancerous conditions at earlier stages in those with Lynch syndrome but results were not statistically significant and a survival benefit has yet to be shown.[21] Transvaginal ultrasound (TVUS) is not a highly effective surveillance mechanism for endometrial cancer in patients with Lynch syndrome; however, TVUS in conjunction with endometrial biopsy has been recommended for surveillance.
  - Gastroduodenoscopy for gastric cancer surveillance and urine cytology for urinary tract cancer surveillance are recommended based on expert opinion only, in the absence of adequate supportive evidence.

Based on an indirect chain of evidence with adequate evidence of benefit to unaffected family members found to have Lynch syndrome, the EGAPP working group recommended testing all patients with CRC for MMR gene variants. Although MMR gene sequencing of all patients is the most sensitive strategy, it is highly inefficient and cost-ineffective and not recommended. Rather, a screening strategy of MSI or IHC testing (with or without optional *BRAF* testing) is recommended and retains a relatively high sensitivity. Although a particular strategy was not recommended by the EGAPP Working Group, several are potentially effective; efficiency and cost-effectiveness may depend upon local factors.

American Society of Clinical Oncology (ASCO)/ Society of Surgical Oncology (SSO) Recommendations

As the EGAPP recommendations have noted, the evidence to date is limited regarding benefits derived from patients with CRC who undergo testing and are found to have Lynch syndrome. However, professional societies have reviewed the evidence and concluded that genetic testing likely has direct benefits for at least some patients with CRC and Lynch syndrome who choose prophylactic surgical treatment.

Early documentation of the natural history of CRC in highly selected families with a strong history of hereditary CRC indicated risks of synchronous and metachronous cancers as high as 18% and 24%[22] in patients who already had CRC. As a result, in 1996, the Cancer Genetic Studies Consortium, a temporary NIH-appointed body, recommended that if CRC is diagnosed in patients with an identified variant or a strong family history, a subtotal colectomy with ileorectal anastomosis (IRA) should be considered in preference to segmental resection.[23] Although the average risk of a second primary is now estimated to be somewhat lower overall in patients with Lynch syndrome and CRC, effective prevention measures remain imperative. One study suggested that subtotal colectomy with IRA markedly reduced the incidence of second surgery for metachronous cancer from 28% to 6% but could not rule out the impact of surveillance.[24] A mathematical model comparing total colectomy and IRA to hemicolectomy resulted in increased life expectancies of 2.3, 1, and 0.3 years for ages 27, 47, and 67,

respectively; for Duke's A, life expectancies for the same ages are 3.4, 1.5, and 0.4, respectively.[25] Based on this work, the joint ASCO and SSO review of risk-reducing surgery in hereditary cancers recommends offering both options to the patient with Lynch syndrome and CRC, especially those who are younger.[26] This ASCO/SSO review also recommends offering Lynch syndrome patients with an index rectal cancer the options of total proctocolectomy with ileal pouch anal anastomosis or anterior proctosigmoidectomy with primary reconstruction. The rationale for total proctocolectomy is the 17% to 45% rate of metachronous colon cancer in the remaining colon after an index rectal cancer in Lynch syndrome patients.

Vos (2020) evaluated the yield to detect Lynch syndrome in a prospective cohort of 3,602 newly diagnosed CRC cases below age 70.[27] The standard testing protocol included IHC or MSI testing, followed by *MLH1* hypermethylation testing. Testing identified *MLH1* hypermethylation in a majority of cases tested (66% of 264). The percentage of MMR deficient CRC explained by hypermethylation increased with age, while the percentage of patients with hereditary CRC decreased with age. Of the 47 patients who underwent genetic testing, 55% (26/47) were determined to have Lynch syndrome. The authors estimated that only 78% of these cases would have been identified by the revised Bethesda guidelines. The percentage by age was 86% (6/7) in those under 40 years, 57% (17/29) in patients aged 40 to 64 years, and 30% (3/10) in patients 65 to 69 years of age and the number needed to test to identify one case of Lynch syndrome after prescreening was 1.2 (95% confidence interval [CI] 1.0 to 2.0) in patients under 40 years, 4.1 (95% CI 3.1 to 5.5) in patients 40 to 64 years of age, and 21 (95% CI 11 to 43) in CRC patients aged 65 to 69.

EPCAM TESTING

Several studies characterized *EPCAM* deletions and established their correlation with the presence of *EPCAM-MSH2* fusion messenger RNAs (apparently non-functional) and with the presence of *MSH2* promoter hypermethylation, and, most importantly, have shown the co-segregation of these *EPCAM* variants with Lynch-like disease in families.[28-33] Because studies differ slightly in how patients were selected, prevalence of these *EPCAM* variants is difficult to estimate, but may be in the range of 20% to 40% of patients/families who meet Lynch syndrome criteria, do not have a MMR variant, but have MSI-high tumor tissue. Kempers (2011) reported that carriers of an *EPCAM* deletion had a 75% (95% CI 65 to 85) cumulative risk of CRC by age 70, not significantly different from that of carriers of an *MSH2* deletion (77%, 95% CI 64 to 90); mean age at diagnosis was 43 years. However, the cumulative risk of endometrial cancer was low at 12% (95% CI 0 to 27) by age 70, compared to carriers of a variant in *MSH2* (51%, 95% CI 33 to 69, p=0.0006).[34]

BRAF TESTING

BRAF V600E or *MLH1* promoter methylation testing are optional screening methods that may be used when IHC testing shows a loss of MLH1 protein expression by IHC testing for *MLH1*. The presence of *BRAF* V600E or absence of MLH1 protein expression rarely occurs in Lynch syndrome and would eliminate the need for further germline variant analysis for a Lynch syndrome diagnosis.[7, 35, 36]

Capper (2013) reported on a technique of *BRAF* V600E-specific (VE1) IHC testing for *BRAF* variants on a series of 91 MSI-H CRC patients.[37] The authors detected *BRAF*-mutated CRC with 100% sensitivity and 98.8% specificity. VE1 positive lesions were detected in 21% of *MLH1*-negative CRC patients who could be excluded from MMR germline testing for Lynch syndrome. Although additional studies are needed to confirm the efficacy of this technique,

VE1 IHC testing for *BRAF* may be an alternative to *MLH1* promoter methylation analysis and a method for avoiding further MMR testing.

LYNCH SYNDROME AND ENDOMETRIAL CANCER GENETIC TESTING

The ASCO/SSO review discussed above also recommends offering prophylactic total abdominal hysterectomy to female patients with CRC who have completed childbearing or to women undergoing abdominal surgery for other conditions, especially when there is a family history of endometrial cancer.[26] This recommendation is based on the high rate of endometrial cancer in variant-positive individuals (30 to 64% in studies that may be biased by strong family history; overall, possibly as low as 20 to 25%[11]) and the lack of efficacy of screening.

The estimated the risk of endometrial cancer in variant carriers is 34% by age 70 (95% CI 17 to 60%), and of ovarian cancer is 8% by age 70 (95% CI 2 to 39%).[38] Risks do not appear to appreciably increase until after age 40. When surgery is chosen, oophorectomy should also be performed because of the high incidence of ovarian cancer in Lynch syndrome (12%).[24] As already noted, in one retrospective study, women who chose this option had no gynecologic cancer over 10 years whereas about one-third of women who did not have surgery developed endometrial cancer, and 5.5% developed ovarian cancer.[9]

In another retrospective cohort study, hysterectomy improved survival among female colon cancer survivors with Lynch syndrome.[39] This study estimated that for every 100 women diagnosed with Lynch syndrome-associated CRC, about 23 will be diagnosed with endometrial cancer within 10 years absent a hysterectomy. Recent data on variant-specific risks suggests that prophylactic gynecological surgery benefits for carriers of *MSH6* variants may offer less obvious benefits compared to harms as lifetime risk of endometrial cancer is lower than for carriers of *MLH1* or *MSH2* variants, and lifetime risk of ovarian cancer is similar to the risk for the general population.[38] An alternative to prophylactic surgery is surveillance for endometrial cancer using transvaginal ultrasound and endometrial biopsy. Evidence indicates that such surveillance significantly reduces the risk of interval cancers, but no evidence as yet indicates surveillance reduces mortality due to endometrial cancer. Surveillance in Lynch syndrome populations for ovarian cancer has not yet been demonstrated to be successful at improving survival.

Several groups have recommended screening endometrial cancer patients for Lynch syndrome. At the 2010 Jerusalem Workshop on Lynch Syndrome it was proposed that all incident cases of endometrial cancer be screened for Lynch syndrome using MMR-IH.[40] Clarke and Cooper (2012) noted that Sloan Kettering Cancer Center screens all patients less than 50 years of age with endometrial cancer using MMR-IHC, as well as patients older than 50 with suggestive tumor morphology, lower uterine segment (LUS) location, personal/family history, or synchronous cell carcinoma of the ovary.[41] Kwon (2011) recommended MMR-IHC screening of women with endometrial cancer at any age with at least one first-degree relative with a Lynch syndrome associated cancer.[42]

However, in the case of *EPCAM* deletion carriers, three studies found three cases of endometrial cancer in 103 female carriers who did not undergo preventive hysterectomy.[34, 43, 44] Women with *EPCAM* deletions consequently have a life-time risk of developing endometrial cancer decreased by 10-fold when compared with MMR gene variant carriers. This might support a clinical management scenario rather than prophylactic surgery.[43]

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)[45]

Lynch Syndrome

The NCCN Genetic/Familial High-Risk Assessment: Colorectal guidelines (v.3.2024) recommend that all colorectal and endometrial cancers should undergo tumor testing with MSI and/or IHC for the four MMR genes and *EPCAM*.

The guidelines state that direct referral for germline genetic testing to rule out Lynch syndrome may be preferred in patients with a strong family history or if diagnosed before age 50.

Criteria that may justify Lynch syndrome testing according to this guideline are:

- A known Lynch syndrome variant in the family
- MMR deficiency on tumor testing
- Diagnosis of a Lynch syndrome-related cancer, and:
    - Cancer diagnosis prior to age 50, or
    - A synchronous or metachronous Lynch syndrome-related cancer, or
    - One first- or second-degree relative with a Lynch syndrome-related cancer diagnosed before age 50, or
    - Two or more first- or second-degree relatives with a Lynch syndrome-related cancer, regardless of age
- A family history of any of the following (on the same side of the family):
    - One or more first-degree relatives with colorectal or endometrial cancer diagnosed before age 50
    - One or more first-degree relatives with a colorectal or endometrial cancer and another synchronous or metachronous Lynch syndrome-related cancer
    - Two or more first- or second-degree relatives with Lynch syndrome-related cancers, including at least one diagnosed before age 50
    - Three or more first- or second-degree relatives with Lynch syndrome-related cancers, regardless of age
- A >5% risk based on predictive models (e.g., MMRpro, PREMM$_5$, or MMRpredict

The guideline also indicated that abnormal *MLH1* expression by IHC in colorectal or endometrial cancers should be followed by tumor *MLH1* promoter methylation testing, or, for CRCs, testing for a *BRAF* V600E variant prior to genetic testing to exclude a diagnosis of Lynch syndrome. However, the guideline notes, “the absence of a *BRAF* V600E [pathogenic variant] does not rule out *MLH1* methylation.”

Polyposis Syndrome

The NCCN guidelines also address familial adenomatous polyposis (classical and attenuated) and *MUTYH*-associated polyposis, and they recommend genetic testing for patients with a personal history of 20 or more adenomas, known familial pathogenic variants in adenomatous polyposis genes, or multifocal/bilateral congenital hypertrophy of retinal pigment epithelium (CHRPE). Additionally, they recommend considering genetic testing for those with a personal history of 10 to 19 adenomas, unilateral CHRPE, some adenomas and clinical indications of serrated polyposis syndrome, a personal history of other APC-associated cancers (desmoid tumor, hepatoblastoma, cribriform-morular variant of papillary thyroid cancer), or to differentiate AFAP from MAP or other types of colonic polyposis.

AMERICAN COLLEGE OF GASTROENTEROLOGY

The American College of Gastroenterology (ACG) issued practice guidelines for the management of patients with hereditary gastrointestinal cancer syndromes.[46]

Lynch Syndrome

ACG recommends that all newly diagnosed CRCs should be evaluated for mismatch repair deficiency, and that analysis may be done by immunohistochemical (IHC) testing for the *MLH1/MSH2/MSH6/PMS2* proteins and/or testing for microsatellite instability; tumors that demonstrate loss of *MLH1* should undergo *BRAF* testing or analysis for *MLH1* promoter hypermethylation. Individuals who have a personal history of a tumor showing evidence of mismatch repair deficiency (and no demonstrated *BRAF* variant or hypermethylation of *MLH1*), a known family variant associated with LS, or a risk of ≥5% chance of LS based on risk prediction models should undergo genetic evaluation for LS. Genetic testing of patients with suspected LS should include germline variant genetic testing for the *MLH1*, *MSH2*, *MSH6*, *PMS2*, and/or *EPCAM* genes or the altered gene(s) indicated by IHC testing.

Adenomatous polyposis syndromes

Individuals who have a personal history of more than 10 cumulative colorectal adenomas, a family history of one of the adenomatous polyposis syndromes, or a history of adenomas and FAP-type extracolonic manifestations (duodenal/ampullary adenomas, desmoid tumors, papillary thyroid cancer, congenital hypertrophy of the retinal pigment epithelium, epidermal cysts, osteomas) should undergo assessment for the adenomatous polyposis syndromes. Genetic testing of patients with suspected adenomatous polyposis syndromes should include *APC* and *MUTYH* gene variant analysis.

U.S. MULTI-SOCIETY TASK FORCE ON COLORECTAL CANCER

In 2014, the Multi-Society Task Force published guidelines regarding Lynch syndrome testing and indicated, “the use of genetic panels might uncover patients and families with forms of attenuated polyposis, such as *MYH*-associated polyposis, attenuated familial adenomatous polyposis, and polymerase proofreading polyposis; there is often blurring of the clinical presentations of these syndromes and LS (Lynch Syndrome).”[47]

SUMMARY

There is enough research to show that genetic testing for *APC*, *MUTYH*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, and *EPCAM* can improve health outcomes for some cancer patients and their families. There are many clinical practice guidelines that recommend genetic testing for certain people at high risk for these colorectal cancer syndromes. Therefore, genetic testing for any combination of these genes variants may be considered medically necessary when policy criteria are met.

There is enough research to show that tumor testing for a *BRAF* variant can help to diagnose Lynch syndrome in patients with a particular type of colorectal tumor, which can improve health outcomes for patients and their families. Therefore, testing for *BRAF* variants or *MLH1* promoter methylation may be considered medically necessary when policy criteria are met.

There is not enough research to show that genetic testing for Lynch, APC-associated, and MUTYH-associated polyposis syndromes can improve risk assessment and lead to better health outcomes for patients when policy criteria are not met. This includes testing with panel tests that contains genes other than *APC*, *MUTYH*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, and *EPCAM*. Therefore, genetic testing that does not meet the policy criteria, such as panel testing that includes testing for genes other than *APC*, *MUTYH*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, and *EPCAM,* is considered investigational.

CODES

Codes	Number	Description
CPT	0101U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated [15 genes (sequencing and deletion/duplication), EPCAM and GREM1 (deletion/duplication only)]
	0130U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis), targeted mRNA sequence analysis panel (APC, CDH1, CHEK2, MLH1, MSH2, MSH6, MUTYH, PMS2, PTEN, and TP53) (List separately in addition to code for primary procedure) (Use 0130U in conjunction with 81435, 0101U)
	0238U	Oncology (Lynch syndrome), genomic DNA sequence analysis of MLH1, MSH2, MSH6, PMS2, and EPCAM, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions
	81201	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; full gene sequence
	81202	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; known familial variants
	81203	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; duplication/deletion variants
	81210	BRAF *(*B-Raf proto-oncogene, serine/threonine kinase*)* (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
	81288	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; promoter methylation analysis
	81292	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81293	;known familial variants
	81294	;duplication/deletion variants
	81295	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81296	;known familial variants
	81297	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary duplication/deletion variants duplication/deletion variants
	81298	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81299	;known familial variants
	81300	;duplication/deletion variants
	81301	Microsatellite instability analysis (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) of markers for mismatch repair deficiency (eg, BAT25, BAT26), includes comparison of neoplastic and normal tissue, if performed

Codes	Number	Description
	81317	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81318	;known familial variants
	81319	;duplication/deletion variants
	81401	Molecular pathology procedure, Level 2
	81406	Molecular pathology procedure, Level 7
	81435	Hereditary colon cancer-related disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis), genomic sequence analysis panel, 5 or more genes, interrogation for sequence variants and copy number variants; genomic sequence analysis panel, must include sequencing of at least 10 genes, including APC, BMPR1A, CDH1, MLH1, MSH2, MSH6, MUTYH, PTEN, SMAD4, and STK11
	~~81436~~	~~;duplication/deletion analysis panel, must include analysis of at least 5 genes, including MLH1, MSH2, EPCAM, SMAD4, and STK11~~ (Deleted 01/01/2025)
HCPCS	None

Genetic Testing for Cutaneous Malignant Melanoma

Effective: April 1, 2024

Next Review: February 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genetic markers for cutaneous malignant melanoma (CMM) are being evaluated in those with a family history of the disease and to estimate risk for those who do not have family history of CMM.

MEDICAL POLICY CRITERIA

Genetic testing for variants associated with hereditary cutaneous malignant melanoma or associated with susceptibility to cutaneous malignant melanoma is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

GENETICS OF CUTANEOUS MALIGNANT MELANOMA

A genetic predisposition to cutaneous malignant melanoma (CMM) is suspected in specific clinical situations:

- Melanoma has been diagnosed in multiple close blood relatives;
- Multiple primary melanomas are identified in a single patient; and
- In the case of early age of onset.

A positive family history of melanoma is the most significant risk factor; it is estimated that approximately 10% of melanoma cases report a first- or second-degree relative with melanoma. Hereditary melanoma, caused by single gene disorder accounts for about half of these.[1]

Multiple genes associated with high risk for melanoma have been identified:

- *CDKN2A*, located on chromosome 9p21, encodes proteins that act as tumor suppressors. Mutations at this site can alter the tumor suppressor function.
- *CDK4* is an oncogene located on chromosome 12q13. CDK4 is a rare cause of hereditary melanoma than CDKN2A and is phenotypically similar.
- *BAP1*, which is located on 3p21, encodes a protein that acts as a tumor suppressor, and is associated with both cutaneous and uveal melanoma.
- *POT1*, located on 7q31.33 is associated with cutaneous melanoma and other cancers. Germline *POT1* variants have been identified in fewer than 100 families.

Additional genes that may be associated with CMM include genes involved in defined tumor syndromes in which melanoma risk may be increased (e.g., *PTEN*), and variants that suggest increased risk, but low-to-intermediate melanoma penetrance (e.g., *MITF, MC1R*).[1-3]

The incidence of *CDKN2A* disease-associated variants in the general population is very low. For example, it is estimated that in Queensland, Australia, an area with a high incidence of melanoma, only 0.2% of all patients with melanoma will harbor a *CDKN2A* disease-associated variants. Variants are also infrequent in those with an early age of onset or those with multiple primary melanomas.[4] However, the incidence of *CDKN2A* mutations increases with a positive family history; *CDKN2A* disease-associated variants will be found in 5% of families with first-degree relatives, rising to 20–40% in kindreds with three or more affected first-degree relatives.[5] Variant detection rates in the *CDKN2A* gene are generally estimated as 20–25% in hereditary CMM but can vary between 2% and 50%, depending on the family history and population studied.

Hereditary CMM has been described as a family in which either two first-degree relatives are diagnosed with melanoma or a family with three melanoma patients, irrespective of the degree of relationship.[6] Others have defined hereditary CMM as having at least three (first-, second-, or third-degree) affected members or two affected family members in which at least one was diagnosed before age 50 years, or pancreatic cancer occurred in a first- or second-degree relative, or one member had multiple primary melanomas.[7]

Other malignancies are associated with hereditary CMM. Pathogenic *CDKN2A* variants in particular are associated with an increased risk for pancreatic cancer. Uveal melanoma is the most common cancer associated with *BAP1* tumor predisposition syndrome (TPD). *BAP1* variants are also associated with cutaneous melanoma, renal cell carcinoma and mesothelioma. The incidence of de novo *BAP1* variants is not known, penetrance is incomplete, and manifestations vary within affected families.[2] Core cancers associated with

POT1-TPD are cutaneous melanoma, chronic lymphocytic leukemia, angiosarcoma and glioma. The penetrance and complete phenotype of *POT1* pathogenic variants are not well understood.[3]

Hereditary forms of CMM can occur either with or without a family history of multiple dysplastic nevi. Families with both CMM and multiple dysplastic nevi have been referred to as having familial atypical multiple mole and melanoma syndrome (FAMMM). This syndrome is difficult to define since there is no agreement on a standard phenotype, and dysplastic nevi occur in up to 50% of the general population. Atypical or dysplastic nevi are associated with an increased risk for CMM. Initially, the phenotypes of atypical nevi and CMM were thought to co-segregate in FAMMM families, leading to the assumption that a single genetic factor was responsible. However, it was subsequently shown that in families with *CDKN2A* variants, there were family members with multiple atypical nevi who were non-carriers of the *CDKN2A* familial variant. *CDK4* variants are detected in fewer than one percent of patients with FAMMM syndrome.[8] Thus, the nevus phenotype cannot be used to distinguish carriers from non-carriers of CMM susceptibility in these families.

MANAGEMENT

No widely accepted guidelines for the management of families with hereditary risk of melanoma exist.[9] Badenas (2012) suggested several parameters to guide genetic testing for melanoma: in countries with a low to medium incidence of melanoma, genetic testing should be offered to families with two cases of melanoma or to an individual with two primary melanomas (the rule of two); in countries with high incidence of melanoma, genetic testing should be offered to families with three cases of melanoma, or to an individual with three primary melanomas (the rule of three).[10] Delaunay (2017) suggested a modification to the recommendations by Badenas. In countries with a low to medium incidence of melanoma, Delaunay propose that the rule of two should guide genetic testing only if there is an individual with melanoma before the age of 40, otherwise the rule of three should apply.[11]

In general, individuals with increased risk of melanoma are educated on prevention strategies such as reducing sun exposure and on skin examination procedures.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[12] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

- The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
- The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and

- The clinical utility of the test, which describes how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

ANALYTIC VALIDITY

No published data on the analytic validity of genetic testing for variants associated with cutaneous malignant melanoma were identified.

CLINICAL VALIDITY

Clinical validity is related to interpretation of the results of genetic analysis for the individual patient. One issue common to genetic testing for any type of cancer susceptibility, is determining the clinical significance of individual variants. For example, variants in the *CDKN2A* gene can occur along its entire length, and some of these variants represent benign variants. Interpretation will improve as more data accumulate regarding the clinical significance of individual variants in families with a known hereditary pattern of melanoma. However, the penetrance of a given variant will also affect its clinical significance, particularly because the penetrance of *CDKN2A* variants may vary with ethnicity and geographic location.[4, 5] For example, exposure to sun and other environmental factors, as well as behavior and ethnicity may contribute to penetrance. Bishop estimated that the calculated risk of developing melanoma before age 80 years in carriers of *CDKN2A* variants ranged from 58% in Europe to 91% in Australia.[13]

Interpretation of a negative test is another issue. Melanoma incidence has steadily increased since 1975. Potential reasons include increased exposure to ultraviolet radiation, increased skin cancer detection, and increased longevity.[14] *CDKN2A* and other germline variants associated with high risk for melanoma are relatively uncommon. Family history of melanoma can be associated with other shared heritable traits (e.g., fair skin, red hair), as well as shared environmental exposures. Therefore, patients with a strong family history and normal genetic test results must not be falsely reassured that they are not at increased risk.[4]

Simonin-Wilmer (2023) published a population-based study comparing *POT1* assessment of 2928 melanoma cases to 3298 controls, all of European ancestry.[15] Forty-three *POT1* protein-altering variants were identified. The variants were divided into three groups. Group 1 included 14/43 variants deemed pathogenic. Group 2 included 4/43 variants that were possibly pathogenic, and the remaining 25/43 variants were in Group 3. In the study, 126 cases and 149 controls had a Group 3 variant (p=0.66), indicating no increased risk for melanoma. For Groups 1 and 2 combined, nearly twice as many cases as controls had Group 1 or 2 variants, but the difference was not statistically significant (p=0.096). The authors concluded that about 0.5% of melanoma cases have a pathogenic *POT1* variant.

Bruno (2022) published a prospective study of multi-gene panel testing related to melanoma involving 940 cutaneous melanoma index cases from 1044 Italian families.[16] The panel included the *CDKN2A*, *CDK4*, *BAP1*, *POT1*, *ACD*, *TERF2IP*, *MITF*, and *ATM* genes. The panel test revealed 89 variants, with 52 occurring on the *CDKN2A* gene. Intermediate risk *MITF* (18) or *ATM* (10) variants were detected in 28 tests. Other gene variants the panel test detected were *CDK4* (1), *BAP1* (5), and *POT1* (4). The presence of pancreatic cancer in the proband and/or family increased the likelihood of detecting a variant, especially in *CDKN2A* (15/52) and *ATM* (4/10). Participants older than 60 years at melanoma diagnosis had fewer detectable variants [odds ratio (OR)=0.13, p=0.008].

De Simone (2020) conducted a retrospective review of melanoma predisposition variants (e.g., *CDKN2A*, *CDK4*) in 888 patients with melanoma from central Italy.[17] Overall, the study included 309 patients with multiple primary melanomas, 435 patients with familial melanoma, and 144 cases with both multiple primary melanomas and familial melanoma. Patients were divided in two clinical categories: "low significance" and "high significance" based on personal and family history. In the sample, 128 patients (72% belonging to the "high significance" category, 28% belonging to the "low significance" category) were found to carry a DNA change defined as pathogenic, likely pathogenic, variant of unknown significance (VUS)-favoring pathogenic or VUS.

Cust (2018) used data from two large case-control studies to assess the incremental contribution of gene variants to risk prediction models using traditional phenotype and environmental factors.[18] Data from 1035 cases and controls from an Australian study and 1460 cases and controls from a United Kingdom study were used in the analyses. The logistic regression models contained the following variables: presence of 45 single nucleotide polymorphisms (among 21 genes); family history of melanoma; hair color; nevus density; nonmelanoma skin cancer; blistering sunburn as a child; sunbed use; freckling as an adult; eye color; and sun exposure hours on weekends and vacation. When polygenic risk scores were added to the model with traditional risk factors, the area under the receiving operator curve (AUC) increased by 2.3% for the Australia population and 2.8% for the United Kingdom population. The *MC1R* gene variants, which are related to pigmentation, were responsible for most of the incremental improvement in the risk prediction models.

Gironi (2018) conducted genetic testing in Italian families prone to cutaneous melanoma to elucidate distinctive clinical and histological features of melanomas in *CDKN2A* mutation carriers.[19] Three hundred patients with cutaneous melanoma (CM) were enrolled and interviewed about their personal and family history of CM and other cancers. Specifically, patients were eligible for genotyping if they had a histologically proven diagnosis of one or more CM and met at least one of the following inclusion criteria: 1) CM diagnosis at less than or equal to 40 years of age; 2) MPM; 3) family history of CM; and/or 4) Personal and/or family history of non-cutaneous cancers suggestive of familial cancer syndrome related to germline mutations of *CDKN2A*, *CDK4, MITF*, and *BAP1* genes. Genotyping revealed 100 patients with wildtype (WT) *CDKN2A* genes and 32 patients with *CDKN2A* variants that were subsequently analyzed according to histological and clinical features. The WT group did not significantly differ from the *CDKN2A* mutation-positive group with respect to phototype (p=0.759) or number of total common melanocytic nevi (p=0.131). However, a personal history of previously excised dysplastic nevi was more frequent among *CDKN2A* variant-positive patients compared to WT (62.5% vs. 26%; p<0.001). A positive family history of CM and/or pancreatic cancer was detected in 90.6% of mutation-positive patients compared to 37% of the WT group (p<0.001). This significance was maintained for CM or pancreatic cancer, individually (78.1% vs. 29%; p<0.001 and 34.4% vs. 10%; p<0.001). There were 54 (41%) patients in this study with at least 1 family member with a history of CM. Among these patients, 25/54 (46.3%) carried a *CDKN2A* germline mutation. There were 21 (16%) of patients with a family history of pancreatic cancer. Among these patients, 11/21 (52.4%) carried a *CDKN2A* germline mutation. Patients with a *CDKN2A* germline mutation developed a statistically significant higher number of MPMs compared to the WT group (mean, 1.88 vs. 1.18; p<0.001). However, while most patients in both genotype groups developed 2 primary melanomas (61% *CDKN2A*, 87.5% WT), 3 or 4 MPMs were observed more frequently in patients with a *CDKN2A* mutation. All *CDKN2A* carriers were found to develop superficial spreading melanomas whereas WT patients generated mostly nodular melanomas (NMs) or lentigo maligna and lentigo maligna

melanomas (LM-LMMs) (p=0.006). There was no significant difference in *CDKN2A* status with respect to meeting inclusion criteria for sentinel node biopsy (15.6% *CDKN2A*, 22% WT; p=0.302). Additionally, 0/5 (0%) patients who underwent the procedure with a *CDKN2A* variant showed metastases compared to 4/22 (18.2%) of WT patients.

Artomov (2017) assessed the rate of rare genetic variants including *CDKN2A* among patients with familial cutaneous melanoma (CM, n=273) in the United States and Greece.[20] Eleven genes that exhibited borderline association (p<0.0001) were independently validated using The Cancer Genome Atlas melanoma cohort (n=379) and a matched set of 3563 European controls with *CDKN2A* (p=0.009), *BAP1* (p=0.03), and *EBF3* (p<0.001), a candidate risk locus, all showing evidence of replication. *EBF3* was then evaluated using germline data from a set of 132 familial melanoma cases and 4769 controls of UK origin (joint p<0.0001). Somatically, loss of *EBF3* expression correlated with progression, poorer outcome, and high *MITF* tumors.

In 2017, Borroni published an Italian case series of 92 consecutive, unrelated patients with familial atypical mole/multiple melanoma syndrome (FAMMM) that were offered genetic counseling and testing for *CDKN2A* and *CDK4* variants.[21] FAMMM is characterized by primary cutaneous melanoma in at least two relatives and/or two or more primary cutaneous melanomas in the same patient. Genetic testing was extended to family members of patients with identified variants. *CDKN2A* variants were found in 19 of the 92 unrelated patients (20.6%) and in 14 healthy relatives. Of these relatives with variants, 11 later underwent excision of dysplastic nevi.

In 2016, Di Lorenzo published a study of 400 patients with cutaneous melanoma who were observed in a six-year period at an Italian university.[22] Forty-eight patients have met the criteria of the Italian Society of Human Genetics (SIGU) for the diagnosis of familial melanoma and were screened for *CDKN2A* and *CDK4* variants. Genetic testing revealed that none of the families carried variants in the *CDK4* gene and only one patient harbored the rare *CDKN2A* p.R87W variant. The study did not identify a high variant rate of *CDKN2A* in patients affected by familial melanoma or multiple melanomas. This difference could be attributed to different factors, including the genetic heterogeneity of the Sicilian population. It is likely that, as in the Australian people, the inheritance of familial melanoma in this island of the Mediterranean Sea is due to intermediate/low-penetrance susceptibility genes, which, together with environmental factors (as latitude and sun exposure), could determine the occurrence of melanoma.

Bruno (2016) reported on the multiMEL study, in which genetic testing for *CDKN2A* and *CDK4* variants were performed on 587 consecutive patients with MPM and 587 consecutive patients with single primary melanoma (SPM).[23] Rates of the variants were 19.1% and 4.4% in patients with multiple primary versus single primary melanoma. Subgroup analyses by familial versus sporadic melanoma showed that among patients with familial MPM and familial SPM, the mutation rates were 44.4% and 24.6%, respectively, compared with sporadic MPM and sporadic SPM variant rates of 10.8% and 2.1%, respectively.

Mangas (2016) measured the rate of *CDKN2A* variants among individuals considered high risk for melanoma, defined as families with at least two cases of melanoma or individuals with multiple melanomas.[24] A total of 57 individuals were tested, 41 of which were considered the index cases. Of the 41, *a CDKN2A* variant was identified in four index cases.

Puig (2016) conducted genetic testing for *CDKN2A* variants among patients with melanoma in Latin America and Spain.[25] The variant rates among patients with familial melanoma were 23.9% and 14.1% in Latin America and Spain, respectively. The *CDKN2A* variant rates were

lower among patients in Latin America and Spain with sporadic MPM, 10.0% and 8.5%, respectively.

A 2016 study by Wendt evaluated *MC1R* variants and melanoma risk in a hospital-based case-control study that included 991 melanoma patients and 800 controls.[26] *MC1R* variants were associated with a higher risk of melanoma after adjustment for age, sex, and ultraviolet radiation exposure (≥2 variants, OR, 2.13 [95% confidence interval [CI], 1.66-2.75], P < .001; P for trend <.001).

Harland (2014) conducted a case control study on patients with melanoma from Australia, Spain, and United Kingdom.[27] *CDKN2A* variant rates for each of the populations were similar (2.3%, 2.5%, and 2.0% in patients from Australia, Spain, and United Kingdom, respectively). Case-control analyses showed that the strongest predictor of carrying a variant was having multiple primaries odds ratio [OR] = 5.4, 95% CI = 2.5 to 11.6; and having three primaries, OR=32.4, 95% CI=14.7 to 71.2). Another predictor of carrying a variant is having a strong family history of melanoma: having 1 relative, OR = 3.8, 95% CI = 1.9 to 7.5; and having two or more relatives, OR = 23.2, 95% CI = 11.3 to 47.6).

Potrony (2014) measured the rate of *CDKN2A* variants among patients in Spain with sporadic multiple primary melanoma (MPM) and familial melanoma.[28] Variant rates were 14.1% in patients with familial melanoma and 8.5% in patients with sporadic multiple primary melanoma.

In 2013, Puntervoll published a description of the phenotype of individuals with *CDK4* variants in 17 melanoma families (209 individuals; 62 cases, 106 related controls, 41 unrelated controls).[29] The incidence of atypical nevi was higher in those with *CDK4* variants (70% in melanoma patients; 75% in unaffected individuals) than in those without *CDK4* variants (27%; p<0.001). The distribution of eye color or hair color was not statistically different between *CDK4* variant-positive individuals (with or without melanoma) and variant-negative family members. The authors concluded that “it is not possible to distinguish *CDK4* melanoma families from those with *CDKN2A* variant based on phenotype.” Therefore, the clinical significance of this genetic distinction is currently unclear.

In 2012, Cust classified 565 patients with invasive cutaneous melanoma diagnosed between 18 to 39 years of age, 518 sibling controls, and 409 unrelated controls into *MC1R* categories defined by presence of high risk or other alleles.[30] Compared with sibling controls, two *MC1R* high-risk alleles (R151C, R160W) were associated with increased odds of developing melanoma (OR=1.7; 95% CI, 1.1 to 2.6; OR=2.0; 95% CI, 1.2 to 3.2, respectively), but these associations were no longer statistically significant in analyses adjusted for pigmentation, nevus count, and sun exposure. Compared with unrelated controls, only the R151C high-risk allele was associated with increased odds of developing melanoma in adjusted analysis. There was no association between other *MC1R* alleles (not considered high risk) and odds of developing melanoma in unadjusted or adjusted analyses. In 2010, Psaty published an article on identifying individuals at high risk for melanoma and emphasized the use of family history.[31]

In 2012, two studies further examined the association of *MC1R* variants and melanoma in southern European populations.[32, 33] Ibarrola-Villava conducted a case-control study in three sample populations from France, Italy, and Spain.[32] Susceptibility genotypes in three genes involved in pigmentation processes were examined in 1639 melanoma patients (15% familial) and 1342 controls. *MC1R* variants associated with red hair color were successfully genotyped in 85% of cases and 93% of controls. Two other genes not associated with familial cutaneous

melanoma—TYR, which encodes a tyrosinase, and SLC45 A2, which encodes a melanosome enzyme were also were studied. In univariate logistic regression analysis, *MC1R* red hair color variants were significantly associated with the odds of developing melanoma in a dose-dependent fashion: OR for one allele: 2.2 (95% CI, 1.9 to 2.6); OR for two alleles: 5.0 (95% CI, 2.8 to 8.9). In analysis stratified by self-reported phenotype, these variants were statistically associated with increased odds of melanoma not only in individuals with fair phenotype (eye, hair and skin color) but also in those with dark/olive phenotype. The authors suggested that *MC1R* genotyping to identify elevated risk in Southern European patients considered not at risk based on phenotype alone warranted further investigation. Effects on health outcomes are unknown.

Ghiorzo (2012) studied 49 *CDKN2A*- variant positive and 390 *CDKN2A*- variant negative Italian patients with cutaneous melanoma.[33] *MC1R* variants were associated with increased odds of melanoma only in *CDKN2A*- variant-negative patients in a dose-dependent fashion: OR for one high-risk allele: 1.5 (95% CI, 1.1 to 2.0); OR for two high-risk alleles, 2.5 (95% CI, 1.7 to 3.7). In multivariate logistic regression, effects of *MC1R* variants were statistically significant in most *CDKN2A* variant-negative subgroups and few variant-positive subgroups defined by phenotype (eye and hair color, skin complexion and phototype, presence or absence of freckles or atypical nevi, and total nevus count), sun exposure, and history of severe sunburn. In contrast, first-degree family history of cutaneous melanoma increased the odds of developing melanoma in both variant-positive (OR=71.2; 95% CI, 23.0 to 221.0) and variant-negative (OR=5.3; 95% CI, 2.0 to 14.3) patients, although uncertainty in the estimates of association was considerable. Family history of cutaneous nevi (at least 1=one first-degree relative with >10 nevi and /or atypical nevi) increased the odds of melanoma in variant-positive cases only (OR=2.44; 95% CI, 1.3 to 4.5). This finding underscores the significance of nongenetic factors (e.g., sun exposure, and history of severe sunburn) for development of melanoma and the complexity of interpreting a positive family history.

In 2010, Kanetsky conducted a study to describe associations of *MC1R* (melanocortin one receptor gene) variants and melanoma in a U.S. population and to investigate whether genetic risk is modified by pigmentation characteristics and sun exposure.[34] The study population included melanoma patients (n=960) and controls (n=396) who self-reported phenotypic characteristics and sun exposure information. Logistic regression was used to estimate associations of high- and low-risk *MC1R* variants and melanoma, overall and within phenotypic and sun exposure groups. Carriage of two low-risk, or any high-risk *MC1R* variant was associated with increased risk of melanoma (odds ratio [OR], 1.7; 95% confidence interval [CI], 1.0 to 2.8; OR=2.2; 95% CI, 1.5 to 3.0, respectively). However, risk was noted to be stronger in or limited to people with protective phenotypes and limited sun exposure, such as those who tanned well after repeated sun exposure (OR=2.4), had dark hair (OR=2.4), or had dark eyes (OR=3.2). The authors concluded that these findings indicate *MC1R* genotypes provide information about melanoma risk in those individuals who would not be identified as high risk based on their phenotypes or exposures alone. However, how this information impacts patient care and clinical outcomes is unknown.

In 2009, Yang conducted a study to identify modifier genes for CMM in CMM-prone families with or without *CDKN2A* variants.[35] Investigators genotyped 537 individuals (107 CMM) from 28 families (19 *CDKN2A*-positive, nine *CDKN2A*-negative) for genes involved in DNA repair, apoptosis, and immune response. Their analyses identified some candidate genes, such as *FAS, BCL7A, CASP14, TRAF6, WRN, IL9, IL10RB, TNFSF8, TNFRSF9*, and *JAK3*, that were associated with CMM risk; after correction for multiple comparisons, *IL9* remained significant.

The effects of some genes were stronger in *CDKN2A* variant-positive families (*BCL7A, IL9*), and some were stronger in CDKN2A-negative families (*BCL2L1*). The authors considered these findings supportive of the hypothesis that common genetic polymorphisms in DNA repair, apoptosis, and immune response pathways may modify the risk of CMM in CMM-prone families, with or without *CDKN2A* variants.

CLINICAL UTILITY

Although genetic testing for *CDKN2A* variants is recognized as an important research tool, its clinical use will depend on how results of genetic analysis can be used to improve patient management. Currently, management of patients considered high risk for malignant melanoma focuses on reduction of sun exposure, use of sunscreens, vigilant cutaneous surveillance of pigmented lesions, and prompt biopsy of suspicious lesions. Presently, it is unclear how genetic testing for *CDKN2A* would alter these management recommendations. The following clinical situations can be considered.

Affected Individual with a Positive Family History

If an affected individual has a *CDKN2A* or other germline gene variant associated with high risk for melanoma, they may be at increased risk for being diagnosed at an advanced stage and for having poorer survival than people without detectable gene variants.

Pissa (2023) compared melanoma survival rates before and after initiation in 1987 into a familial dermatologic surveillance program for Swedish families with *CDKN2A* pathologic variants.[36] The study included 473 people with melanoma from 261 families who were diagnosed between 1958 and 2009, with follow-up through 2011. Of the melanoma cases, 96 belonged to 31 families that harbored a *CDKN2A* variant; and 377 were from 230 families that did not have a *CDKN2A* variant. Four cohorts were compared:

1. MUT-pre (n=53): *CDKN2A* carriers (MUT), or relative of a carrier, with first invasive melanoma before inclusion in the surveillance program.
2. MUT-post (n=43): *CDKN2A* carriers (or relative of a carrier) with first invasive melanoma after inclusion in the surveillance program.
3. WT-pre (n=255): *CDKN2A*-negative participants, i.e., wild type (WT), or relative of participant with negative *CDKN2A* test, with first invasive melanoma before inclusion in the surveillance program.
4. WT-post (n=122): *CDKN2A*-negative participants (or relative of participant with negative *CDKN2A* test) with first invasive melanoma after inclusion in the surveillance program.

Overall, worse melanoma-specific survival was associated with tumor T-stage 2-4 (hazard ratio [HR] 5.45, 95%, CI 3.15-9.43, p=0.023), male sex (HR 1.80, 95% CI 1.15-2.83, p=0.011), and diagnosis at >50 years (HR 1.69, 95% CI 1.08-2.64, p=0.023). Survival was not significantly different in the MUT-pre cohort compared to the MUT-post cases, both when unadjusted for age, sex, and T-stage (HR 2.16, 95% CI 0.79-5.94, p=0.134) and after adjusting for factors associated with worse survival (HR 1.17, 95% CI 0.77-2.15, p=0.344). Survival was also similar in the WT-pre compared to the WT-post cohort, using both unadjusted (p=0.444) and adjusted (p=0.781) models. Survival was worse in the MUT-pre cohort compared to the WT-pre cases using both the unadjusted (HR 2.33, 95% CI 1.33-4.08, p=0.003) and adjusted (HR 2.70, 95% CI 1.46-5.00, p=0.001) models. Survival was not significantly different between the MUT-post and WT-post cases in either the unadjusted (HR 0.81, 95% CI 0.30-2.20, p=0.678) or adjusted (HR 1.57, 95% CI 0.6-4.20, p=0.300) models. A secondary analysis was performed

to assess whether worse survival in the MUT-pre cohort was associated with second invasive melanoma, but the survival difference between the two cohorts persisted (HR 2.83, 95%, CI 1.23-6.52, p=0.015).

The authors suggest that inclusion in the surveillance program benefited the families with *CDKN2A* variants because the MUT-pre cohort had worse survival than the WT-pre cohort, and the survival rates were similar in the post-surveillance cohorts. However, neither of the post-surveillance cohorts had significantly different survival when compared to the pre-surveillance cohorts. Importantly, the study does not address whether the difference in survival could be due to other factors, such as treatment differences over the study period. Genetic testing for *CDKN2A* was performed for at least one member of each family, but the genetic status was not known for all study participants and there was no randomization of the surveillance intervention or genetic testing. Therefore, conclusions about the benefit of genetic testing for hereditary melanoma in the study population cannot be drawn.

The National Cancer Institute familial melanoma study compared trends in melanoma thickness in high-risk families to trends in the general U.S. population using Surveillance, Epidemiology, and End Results (SEER) data. Sargen (2021) followed 293 melanoma cases from 56 families. Of 274 melanoma cases with genetic test information, 160 had either a *CDKN2A* or *CDK4* variant, and 114 had neither gene variant. The study found smaller thickness ($p<0.001$) and earlier stage diagnosis ($p<0.001$) of invasive melanoma in people from melanoma-prone families in the surveillance program compared to tumors that were diagnosed before study involvement. However, changes in tumor thickness and stage were similar in families with and without *CDKN2A* or *CDK4* variants ($p<0.05$). During the course of the study reductions in tumor thickness and disease stage in the high-risk study participants generally paralleled reductions seen in the general population obtained from SEER data. While a trend was seen for lower thickness in the study population compared to SEER data, the difference was not significant in the high risk cases pre-study ($p=0.922$) or after study enrollment when assessed for mean thickness ($p=0.20$) and changes over time ($p=0.198$).[8]

People with hereditary melanoma may also be at increased risk for a second primary melanoma compared with the general population. However, limited and protected sun exposure and increased surveillance would be recommended to any patient with a history of malignant melanoma, regardless of the presence of a *CDKN2A* or pathogenic variant. A positive result will establish a familial variant, thus permitting targeted testing for the rest of the family. Additionally, a positive mutation in an affected family member increases the likelihood of its clinical significance if detected in another family member; but, as described earlier, a negative test result is not interpretable.

Unaffected Individual in a High-Risk Family

If the unaffected individual is the first to be tested in the family (i.e., no affected relative has been previously tested to define the target variant), it is very difficult to interpret the clinical significance of a variant, as described. The likelihood of clinical significance is increased if the identified variant is the same as one reported in other families, although the issue of penetrance is a confounding factor. If the unaffected individual has the same variant as an affected relative, then the patient is at high risk for melanoma. However, again it is unclear how this would affect the management of the patient. Even patients who have a genetic test result that rules out a known familial variant associated with melanoma (i.e., “true negatives”) may

still be considered at increased risk for melanoma.[8] Increased sun protection and surveillance are recommended for any patient in a high-risk family.

Published data on genetic testing of the *CDKN2A* and *CDK4* genes focus on the underlying genetics of hereditary melanoma, identification of variants in families at high risk of melanoma, and risk of melanoma in those harboring these variants. Other studies have focused on the association between *CDKN2A* and pancreatic cancer.[37-39] One publication added the caution that differences in melanoma risk across geographic regions justify the need for studies in individual countries before counseling should be considered.[40]

Stump (2020) investigated whether genetic counseling and test reporting for *CDKN2A* carrier status promoted objective reductions in sun exposure.[41] Participants were recruited from two types of pedigrees: families with an identified *CDKN2A* mutation and families with a similar melanoma history but no identified *CDKN2A* mutation. Subjects from *CDKN2A*-positive families were derived from three kindreds and accounted for 32 carriers and 46 noncarriers. No-test control subjects (n=50) were derived from nine *CDKN2A*-negative families. The daily standard erythemal dose (SED; J/m2) of ultraviolet radiation (UVR) exposure was measured with a wrist-worn, battery-powered dosimeter over three 27-day periods. Complete dosimetry data was available for 75.8% of participants, with missing data due to technical issues, device loss, or device damage. The average number of days coded as "not worn" ranged from 7 to 10 days in each assessment period. Both carriers and no-test controls exhibited a significant decrease in UVR dose at one year compared to baseline ($p < 0.01$). No change from baseline was noted for noncarriers at any timepoint. However, these outcomes do not account for the use of sunscreen or sun-protective clothing. Skin pigmentation was assessed via reflectance spectroscopy, yielding a Melanin Index (MI) score in which higher scores represent greater melanin content. Measurements from the face and wrist were standardized to measurements obtained from non-exposed sites to account for differences in skin tone. Data from patients using artificial tanning products within a week of testing were excluded. Only carriers exhibited a significant decrease in skin pigmentation at the wrist at one year ($p < 0.001$). However, no corresponding changes in facial pigmentation were detected for any group. Both carriers and no-test controls self-reported fewer sunburns than non-carriers ($p < 0.05$). Noncarriers did not demonstrate changes in any measure of UVR exposure, however, daily UVR exposure was higher among noncarriers compared to no-test controls at baseline ($p = 0.03$). Despite the incorporation of propensity score matching in their statistical methods, the authors acknowledge that they cannot exclude yet-to-be identified confounding factors driving between-group differences in their non-equivalent control study design. The study did not assess key health outcomes such as melanoma incidence.

Aspinwall (2018) compared potential informational and motivational benefits from genetic testing for melanoma among individuals from high risk families who were variant-positive (n=28), variant-negative (n=41), and unknown carrier status (n=45).[42] High risk individuals were defined as those related to a patient with a known *CDKN2A* variant or those with a significant family history of melanoma (>3 cases) but no identified variant. All participants received genetic counseling, which included a risk estimate of developing melanoma during their lifetime. Outcomes, measured after one month and one year followup, included: feeling informed and prepared to manage risk; motivation to reduce sun exposure; motivation to perform screening; and negative/positive emotions about melanoma risk. Individuals who were tested (both variant-positive and variant negative) reported feeling significantly more informed and prepared to manage risk compared to those not tested. All participants had low negative emotions concerning melanoma risk.

Dalmasso (2018) conducted a retrospective case-control study to determine if there was an association between *CDKN2A* variants and survival among patients with melanoma.[43] From consecutive patients with the diagnosis of melanoma and genetic testing data from a single hospital, 106 variant-positive cases and 199 variant-negative controls, matched by age and sex, were included in the analyses. The overall rate of deaths in both groups was 17%. Melanoma-specific mortality was 10.8% in the variant-positive group and 7.8% in the variant-negative group. There were no statistically significant differences in overall or melanoma-specific survival between the two groups.

In 2018, Stump reported changes in sun protection and stress levels following genetic counseling and test reporting for the *CDKN2A/p16* variant.[44] Participants included 18 minors from melanoma-prone families, with a mean age of 12.4. Nine were carriers and nine were noncarriers. Compared to baseline, at one-year post-disclosure, all subjects self-reported significantly fewer sunburns. In addition, a greater proportion reported sun protection adherence. There were no significant differences between genotypes. Depressive symptoms and cancer worry declined and anxiety symptoms, which began low, remained unchanged post-disclosure. In interviews, all mothers of the subjects indicated that genetic testing was beneficial. Reasons included that it promoted risk awareness (90.9%) and sun protection (81.8%) without making their children scared (89.9%). Independent practice of sun protection by their children was reported by 45.4% of mothers.

Two behavioral studies were published in 2016. Levin examined behavior patterns in families in Norway in which a *CDKN2A* variant was identified.[45] The authors reported that 66 % (95/144) of carriers' first-degree relatives contacted the researchers within the study period, 98% (126/128) of all relatives who came for genetic counseling requested genetic testing, and 93 % (66/71) of those with variants wanted referral for yearly skin examinations. Wu studied the impact of melanoma genetic test reporting and counseling on the frequency of discussion about preventive behaviors between 24 counseled adults and their children and grandchildren.[46] Conversations about preventive behaviors were assessed before testing and at one and six months after testing, using open-ended questions. The authors reported that these discussions declined after test reporting, with a faster decline in variant non-carriers, and that there was a large gap between the number of participants who intended to have preventive behavior discussions and the number that reported having had such discussions at follow-up.

In 2013, Aspinwall reported outcomes for 37 patients (62%) of this cohort who were available for two-year follow-up.[47, 48] Anxiety, depression, and cancer-specific worry declined over two years, although baseline values were low and the declines are of uncertain clinical significance. Adherence to annual total body skin examinations and monthly skin self-examinations varied by carrier status; however, without a comparison group, it is not possible to attribute any change in adherence to knowledge of test results.

In 2012, Branstrom examined a survey of self-reported genetic testing perceptions and preventive behaviors in 312 family members with increased risk of melanoma.[49] Fifty-three percent had been diagnosed with melanoma, and 12% had a positive susceptibility genetic test. The study indicated that a negative test might be associated with an erroneous perception of lower risk and fewer preventive measures.

In a 2011 retrospective case-control study, van der Rhee sought to determine whether a surveillance program of families with a Dutch founder variant in *CDKN2A* (the p16-Leiden

variant) allowed for earlier identification of melanomas.[50] Characteristics of 40 melanomas identified in 35 unscreened patients (before heredity was diagnosed) were compared with 226 melanomas identified in 92 relatives of those 35 unscreened melanoma patients who were found to have the *CDKN2A* variant and participated in a surveillance program over a 25-year period. Surveillance comprised a minimum of an annual total skin evaluation, which became more frequent if melanoma was diagnosed. Melanomas diagnosed during surveillance were found to have a significantly lower Breslow thickness (median thickness, 0.50 mm) than melanomas identified in unscreened patients (median thickness, 0.98 mm), signifying earlier identification with surveillance. However, only 53% of melanomas identified in the surveillance group were detected on regular screening appointments. Additionally, there was no correlation between length of screening intervals (for intervals <24 months) and melanoma tumor thickness at the time of diagnosis. The authors also noted that despite understanding the importance of surveillance, patient noncompliance was still observed in the surveillance program, and almost half of patients were noncompliant when first diagnosed with melanoma.

In a 2008 study, Aspinwall found short-term change in behavior among a small group of patients without melanoma who were positive for the *CDKN2A* variant.[51] In this prospective study of 59 members of a *CDKN2A* variant-positive pedigree, behavioral assessments were made at baseline, immediately after *CDKN2A* test reporting and counseling, and at one month follow-up (42 participants). Across multiple measures, test reporting caused *CDKN2A* disease-associated variant carriers without a melanoma history to improve to the level of adherence reported by participants with a melanoma history. *CDKN2A*-positive participants without a melanoma history reported greater intention to obtain total body skin examinations, increased intentions and adherence to skin self-examination recommendations, and increased number of body sites examined at one month.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

The current (v1.2024) National Comprehensive Cancer Network (NCCN) clinical guidelines on melanoma state:[52]

- Follow-up recommendations for all patients with cutaneous melanoma:
    - Consider genetic counseling referral for *p16/CDKN2A* testing in the presence of three or more invasive cutaneous melanomas, or a mix of invasive melanoma, pancreatic cancer, and/or astrocytoma diagnoses in an individual or family.
    - Multigene panel testing that includes *CDKN2A* is also recommended for patients with invasive cutaneous melanoma who have a first-degree relative diagnosed with pancreatic cancer.
    - Testing for other genes that can harbor melanoma-predisposing mutations may be warranted.
- Risk Factors for Development of Single or Multiple Primary Melanomas:
    - Genetic predisposition: Presence of germline mutations or polymorphisms predisposing to melanoma (e.g. *CDKN2a*, *CDK4*, *MC1R*, *BAP1* [especially for uveal melanoma], *TERT*, *MITF*, *PTEN* and potential other genes).
    - Family history of cutaneous melanoma (especially if multiple); pancreatic, renal, and/or breast cancer; astrocytoma; uveal melanoma; and/or mesothelioma.

AMERICAN CANCER SOCIETY

According to the American Cancer Society, genetic testing for *CDKN2A* and other genes associated with melanoma is available, but “doctors aren’t sure how useful they are at this time.”[53]

AMERICAN SOCIETY OF CLINICAL ONCOLOGY

In 2010, the American Society of Clinical Oncology (ASCO) updated its policy statement on genetic and genomic testing for cancer susceptibility.[54] ASCO recommends that “genetic tests with uncertain clinical utility, including genomic risk assessment, be administered in the context of clinical trials.”

In 2014, the ASCO commissioned another update to its policy statement on genetic and genomic testing for cancer susceptibility.[55] The ASCO "affirms that it is sufficient for cancer risk assessment to evaluate genes of established clinical utility that are suggested by the patient's personal and/or family history."

AMERICAN ACADEMY OF DERMATOLOGY

In 2019, the American Academy of Dermatology published guidelines for the care and management of primary cutaneous melanoma.[56] Referral for genetic counseling and possible germline genetic testing for select patients with cutaneous melanoma was recommended for consideration with a level IIIC grade of evidence. The Work Group explained that "there is no strong evidence that genetic evaluation is either harmful or helpful."

SUMMARY

There is not enough research to show that genetic testing for cutaneous melanoma can improve health outcomes, including for people with melanoma or a family history of melanoma. There are no clinical guidelines based on research that specifically recommend this type of testing. Therefore, genetic testing for variants associated with hereditary cutaneous malignant melanoma or associated with susceptibility to cutaneous malignant melanoma is considered investigational.

Medical Policy Manual Genetic Testing, Policy No. 10

Cytochrome p450 and VKORC1 Genotyping for Treatment Selection and Dosing

Effective: April 1, 2025

Next Review: February 2025
Last Review: March 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

CYP450 and *VKORC1* genotyping may help to tailor drug selection and dosing to individual patients based on their predicted drug metabolism. The goal of this testing it to lead to early selection and optimal dosing of the most effective drugs, while minimizing treatment failures or toxicities.

MEDICAL POLICY CRITERIA

Note: For panel testing related to behavioral health disorders, including medication selection, please refer to Genetic Testing Policy No. 53, Genetic Testing for Diagnosis and Management of Behavioral Health Conditions.

I. *CYP2C19* genotyping may be considered **medically necessary** for the following indications:

   A. To aid in the choice of clopidogrel (Plavix®) versus alternative anti-platelet agents; or

   B. To guide decisions on the optimal dosing for clopidogrel.

II. *CYP2D6* genotyping to determine drug metabolizer status may be considered **medically necessary** for patients with:

   A. Gaucher disease type I being considered for treatment with eliglustat (Cerdelga™); or

   B. Huntington disease being considered for treatment with tetrabenazine (Xenazine ®) in a dosage greater than 50mg per day.

III. *CYP2C9* genotyping to determine drug metabolizer status may be considered **medically necessary** for patients with relapsing forms of multiple sclerosis (i.e., clinically isolated syndrome, relapsing-remitting disease, and active secondary progressive disease) being considered for treatment with siponimod (Mayzent®).

IV. Except as defined in Criteria I, II, or III above, *CYP450 (*including *CYP2C9, CYP2C19, CYP2D6, and CYP4F2)* and *VKORC1* genotyping is considered **investigational** for medication selection and dose management, including but not limited to:

   A. Panels that include testing for more than one *CYP450* gene

   B. Testing for the following: anti-tuberculosis medications, atomoxetine HCl, beta blockers, codeine, efavirenz, H. pylori infection, immunosuppressant for organ transplantation, tamoxifen, and warfarin.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence of testing
6. Medical records related to this genetic test:
   - History and physical exam including any relevant diagnoses related to the genetic testing
   - Date of blood draw
   - Conventional testing and outcomes
   - Conservative treatments, if any

BACKGROUND

Drug efficacy and toxicity vary substantially across individuals. Because drugs and doses are typically adjusted, if needed, by trial and error, clinical consequences may include a prolonged time to optimal therapy. In some cases, serious adverse events may result.

Various factors may influence the variability of drug effects, including age, liver function, concomitant diseases, nutrition, smoking, and drug-drug interactions. Inherited (germline) DNA sequence variation (polymorphisms) in genes coding for drug metabolizing enzymes, drug receptors, drug transporters, and molecules involved in signal transduction pathways also may have major effects on the activity of those molecules and thus on the efficacy or toxicity of a drug.

It may be possible to predict therapeutic failures or severe adverse drug reactions in individual patients by testing for important DNA polymorphisms (genotyping) in genes related to the metabolic pathway (pharmacokinetics) or signal transduction pathway (pharmacodynamics) of the drug. Potentially, test results could be used to optimize drug choice and/or dose for more effective therapy, avoid serious adverse effects, and decrease medical costs.

CYP450

The cytochrome p450 family (CYP450) is a major subset of drug-metabolizing enzymes. The CYP450 family of enzymes includes but is not limited to:

- CYP2D6 which metabolizes approximately 25% of all clinically used medications (e.g., dextromethorphan, beta-blockers, antiarrhythmics, antidepressants, and morphine derivatives), including many of the most prescribed drugs.
- CYP2C19 which metabolizes several important types of drugs, including proton-pump inhibitors, diazepam, propranolol, imipramine, and amitriptyline.

Some *CYP450* genes are highly polymorphic, resulting in enzyme variants that may have variable drug-metabolizing capacities among individuals. The *CYP450* metabolic capacities may be described as follows:

- Extensive metabolizers (EM)
  - Have two active *CYP450* enzyme gene alleles, resulting in an active enzyme molecule
- Poor metabolizers (PMs)
  - Lack active *CYP450* enzyme gene alleles
  - May suffer more adverse events at usual doses of active drugs due to reduced metabolism and increased concentrations
  - May not respond to administered prodrugs that must be converted by CYP450 enzymes into active metabolites
- Intermediate metabolizers (IMs)
  - Have one active and one inactive *CYP450* enzyme gene allele
- Ultrarapid metabolizers (UMs)
  - Have more than two active *CYP450* gene alleles
  - May not reach therapeutic concentrations at usual, recommended doses of active drugs
  - May suffer adverse events from prodrugs that must be converted by CYP450 enzymes into active metabolites

It is important to note that many drugs are metabolized by more than one enzyme, either within or outside of the CYP450 family. Reduced activity in a particular CYP450 enzyme because of genotype may not affect outcomes when other metabolic pathways are available and when other confounders influence drug metabolism, such as interactions between different metabolizing genes, interactions of genes and environment, and interactions among different non-genetic factors.

CYP450 GENOTYPING

The purpose of *CYP450* genotyping is to tailor drug selection and dosing to individual patients based on their gene composition for drug metabolism. In theory, this should lead to early selection and optimal dosing of the most effective drugs, while minimizing treatment failures or toxicities.

Diagnostic genotyping tests for certain CYP450 enzymes are now available:

- The AmpliChip® (Roche Molecular Systems, Inc.) is an U.S. Food and Drug Administration (FDA)-approved, microarray-based pharmacogenomic test. The assay distinguishes 29 known polymorphisms in the *CYP2D6* gene and two major polymorphisms in the *CYP2C19* gene.[1]
- The INFINITI *CYP2C19* Assay (AutoGenomics, Inc.) was cleared for marketing in October 2010 based on substantial equivalence to the AmpliChip *CYP450* test. It is designed to identify variants within the *CYP2C19* gene (*2, *3, and *17).
- The Spartan RX *CYP2C19* Test System (Spartan Bioscience), designed to identify variants in the *CYP2C19* gene (*2, *3, and *17 alleles), was cleared for marketing in August 2013 based on substantial equivalence to the INFINITI *CYP2C19* Assay.
- Verigene *CYP2C19* Nucleic Acid Test (Nanosphere Inc.), designed to identify variants within the *CYP2C19* gene, was cleared for marketing in November 2013 based on substantial equivalence to the INFINITI *CYP2C19* Assay.
- The xTAG® *CYP2D6* Kit (Luminex Molecular Diagnostics) was cleared for marketing in August 2010 based on substantial equivalence to the AmpliChip *CYP450* test. It is designed to identify a panel of nucleotide variants within the polymorphic *CYP2D6* gene on chromosome 22.
- The xTAG® *CYP2C19* Kit v3 (Luminex Molecular Diagnostics), designed to identify variants in the *CYP2C19* gene (*2, *3, and *17 alleles) was cleared for marketing in September 2013 based on substantial equivalence to the INFINITI *CYP2C19* Assay.
- Some tests are offered as in-house laboratory-developed test services. These tests do not require FDA approval.
- Several manufacturers market panels of diagnostic genotyping tests for *CYP450* genes, such as the YouScript Panel (Genelex Corp.), which includes *CYP2D6, CYP2C19, CYP2C9, VKORC1*, *CYP3A4* and *CYP3A5*. Other panel tests include both *CYP450* genes and other non-*CYP450* genes involved in drug metabolism, such as the GeneSight Psychotropic panel (Assurex Health Inc.).

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[2] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used

terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles: (1) analytic validity, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent; (2) clinical validity, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and (3) clinical utility (i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes).

Following is a summary of the key literature. The following limitations in the current evidence for therapeutic agents other than clopidogrel and eliglustat were noted:

- The available evidence is not sufficient to establish how *CYP450* genotyping improves patient management with respect to drug selection and dosing compared to standard treatment without genotyping.
- It is not known if genotyping improves patient outcomes such as therapeutic effect, time to effective dose, and adverse event rate.
- In general, most published *CYP450* pharmacogenomic studies are retrospective evaluations of *CYP450* genotype associations, reporting intermediate outcomes (e.g., circulating drug concentrations) or less often, final outcomes (e.g., adverse events or efficacy). Studies are mostly small and under-powered.
- There is a lack of randomized, prospective studies evaluating the clinical utility of *CYP450* genotyping for any of the indications discussed below.

ANTI-TUBERCULOSIS MEDICATIONS

A number of studies have reported an association between *CYP2E1* status and the risk of liver toxicity from antituberculosis medications.

Systematic Reviews

Wang (2016) reported a meta-analysis of 26 studies with a total of 7,423 participants, evaluating the association of *CYP2E1* variants and susceptibility to antituberculosis drug-induced hepatotoxicity. The overall odds ratios of relevant studies demonstrated that the *CYP2E1 RsaI/PstI C1/C1* genotype was associated with an elevated risk of liver toxicity (odds ratio [OR] 1.32, 95% confidence interval [CI] 1.03 to 1.69, p=0.027), but for the *DraI* variant there was no increase in risk (OR 1.05, 95% CI 0.80 to 1.37, p=0.748).

In a meta-analysis, Sheng (2014) investigated the potential association between cytochrome P450 2E1 (*CYP2E1*) polymorphisms and the risk of anti-tuberculosis drug-induced hepatotoxicity (ATDH).[3] Compared with the wild genotype (*C1/C1*), the OR of ATDH was 1.41 (95% CI 1.1 to 1.82, p=0.007) for the *PstI/RsaI* polymorphism, and 0.78 (95% CI 0.51 to 1.18, p=0.23) for the *DraI* polymorphism. Compared with individuals with N-acetyltransferase 2 (NAT2) fast or intermediate acetylator genotype and *C1/C1* genotype patients who were NAT2 slow acetylators and carried the high activity *CYP2E1 C1/C1* genotype had higher risk for ATDH (OR 3.10, p<0.0001). Authors concluded the meta-analysis indicated that the *CYP2E1 C1/C1* genotype may be a risk factor for ATDH.

A meta-analysis of available trials was reported by Deng (2013).[4] Compared with wild type genotype, patients with any variant genotype had an increased risk of liver toxicity (OR 1.36, 95% CI 1.09 to 1.69). Patients who were slow metabolizers had the highest risk of toxicity (OR 1.88, 95% CI 1.14 to 3.09), and this overall risk was also increased in Asian patients. This study does not address the question of whether genetic testing can reduce liver damage from anti-tuberculosis medications, compared to the usual strategy of monitoring liver enzymes and adjusting medications based on enzyme levels.

Randomized Controlled Trials

No randomized controlled trials (RCTs) evaluating the clinical utility of *CYP450* testing for use in prescribing anti-tuberculosis medications were identified.

Nonrandomized Studies

Evidence of the relationship between *CYP450* genotype and ATDH is limited to small observational studies.[5-7]

Section Summary

The clinical utility of testing for *CYP450* genotyping is uncertain, since management changes for anti-tuberculosis medications based on genotyping results has not been evaluated.

BETA BLOCKER SELECTION AND DOSING

Systematic Reviews

A systematic review by Mottet (2016) examined the influence of pharmacogenetics on heart failure treatment.[8] The authors noted that while studies indicate that *CYP2D6* variants affect the pharmacokinetics of metoprolol, there is limited evidence on the topic and the clinical impact of the relationship has not been established.

Randomized Controlled Trials

No prospective randomized controlled trials of genotype-directed beta blocker selection and dosing have been reported.

Nonrandomized Studies

Existing studies have reported contradictory findings concerning the association of the *CYP2D6* genotype and the response to beta blockers. Some have reported that *CYP2D6* variants are associated with altered responses to these medications,[9, 10] with a few studies indicating that lipophilic beta selective adrenergic receptor antagonists, such as metoprolol used in treating hypertension, may exhibit impaired elimination in patients with *CYP2D6* polymorphisms.[11-15] In addition, increased risk of bradycardia was observed in patients found to be PMs (*CYP2D6 *4/*4*), although the clinical significance of this observation remains to be defined.[11, 16, 17]

In contrast, it has also been reported that no difference in response to metoprolol or carvedilol was observed according to genotype.[18-20]

Section Summary

CYP2D6 genetic variants may be associated with response to beta-blocker treatment, but little evidence currently exists on the clinical utility of testing for *CYP2D6* variants in improving outcomes from beta-blocker treatment.

CLOPIDOGREL: DETERMINING RISK OF ATHEROTHROMBOTIC EVENTS AFTER AN ACUTE CORONARY SYNDROME OR A PERCUTANEOUS CORONARY INTERVENTION

Dual antiplatelet therapy with aspirin and clopidogrel is currently recommended for the prevention of atherothrombotic events after acute myocardial infarction. However, a substantial number of subsequent ischemic events still occur, which may be at least partly due to interindividual variability in the response to clopidogrel. Clopidogrel, a prodrug, is converted by several CYP450 enzymes, including the enzyme coded by *CYP2C19*, to an active metabolite. However, variation in clopidogrel response is an extremely complicated process impacted by a wide range of both genetic and environmental factors, including patient compliance, metabolic state, and drug and food intake.

Prospective, randomized controlled clinical trials are needed to demonstrate the clinical utility of *CYP450* testing in this patient population. Specifically, additional studies are needed that demonstrate reduced recurrence rates for carriers of *CYP2C19* variants who are prospectively treated according to genotype.

Systematic Reviews

Several systematic reviews and meta-analyses have been published, all suggesting that *CYP2C19* gene polymorphisms do not have a substantial or consistent influence on the clinical efficacy of clopidogrel (see below). Meta-analyses have also compared genotype-guided treatment to standard treatment in patients with acute coronary syndrome or those undergoing PCI or stent implantation, with mixed findings.[21-27] However, in the absence of a significant effect of *CYP2C19* variants on clopidogrel efficacy, it is not clear what mechanisms would lead to outcome differences.

Cargnin (2023) published a systematic review and meta-analysis that evaluated the clinical utility of *CYP2C19* genotyping in stroke and transient ischemic attack patients of non-East Asian ancestry.[28] The review investigated the association of *CYP2C19* loss-of-function status with efficacy and safety of clopidogrel-based antiplatelet therapy. Clopidogrel-treated carriers of *CYP2C19* loss-of-function alleles were found at increased risk of stroke compared to non-carriers (risk ratio [RR]: 1.68, 95%CI: 1.04 to 2.71, p= 0.03). However, no significant association was observed with the risk of composite vascular events (RR: 1.15, 95%CI: 0.58 to 2.28, p=0.69) or bleeding (RR: 0.84, 95%CI: 0.38 to 1.86, p=0.67). Similarly, European ancestry patients carrying *CYP2C19* loss-of-funcion alleles displayed a higher risk of stroke (RR: 2.69 (1.11 to 6.51, p=0.03), but not of composite vascular events or bleeding.

Malik (2022) completed a SR with meta-analysis to evaluate the effectiveness of genotype testing-guided P2Y12 inhibitor prescription therapy to patients after PCI for ACS compared to non-genotype guided conventional treatment. The analysis included seven studies (9617 patients). Genotype-guided strategy arm included prasugrel or ticagrelor prescription to patients with loss of function (LOF) of CYP219 alleles (most commonly alleles being *2 and *3) and clopidogrel prescription to those without the LOF allele. The conventional arm included patients treated with clopidogrel without genotype testing. The genotype arm showed decreased major adverse cardiovascular events, improved cardiovascular (CV) mortality,

reduced incidence of myocardial infarction (MI) and decreased incidence of stent thrombosis. Stroke incidence was similar in the two arms.[27]

Wang (2016) reported results of a meta-analysis of 12 studies involving 8,284 patients to evaluate the association between *CYP3A5* variants and the risk of adverse events in patients undergoing clopidogrel therapy.[29] The *CYP3A5* variant was classified as wild-type, heterozygote, and homozygous variant. There was no statistically significant difference in the odds of major adverse cardiovascular events in the three groups classified by *CYP3A5* variant (wild-type plus heterozygote vs. homozygous variant: OR 1.032, 95% CI 0.583 to 1.824, p=0.915, wild-type vs. heterozygote plus homozygous variant: OR 1.415, 95% CI 0.393 to 5.094, p=0.595). There was no significant relation between *CYP3A5* variants and bleeding (homozygous vs. wild-type plus heterozygote: OR 0.798, 95% CI 0.370 to 1.721, p=0.565) or clopidogrel resistance (wild-type plus heterozygote vs. homozygous variant: OR 1.009, 95% CI 0.685 to 1.488, p=0.963; wild-type vs. heterozygote plus homozygous variant: OR 0.618, 95% CI 0.368 to 1.039, p=0.069).

Osnabrugge (2015) reported a systematic review of 11 meta-analyses which summarized studies evaluating the associations between *CYP2C19* genetic status and outcomes in clopidogrel-treated patients.[30] The 11 meta-analyses included a total of 30 primary studies, but not all studies were included in all meta-analyses. Among the 30 primary studies, there were 23 cohort studies and seven post hoc analyses of RCTs. Eight out of 11 meta-analyses on clinical end points reported a statistically significant association between *CYP2C19* genotype and outcomes, with mean effect sizes ranging from 1.26 to 1.96. Five of these eight concluded that there was an association between *CYP2C19* genotype and the clinical end point, two inferred that there was a possible association, and one concluded that the association was not proven because of publication bias. For the outcome of stent thrombosis, all 11 meta-analyses reported a statistically significant association between *CYP2C19* genotype and stent thrombosis, with mean effect sizes ranging from 1.77 to 3.82.

Mao (2013) conducted a systematic review and meta-analysis of studies assessing the effect of *CYP2C19* polymorphisms on clinical outcomes in patients with coronary artery disease treated with clopidogrel.[31] The authors included 21 studies involving 23,035 patients, including prospective cohort studies and post-hoc analyses of RCTs involving patients with coronary artery disease. Carriers (n=6868) of the *CYP2C19* variant allele had a higher risk of adverse clinical events than the 14,429 noncarriers (OR 1.50, 95% CI 1.21 to 1.87, p<0.000). Patients with a loss-of-function *CYP2C19* allele had a higher risk of myocardial infarction (OR 1.62, 95% CI 1.35 to 1.95, p<0.000) and a higher risk of in-stent thrombosis, among those who underwent stent implantation (OR 2.08, 95% CI 1.67 to 2.60, p<0.000).

Bauer (2011) carried out an extensive literature review and meta-analysis of the genetic studies examining the impact of variants of the *CYP2C19* genotype on the clinical efficacy of clopidogrel.[32] Out of 4,203 identified publications, 15 studies met the prespecified inclusion criteria. When comparing carriers of at least one reduced function allele of *CYP2C19* with noncarriers, the unadjusted odds ratios of major adverse events were higher in three studies, lower in one, and not significantly different in eight. For stent thrombosis the odds ratio associated with reduced function allele carrier status was reduced in four studies but showed no significant difference in five. No studies showed a significant positive or negative impact on outcomes as a result of *CYP2C19*17* testing. The overall quality of evidence was graded as low. The authors concluded that “accumulated information from genetic association studies does not indicate a substantial or consistent influence of *CYP2C19* gene polymorphisms on

the clinical efficacy of clopidogrel. The current evidence does not support the use of individualized antiplatelet regimens guided by *CYP2C19* genotype."

Holmes (2011) systematically reviewed studies linking *CYP2C19* testing to treatment with clopidogrel.[33] They identified 32 studies including 42,106 participants. Twenty-one studies included patients with acute coronary syndromes and eight studies included patients with stable coronary heart disease – the latter usually associated with coronary stent placement. While the authors observed a decrease in the measurable concentration of clopidogrel metabolite in patients with a loss-of-function gene on 75 mg of clopidogrel, they were unable to show that this resulted in a clinically meaningful change in outcomes. Of particular note was the observation that when studies were stratified by numbers of outcome events, there was a clear trend toward the null in larger studies, consistent with small-study bias. The strongest data supporting use of testing was in the prediction of stent thrombosis, with a risk ratio of 1.75 (CI 1.50 to 2.03) for fixed effects and 1.88 (CI 1.46 to 2.41) for random effects modeling. Assuming an event risk of 18 per 1000 in the control group they calculated that this corresponded to an absolute increase of 14 stent thromboses per 1000 patients. Holmes et al. noted a trade-off between decreased risk of bleeding with loss of function that in part appeared to mitigate increased susceptibility to thrombosis. They cautioned that efforts to personalize treatment in the loss-of-function setting should be considered carefully because efforts to improve efficacy might be offset by risks of harms such as bleeding.

In a related editorial, Beitelshees (2012) noted that the results of the Holmes (2011) analysis may have been compromised by the fact that patients who did not undergo percutaneous coronary intervention (PCI) were included.[34] They concluded that the association between *CYP2C19* genotype and adverse outcomes with clopidogrel treatment may not be present in all settings and may be strongest for clopidogrel indications with the greatest effects such as patients undergoing PCI. This observation is supported by observations in the CHARISMA genetics study reported by Bhatt.[35] A total of 4,819 patients were genotyped in this study and no relationship between *CYP2C19* status and ischemic outcomes in stable patients was observed. Bhatt also observed significantly less bleeding in this subgroup.

Xi (2017) published a systematic review and meta-analysis on *CYP2C19* genotype and adverse outcomes with clopidogrel treatment following stent implantations in Asian populations.[36] Twenty studies with a total of 15,056 patients were included. MACE, a composite outcome of myocardial infarction and cardiovascular death, was the primary outcome assessed. Patients that had at least one loss-of-function allele had an increased risk of MACE compared with noncarriers (OR 1.99, 95% CI 1.64 to 2.42, $p<0.001$), and a reduced risk of bleeding (OR 0.66, 95% CI 0.46 to 0.96, $p<0.001$). Subgroup analysis indicated that risk of MACE was significantly elevated for patients with a loss-of-function allele among those who had a high loading dose of clopidogrel (600 mg).

Randomized Controlled Trials

Pereira (2020) published results of the TAILOR-PCI randomized trial comparing genotype-guided antiplatelet therapy to standard clopidogrel therapy in 5,302 patients undergoing PCI for acute coronary syndromes or stable coronary artery disease.[37] This was a multicenter trial carried out in the US, Canada, Mexico, and South Korea. Patients in the genotype-guided group who had a loss-of-function *CYP2C19* allele received ticagrelor, while noncarriers and those in the control group received clopidogrel. The primary outcome of the trial was a composite of cardiovascular death, stroke, myocardial infarction, stent thrombosis, and severe

recurrent ischemia at one year. Major and minor bleeding were also assessed. No significant differences were seen for the primary outcome, which occurred in 113/2,641 (4.4%) of the genotype-guided group and 135/2,635 (5.3%) of the control group (HR 0.84, 95% CI 0.65 to 1.07, p=0.16), or any of the 11 prespecified secondary outcomes.

A randomized trial by Claassens (2019) assigned 2,488 patients undergoing PCI to receive either genotype-guided (n=1,242) or standard selection (n=1,246) of oral platelet inhibitors.[38] For the genotype-guided group, patients carrying *CYP2C19*2* or *CYP2C19*3* loss-of-function alleles were treated with ticagrelor or prasugrel, while non-carriers were treated with clopidogrel. The two primary outcomes of this trial were an adverse event composite of death from any cause, myocardial infarction, stent thrombosis, stroke or major bleeding and a bleeding outcome composed of major or minor bleeding at 12 months according to Platelet Inhibition and Patient Outcomes (PLATO) criteria. A non-inferiority analysis indicated that the genotype-guided treatment selection was not inferior to standard treatment selection for the adverse events and was associated with a lower incidence of bleeding (hazard ratio [HR] 0.78, 95% CI 0.61 to 0.98, p=0.04). A prespecified subanalysis of this study found that the *CYP2C19*17* variant was not associated with the thrombotic or bleeding outcomes.[39]

Roberts (2012) reported on the use of a point-of-care *CYP2C19*C* genetic test for treatment selection (standard treatment [prasugrel] versus clopidogrel).[40] In this controlled trial, patients undergoing PCI for acute coronary syndrome or stable angina were randomized to genotyping for treatment selection or standard treatment. In the tested group, carriers were given 10 mg of prasugrel daily. Noncarriers and all patients in the control group were given 75 mg of clopidogrel per day. The primary endpoint was high on-treatment platelet reactivity. This measure is used as a marker of cardiovascular events. In the group with genotyping none of the 23 carriers had high on-treatment platelet reactivity; in the group receiving standard treatment 30% of 23 carriers had high on-treatment platelet reactivity. These authors concluded that rapid genotyping with subsequent personalized treatment reduces the number of carriers treated who exhibit high on-treatment reactivity. The authors do note that alternative approaches using either phenotyping or a combination of both phenotyping and genotyping might optimize treatment decision making.

Han (2017) evaluated the impact of *CYP2C19* genotype in a randomized trial designed to compare the effects of triflusal and clopidogrel in patients with a first-time, non-cardiogenic stroke.[41] The study included 784 patients that were randomized 1:1 to either triflusal or clopidogrel, and the primary endpoint was recurrent stroke (ischemic or hemorrhagic). The median follow-up was 2.7 years, and 597 (76%) of patients completed the trial. There were no significant differences found for individuals with a poor-metabolizer *CYP2C19* genotype (**2/*2*, **2/*3*, or **3/*3*, n=484) by treatment group. Additionally, there were no significant differences in outcomes between genotype groups. However, the authors noted that the required sample size for the study (n=1,080) was not reached.

So (2016) tested a pharmacogenomic strategy to guide anti-platelet therapy in patients with ST-elevation myocardial infarction.[42] There were 102 patients enrolled in the study and they received point-of-care genetic testing for *CYP2C19**2, *ABCB1 TT* and *CYP2C19*17*. Those with either the *CYP2C19*2* or the *ABCB1 TT* allele were randomly assigned to either prasugrel 10 mg daily or an augmented clopidogrel strategy (150 mg daily for six days, then 75 mg daily). The primary endpoint of this trial was high on-treatment platelet reactivity (HPR). There were 59 patients that were carriers of at least one of the two variants. Among these, those randomized to prasugrel treatment had reduced rates of HPR compared to the clopidogrel

treatment group (P2Y12 reaction unit thresholds of >234: 0 vs. 24.1%, p=0.0046; and PRU>208:3.3 vs. 34.5%, p=0.0025, respectively). While the results of this study indicate that prasugrel treatment may be superior to clopidogrel treatment in carriers, the effects of the pharmacogenomic strategy itself were not tested in this trial, as there was no group randomized to a non-pharmacogenomic strategy.

Wang (2016) evaluated the association between *CYP2C19* loss-of-function alleles and the efficacy of clopidogrel in patients with minor stroke or transient ischemic attack.[43] In this trial, 2,933 Chinese patients were randomized to treatment with either clopidogrel plus aspirin or aspirin alone. *CYP2C19* genotype and clinical outcomes including new stroke, other vascular events, and bleeding were assessed. There were 1,726 carriers identified with a loss-of-function allele. After 90 days of follow-up, the clopidogrel plus aspirin treatment was more effective in preventing new stroke than aspirin alone only in noncarriers (non-carrier HR 0.51, 95% CI 0.35 to 0.75; carrier HR 0.93, 95% CI 0.69 to 1.26, p=0.02 for interaction). Similar results were seen for other vascular outcomes. Bleeding was more common in the clopidogrel plus aspirin treatment group than the aspirin only group, but there was no difference by carrier status (2.3% for carriers and 2.5% for noncarriers in the clopidogrel-aspirin group vs. 1.4% for carriers and 1.7% for noncarriers in the aspirin only group, p=0.78 for interaction). These results indicate that for carriers of a *CYP2C19* loss-of-function allele, treatment with aspirin alone may result in better outcomes than combined clopidogrel and aspirin treatment.

Zhang (2016) compared the efficacy and safety of ticagrelor and high-dose clopidogrel in 181 patients with acute coronary syndrome that were intermediate or PMs of clopidogrel in an open-label randomized trial.[44] The primary study outcome was a composite outcome of death, stroke, recurrent myocardial infarction, and stent thrombosis. This outcome occurred in 4.4% of the patients in the ticagrelor group compared with 20.0% if the high-dose clopidogrel group (p<0.001). There was no significant difference in bleeding between the treatment groups. The authors concluded that ticagrelor may be a safer and more efficacious treatment than high-dose clopidogrel in patients that are intermediate or PMs.

Similarly, Doll (2016) evaluated the impact of *CYP2C19* variants in acute coronary syndrome patients randomized to treatment with either prasugrel or clopidogrel.[45] This study was a substudy of the double-blind TRILOGY ACS trial, which included 9,326 patients from 52 countries who had unstable angina or non-ST-segment elevation myocardial infarction (NSTEMI). Of these, 5,736 patients participated in the genetics cohort, and a subset of 2,236 of these additionally participated in a platelet function substudy. Patients were classified as either extensive metabolizers (EM) or reduced metabolizers (RM) based on their *CYP2C19* genotype. The primary study endpoint was a composite of cardiovascular death, recurrent myocardial infarction, or stroke, and there was not difference between metabolizer status groups or treatment groups for this outcome. In multivariate analysis, EM patients had a reduced risk of myocardial infarction compared with RM patients (HR: 0.80), but other individual outcomes were similar. Among patients treated with clopidogrel, RM patients had significantly higher platelet reactivity than EM patients. There was no such difference among those treated with prasugrel.

Pare (2010) retrospectively genotyped 5,059 patients from two large randomized trials (the Clopidogrel in Unstable Angina to Prevent Recurrent Events or “CURE” trial and the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events or “Active” trial) that showed clopidogrel reducing the rate of cardiovascular events when compared with placebo in patients with acute coronary syndromes and atrial fibrillation.[46] Genotyping was

performed for **2*, **3*, and **17* of the *CYP2C19* allele. These investigators observed that the efficacy and safety of clopidogrel compared with placebo was not affected by *CYP2C19* loss of function alleles. Even when data were restricted to evaluation of patients homozygous for loss of function, no increased risk of cardiovascular events was observed. Although the reason for these divergent findings remains unclear, it was noted that in the populations studied, use of stents was substantially less than in previous reports (19% of patients with acute coronary syndromes and only 14.5% in patients with atrial fibrillation).

Nonrandomized Studies

Nonrandomized studies have reported conflicting findings. Several nonrandomized studies found increased risks of thrombotic events in patients treated with clopidogrel who were *CYP2C19* variant carriers.[47-56] However, others have not found such an association.[57-61] In one large retrospective study of 5,059 patients from two large RCTs that compared clopidogrel with placebo in reducing the rate of cardiovascular events, the authors reported that that the efficacy and safety of clopidogrel as compared with placebo was not affected by *CYP2C19* loss-of-function alleles.[46] Even when data were restricted to evaluation of patients homozygous for loss of function, no increased risk of cardiovascular events was observed. One study of patients with symptomatic intracranial atherosclerotic disease found lower odds of thrombotic events or death in individuals with a loss-of-function allele.[62]

Recent studies have suggested that changes in platelet reactivity in carriers may be dose-dependent,[63, 64] and that in PCI patients, heterozygous carriers might require up to triple dosing of clopidogrel to reach a desired target platelet reactivity level.[65, 66] In homozygous carriers, it has been reported that even with higher clopidogrel doses, platelet reactivity cannot be reduced to the level achieved with clopidogrel treatment in noncarriers. In these patients, other drugs such as prasugrel or ticagrelor may be used as treatment alternatives. However, not all studies have found a difference in platelet response to clopidogrel based on *CYP2C16* genotype.[67]

Cavallari (2018) reported outcomes among 1,815 PCI patients at multiple centers who had antiplatelet therapy guided by *CYP2C19* testing.[68] For individuals with a loss-of-function allele, alternative antiplatelet therapies (prasugrel, ticagrelor) were recommended instead of clopidogrel. Patients were followed for major cardiovascular events (myocardial infarction, stroke, or death) for 12 months following PCI. Among the 572 (31.2%) of patients with a loss-of-function allele, the risk for cardiovascular events was significantly higher in those patients prescribed clopidogrel instead of alternative therapy (adjusted HR 2.26, 95% confidence interval 1.18 to 4.32, p=0.013). There was no difference in cardiovascular events between patients with a loss-of-function allele prescribed alternative therapy and patients without a loss-of-function allele.

Desai (2013) reported results of a study of antiplatelet therapy prescribing behavior for antiplatelet therapy for 499 patients with a recent acute coronary syndrome or percutaneous coronary intervention who underwent *CYP2C19* genotyping.[69] Among the 146 subjects (30%) with at least one *CYP2C19* reduced function allele, although providers were more likely to increase antiplatelet therapy intensification than for noncarriers, only 20% had their clopidogrel dose changed or were switched to prasugrel.

U.S. Food and Drug Administration (FDA) Safety Communication

In 2010, the FDA issued a public safety communication and added a boxed warning to the label of Plavix about the availability of genetic testing and alternative drug therapies in patients who are found to be PMs of the drug (patients with *CYP2C19* *2/2, *3/3, or *2/3 genotypes). The FDA endorsement is based on retrospective analyses which suggested that PM status had a higher rate of cardiovascular events or stent thrombosis compared to EM.[66, 70]

Section Summary

Individuals with genetic variants of cytochrome p450 have a decreased ability to metabolize clopidogrel, but the impact on clinically meaningful outcomes is uncertain. Despite this lack of evidence, FDA labeling recommends cytochrome p450 genetic testing for selection and dosing of clopidogrel (Plavix®).

SELECTION OR DOSING OF CODEINE

Codeine is metabolized by *CYP2D6* to morphine. Enhanced *CYP2D6* activity (i.e., in *CYP2D6* ultra-rapid metabolizers) predisposes to opioid intoxication.

U.S. Food and Drug Administration (FDA) Safety Communication

In 2013, in response to reports of deaths that have occurred in children with obstructive sleep apnea who received codeine following tonsillectomy and/or adenoidectomy and had evidence of being UMs of codeine due to a cytochrome *CYP2D6* polymorphism, the FDA added a black box warning to the labeling for codeine, listing its use for postoperative pain management in children following tonsillectomy and/or adenoidectomy as a contraindication. The FDA's guidelines state, "Routine *CYP2D6* genotype testing is not being recommended for use in this setting because patients with normal metabolism may, in some cases, convert codeine to morphine at levels similar to ultra-rapid metabolizers."[71]

In 2007, the U.S. Food and Drug Administration (FDA) issued a warning regarding codeine use by nursing mothers. Nursing infants "may be at increased risk of morphine overdose if their mothers are taking codeine and are ultra-rapid metabolizers of codeine." However, the FDA is not recommending genotyping for any population prior to prescribing codeine because "there is only limited information about using this test for codeine metabolism."[47]

Section Summary

Enhanced *CYP2D6* activity is associated with risk of accelerated codeine metabolism with high levels of circulating morphine in rapid metabolizers, which is thought to have contributed to deaths in infants of nursing mothers prescribed codeine and in pediatric patients post-tonsillectomy. The clinical utility of testing for *CYP450* genotyping is uncertain, since management changes for codeine for nursing mothers based on genotyping results has not been evaluated.

DOSE AND SELECTION OF HIGHLY ACTIVE ANTIRETROVIRAL AGENTS

Efavirenz

Current guidelines recommend efavirenz as a preferred non-nucleoside reverse transcriptase inhibitor component of highly active antiretroviral therapy for HIV-infected patients. Forty to 70% of patients report adverse central nervous system (CNS) effects. While most resolve in the first few weeks of treatment, about 6% of patients discontinue efavirenz due to adverse

effects.[72] Efavirenz is primarily metabolized by *CYP2B6*, and inactivating polymorphisms are associated with higher efavirenz exposure, although plasma levels appear not to correlate with side effects.

Systematic Reviews

No systematic reviews of genotype-directed efavirenz dosing for the treatment of HIV infection have been identified.

Randomized Controlled Trials

No randomized prospective trials of genotype-directed efavirenz dosing for the treatment of HIV infection have been reported.

Nonrandomized Studies

Limited reports suggest that *CYP2B6* PMs have markedly reduced side effects while maintaining viral immunosuppression at substantially lower doses.[73, 74] Simulations of such dose adjustments support this position.[75] Additional studies also report an association between polymorphism in *CYP2B6* gene and early discontinuation of efavirenz treatment. However, further research is needed in order to examine the clinical utility of the observed association.

Gross (2017) assessed the role of *CYP2B6* genotypes in an observational cohort study of efavirenz-based regimens in Botswana.[76] The primary endpoint of the study was a composite of death, loss to care, or HIV RNA above 25 copies/ml at six months. Among the 801 participants, the slow-metabolism alleles were associated with reduced efavirenz clearance, but not with the study outcomes or CNS toxicity.

Cabrera (2009) reported on an evaluation in 32 patients of the relationship between *CYP2B6* polymorphisms and efavirenz clearance.[77] Although they reported that *CYP2B6* polymorphisms accounted for only 27% of interindividual variability, they noted decreased clearance of 50% in the patient group with the *G/T* genotype and 75% with the *T/T* genotype. Based on this observation, they suggested a gradual reduction in dose of efavirenz be considered in patients with these phenotypes. They proposed use of a model to incorporate factors that affect drug levels. However, based on the complexity of factors involved in dosing, they concluded drug treatment should be carefully evaluated using therapeutic drug monitoring and assessment of clinical efficacy.

Gallien (2017) assessed the role of *CYP2B6* polymorphisms and efavirenz-induced CNS symptoms in a substudy of the ANRS ALIZE trial that included 191 patients.[78] The authors reported an association between the *CYP2B6 516T* allele and higher plasma efavirenz levels, and the occurrence of a first central nervous system event.

Two studies have been published that demonstrated an association between markers and early efavirenz discontinuation: one evaluating 373 patients for polymorphisms in *CYP2B6* and constitutive androstane receptor (CAR)[1], and one evaluating genotyping for 23 markers in 15 genes[70]. Both articles recommended further study to determine the clinical utility of these associations.

Lee (2014) evaluated the effect of *CYP2B6* G516T polymorphisms on the plasma efavirenz concentrations in HIV-infected patients, with or without concomitant rifampicin use.[79] The

study included 171 HIV-infected patients including 18 with tuberculosis, 113 (66.1%) with *CYP2B6 G516G*, 55 (32.2%) with *G/T*, and 3 (1.8%) with *T/T* genotype. Patients with *G/T* or *T/T* genotype had a significantly higher plasma efavirenz concentration than those with *G/G* genotype (2.50 vs. 3.47 mg/L for *G/T* genotype and 8.78 mg/L for *T/T* genotype; p<0.001).

Bienvenu (2014) evaluated the effect of single nucleotide polymorphisms (SNPs) in five drug metabolizing enzymes on plasma efavirenz levels and treatment response in patients treated with efavirenz alone (n=28) and when treated with cotreated with efavirenz and rifampicin-based TB treatment (n=62).[80] Serum efavirenz levels differed based on *CYP1A2* genotype (T/G vs. T/T) when patients were cotreated with efavirenz and rifampicin, but not when patients received efavirenz alone. High serum efavirenz levels were associated with *CYP2B6 516T/T* genotype, both with and without rifampicin treatment. *CYP2B6 516T/T* and *983T/T* genotypes predicted supratherapeutic efavirenz levels (positive predictive value, 100%), particularly in the absence of rifampicin.

A small cohort study by Bolton Moore (2017) compared genotype-directed efavirenz dosing to a pharmacokinetic model of efavirenz exposure based on FDA-approved doses in young children aged 3 to 36 months.[81] This analysis predicted that genotype-directed dosing would avoid subtherapeutic levels in nearly one-third of those with a *516GG/GT* genotype and excessive levels in more than half of those with *516T/T* genotypes.

A study by Mollan (2017) evaluated the relationship between *CYP2B6* and *CYP2A6* genotypes and risk of suicide in four efavirenz clinical trials and found that genotypes associated with higher plasma efavirenz levels were also associated with suicide risk.[82] The association was strongest among white participants.

Other Antiretroviral Therapies

While the preponderance of the evidence related to *CYP450* genetic testing for antiretroviral therapies has focused on efavirenz, there has been some investigation of pharmacogenomics testing for other antiretroviral therapies.

In a case-control analysis of 27 patients with nevirapine-induced Stevens-Johnson syndrome (SJS) induced by the non-nucleoside reverse transcriptase inhibitor nevirapine and 78 controls, Ciccacci (2013) found that polymorphisms in *CYP2B6*, but not in *CYP3A4* and *CYP3A5*, were associated with SJS risk.[83] Additionally, in a prospective cohort study including 66 women receiving nevirapine, Oluka (2015). reported that *CYP2B6* genotype was associated with serum nevirapine concentration and CD4 counts.[84] Finally, Lu (2014) reported that *CYP3A5* polymorphisms are associated with serum concentrations of maraviroc, a CCR5 receptor antagonist used for HIV treatment, in healthy control subjects.[85]

Section Summary

Genetic variants in *CYP2B6* are associated with increased side effects for patients treated with efavirenz, leading to some recommendations to reduce dosing based on genotype results. The impact of this strategy on health outcomes has yet to be evaluated; therefore, the clinical utility of genotyping for efavirenz dose is uncertain. Preliminary evidence suggests that *CYP450* polymorphisms may be associated with serum levels and adverse effects of other antiretroviral therapies, but the clinical utility of these findings is also uncertain.

ELIGLUSTAT (CERDELGA™) FOR GAUCHER DISEASE TYPE I.

Eliglustat (Cerdelga™), a small-molecule oral glucosylceramide analogue that inhibits the enzyme glucosylceramide synthase was developed by Genzyme for the treatment of Gaucher disease type 1 in adults.[86] Inhibition of this enzyme reduces the accumulation of the lipid glucosylceramide in the liver, spleen, bone marrow and other organs. Eliglustat is primarily metabolized by *CYP2D6* and, therefore, *CYP2D6* genotype/phenotype greatly impacts the dosing of eliglustat. A small number of adult patients who metabolize eliglustat more quickly or at an undetermined rate, based on *CYP2D6* genotype, will not be eligible for eliglustat treatment.

There are no published studies that demonstrate how genotyping results for *CYP2D6* affect selection and dosing for eliglustat (Cerdelga™).

U.S Food and Drug Administration (FDA) Safety Communication

In 2014, the U.S. Food and Drug Administration (FDA) labeling for eliglustat (Cerdelga™) included information on personalizing initial selection and dose according to genotyping results for *CYP2D6*. The FDA labeling requires that patients be selected on the basis of *CYP2D6* metabolizer status as determined by genotype, with recommendations based on genotype about dosage and concomitant use of *CYP2D6* and *CYP3A* inhibitors.[87]

Section Summary

Individuals with genetic variants of CYP450 have an increased ability to metabolize eliglustat, a small-molecule oral glucosylceramide analogue that inhibits the enzyme glucosylceramide synthase was for the treatment of Gaucher disease type 1. Although the current evidence is limited to industry-sponsored nonrandomized studies on the efficacy of eliglustat, FDA labeling recommends cytochrome p450 genetic testing for selection and dosing of eliglustat. Therefore, *CYP450* genotyping may be considered medically necessary to guide selection and dose management of eliglustat**.**

H. PYLORI INFECTION

Currently, multiple regimens are available for treating *H. pylori* infection. These include proton pump inhibitors (PPI) to suppress acid production, in combination with antibiotic treatment consisting of one or more agents such as amoxicillin, clarithromycin, or metronidazole. Genetic factors may influence the success of *H. pylori* treatment through effects on PPI metabolism. Individuals with polymorphisms in the *CYP2C19* gene, a member of the *CYP450* family, metabolize PPIs more slowly than normal. Observational research suggests that patients who are extensive metabolizers of PPIs have lower eradication rates following standard treatment for *H. pylori*, compared with PMs.

If *CYP2C19* status is known prior to treatment, adjustments could potentially be made in the selection of PPI and/or the dosing schedule to achieve optimal acid suppression in all patients. Improved eradication rates for *H. pylori* could lead to improved health outcomes by reducing the need for re-treatment following treatment failure, reducing recurrences of *H. pylori*-associated disorders, and reducing the morbidity and mortality associated with disease recurrence.

To determine whether treatment decisions based on genetic testing improve health outcomes, direct comparisons with standard treatment selection strategies are needed. Prospective RCTs comparing the two strategies are necessary for reliable comparisons. The optimal trial would isolate the impact of treatment changes made as a result of genetic status, be performed in the

U.S. in a population with rates of *CYP2C19* polymorphisms approximating that of the general U.S. population, use an approach to diagnosing *H. pylori* that reflects usual care in the U.S., and would use a standard treatment regimen recommended for U.S. patients.[88]

Systematic Reviews

Tang (2013) published results from a meta-analysis of RCTs to re-evaluate the impact of *CYP2C19* variants on PPI-based triple therapy for *H. pylori* infection.[89] Authors identified 16 RCT datasets derived from 3,680 patients. There were significant differences in that rate between homozygous (HomEMs) and heterozygous (HetEMs) extensive metabolizers (OR 0.724, 95% CI 0.594 to 0.881), between HomEMs and PMs (OR 0.507, 95% CI 0.379 to 0.679), or between HetEMs and PMs (OR 0.688, 95% CI 0.515 to 0.920), regardless of the PPI being taken. Furthermore, sub-analysis of individual PPIs was carried out to explore the difference across all the PPIs used. A significantly low rate was seen in HomEMs vs. HetEMs taking either omeprazole (OR 0.329, 95% CI 0.195 to 0.553) or lansoprazole (OR 0.692, 95% CI 0.485 to 0.988), and also in HomEMs vs. PMs for omeprazole (OR 0.232, 95% CI 0.105 to 0.515) or lansoprazole (OR 0.441, 95% CI 0.252 to 0.771). However, there was no significant difference between HetEMs and PMs taking either one. No significant differences were observed for rabeprazole or esomeprazole across the *CYP2C19* genotypes of interest.

Authors concluded that carriage of *CYP2C19* loss-of-function variants is associated with increased *H. pylori* eradication rate in patients taking PPI-based triple therapies when omeprazole or lansoprazole is chosen. In the meta-analysis, individual PPIs were pooled without considering the dose, duration of therapy and the type of antibiotic agents, resulting in some confounders for *CYP2C19* phenotypes and the eradication rates of PPI-based therapy. Therefore, results may not be generalizable to clinical practice.

Similar results were seen in a meta-analysis by Morino (2021), which included 25 RCTs of PPI-amoxicillin-clarithromycin regimen among different *CYP2C19* genotypes.[90] In an intention-to-treat analysis, eradication rates were highest among poor metabolizers (86.8% [644/742], 95% CI 83.9 to 88.9%), followed by intermediate (81.2% [1,498/1,844], 95% CI 79.3 to 83.0%) and extensive metabolizers (77.7% [1,137/1,464], 95% CI 75.3 to 79.6%), but these were not significantly different (p=0.696). This analysis also pooled various drug regimens, limiting generalizability.

Randomized Controlled Trials

Choi (2022) published the results of a double-blind, controlled, multicenter study to evaluate whether tegoprazan (50 mg)-based triple therapy (TPZ) was noninferior to lansoprazole (30 mg)- based triple therapy (LPZ) for treating H. pylori. The primary endpoint was the H. pylori eradication rate. Subgroup analyses were performed according to the cytochrome P450 (CYP) 2C19 genotype, the minimum inhibitory concentration (MIC) of amoxicillin and clarithromycin, and underlying gastric diseases. Subgroup analyses according to MICs or CYP2C19 did not show differences in eradication rate.[91]

A randomized, controlled trial comparing a pharmacogenomics-based treatment regimen with a standard regimen was evaluated.[92] This study randomized 300 Japanese patients to a pharmacogenomics-based treatment regimen versus a standard treatment regimen. The TEC Assessment offered the following observations and conclusions concerning this study:

> “Eradication rates after first-line treatment were higher in this study for the pharmacogenomics group compared with the standard treatment group. However, because of numerous variations in treatment protocol within the pharmacogenomics group, it was not possible to determine whether the improvement resulted from the tailored PPI dosages according to *CYP2C19* genetic status, or due to other variations in the treatment protocol unrelated to *CYP2C19* status.
>
> There were numerous variations in the treatment regimen within the experimental group that made it difficult to determine which specific aspects of the treatment regimen may have led to benefit. In particular, it appeared that clarithromycin resistance was an important factor in treatment success, and that there may have been an interaction between clarithromycin resistance and *CYP2C19* status. From the data reported in the study, it was not possible to separate the potential impact of clarithromycin resistance on eradication rates from the impact of pharmacogenetically tailored PPI dosage schedules.
>
> In addition to the limitations on internal validity, the clinical relevance of the study was also limited for several reasons. The treatment approach used was relatively intensive, including genetic testing for *CYP2C19*, esophagogastroduodenoscopy with biopsy for all patients, and testing of *H. pylori* isolates for clarithromycin resistance. This treatment approach was much more intensive than that generally used in the United States, where the diagnosis of *H. pylori* is usually made by noninvasive methods, and initial empiric treatment is instituted without isolating *H. pylori* or testing for resistance. Furthermore, the patient population was from Japan, limiting the generalizability of the results, especially given the ethnic differences in *CYP2C19* genetic status.”

A similar trial by Zhou (2016) compared tailored therapy, based on *CYP2C19* genotype and clarithromycin sensitivity, to triple therapy plus bismuth and concomitant therapy.[93] In this study, 1,050 *H. pylori* patients at three tertiary hospitals in China were randomized to ten days of one of the three treatment regimens. While the authors reported a significantly higher eradication rate in the tailored treatment group in the setting of high antibiotic resistance rates, this study has many of the same limitations noted for the Japanese study described above.

A much smaller trial by Arévalo Galvis (2019) found no significant difference between triple therapy with standard omeprazole compared with personalized therapy based on *CYP2C19* genotype.[94] This trial included 133 patients in Columbia.

Additional RCTs evaluating *H. pylori* eradication rates for different treatment regimens reported that the *CYP2C19* genotype appears to play a role in eradication rates,[95-97] though not all trials have found this to be the case.[98] However, these trials were not designed to compare a pharmacogenomics-based treatment regimen with a standard regimen.

Nonrandomized Studies

Several nonrandomized studies have evaluated the impact of *CYP2C19* variants on PPI metabolism, *H. pylori* eradication, and ulcer healing.[99-102] These studies have had mixed results. Additional small, nonrandomized and retrospective studies of *CYP2C19* gene polymorphisms and *H. pylori* treatment have been published; however, the clinical utility of genotyping was not addressed.[95, 103-114]

Section Summary

The clinical utility of testing for *CYP450* genotyping is uncertain, since management changes to select and dose treatment for H. *pylori* eradication based on genotyping results has not been evaluated.

IMMUNOSUPPRESSANT DOSING FOR ORGAN TRANSPLANTATION

Immunosuppressive drugs administered to organ transplant patients have a narrow therapeutic index with the consequences of rejection or toxicity on either side. In addition, there is variability in patient response, requiring close clinical follow-up and routine therapeutic drug monitoring to maintain safety and efficacy. *CYP3A5* genetic polymorphisms have been evaluated in relation to metabolism of immunosuppressant drugs.

Tacrolimus blood levels are related to *CYP3A5* genetic variants, with an approximately 2.3-fold difference in daily dose required to maintain target concentration between *CYP3A5*3* and *CYP3A5*1* homozygous variants.[115] *CYP3A5*1* carriers have been reported to have a significant delay in reaching target tacrolimus concentrations compared to noncarriers. Although the overall rate of acute rejection episodes was not higher in *CYP3A5*1* carriers, their rejection episodes did occur earlier.[116]

Population-based pharmacokinetic models for clearance of tacrolimus in kidney transplant recipients have been developed for both adult and children.[117, 118] These models predict clearance based on *CYP3A5*3/*3* as well as clinical factors. Results show that oral clearance of tacrolimus is impacted by body weight, hematocrit and time since transplant, in addition to *CYP3A5*3/*3* polymorphisms.

Pharmacogenetic applications for other immunosuppressants (sirolimus and cyclosporine) have also been investigated; however, evidence for clinical utility of genotyping for dosing of these drugs is even less clear than for tacrolimus.

Systematic Reviews

Yang (2021) published a systematic review and meta-analysis of RCTs comparing genotype-guided and conventional tacrolimus dosing in kidney transplant patients.[119] Five RCTs with a total of 684 patients were included, and all trials were judged to be of high quality using GRADE methodology. The proportion of patients with a tacrolimus exposure within the therapeutic range at steady state, which was the primary outcome, was higher among the genotype-guided group (relative risk [RR] 1.40, 95% CI 1.14 to 1.72, p=0.001). However, there were no significant differences between groups in the health outcomes assessed, including incidences of acute graft rejection, delayed graft function, adverse events, or graft survival censored for death, suggesting that there “was no utility in pharmacogenetics for tacrolimus based on the [*CYP3A5*].”

A meta-analysis by Hendijani (2018) focused on the effect of *CYP3A5*1* expression on tacrolimus dose in pediatric transplant patients.[120] Data from 11 studies (n=596) were included. The results of the analysis indicated that *CYP3A5*1* expressers required a tacrolimus dose that was 0.06 mg/kg/day higher to achieve the same blood level as non-expressers.

Rojas (2015) published results from a systematic review and meta-analysis evaluating the effect of the *CYP3A5* polymorphism on kidney transplant recipients treated with tacrolimus. The authors found that *CYP3A5*1* carriers had significantly lower plasma tacrolimus concentration per daily dose per body weight than carriers of the *CYP3A5*3/*3* genotype.[121] It is important to note that this review only included observational studies thereby precluding firm

conclusions. A similar meta-analysis by Khan (2020) of kidney transplant recipients reported that *CYP3A5* genotype was significantly associated with the trough concentration-dose ratio, but not with allograft rejection in European patients.[122]

In a meta-analysis, Rojas (2013) investigated the effect of the *CYP3A5 6986A>G* polymorphism in liver donors and transplant recipients on tacrolimus pharmacokinetics.[123] The meta-analysis demonstrated the trough blood concentration normalized for the daily dose (C) per kilogram body weight (D) (C/D, ng/ml/mg/kg/day) ratio to be significantly higher in recipients with non-expressed donor variants at all time points. In recipients, the variant did not influence the C/D ratio. The authors concluded the presence of the *CYP3A5 6986A>G* polymorphism in the donor affects tacrolimus pharmacokinetics in the recipient for the first month after transplantation. Authors note the evidence provided shows no effect of the recipient genotype; however, the quality of the evidence was low, thereby precluding the drawing of firm conclusions.

Buendia (2014) used a random effects model to conduct a meta-analysis comparing tacrolimus daily dose, trough concentrations, and dose-adjusted trough concentrations across liver transplant donor and recipient genotype pairs.[124] Eight studies (n=694) met inclusion criteria. Significantly lower tacrolimus trough concentrations were found when either the donor or recipient expressed a **1* allele up to 12 months post-transplant, requiring higher daily dose to maintain target drug concentrations.

Randomized Controlled Trials

Based on observations that patients with genetic variants of *CYP3A5* require higher tacrolimus doses to achieve a therapeutic trough concentration (C0), Thervet (2010) conducted an RCT to compare the proportion of tacrolimus-treated renal transplant patients within a targeted C0 range for two tacrolimus dosing strategies, *CYP3A5* genotype-informed dosing or standard dosing.[125] The study included 280 patients, 140 who received standard dosing and 140 who received *CYP3A5* genotype-specific dosing. The genotype-directed therapy group was more likely to achieve the study's primary outcome, proportion of patients with tacrolimus C0 in the target range after six oral doses, than the control group (43.2%, 95% CI 36% to 51.2%; vs. 29.1%, 95% CI 22.8% to 35.5%, p=0.030). The genotype-directed therapy group had fewer dose adaptations (281 vs. 420, p=0.004). Graft function and survival were similar between groups.

An RCT by Min (2018) evaluating genotype-guided tacrolimus dosing after pediatric solid organ transplantation showed similar results to the Thervet (2010) trial regarding reduced time to targeted therapeutic tacrolimus concentrations with the guided approach, but was similarly not powered to assess differences in health outcomes.[126]

Nonrandomized Studies

Passey (2011) used tacrolimus blood trough and dose information from 681 kidney transplant recipients to develop a predictive tool for tacrolimus apparent clearance, from which individual tacrolimus dosing could be extrapolated.[127] The study's final model included *CYP3A5* genotype, along with other clinical factors, but was not validated in an independent population. A similar, but smaller study (n=59) was published by Woillard (2017), which used *CYP3A4* and *CYP3A5* alleles for model development.[128]

Boughton (2013) evaluated the model developed by Passey (2011)[127] in a single-center cohort of renal transplant recipients.[129] The study found a weak correlation (*R*=0.431) between clearance based on dose-normalized tacrolimus trough concentrations and the algorithm-predicted clearance.

Tapirdamaz (2014) studied the influence of SNPs in the genes of donor and recipient calcineurin inhibitor (CNI) enzyme *CYP3A5* and the CNI-transporting ABCB1 on the development of chronic kidney disease (CKD) following liver transplantation (LT).[130] Tacrolimus predose concentrations and *CYP3A5 6986A>G* and *ABCB1 3435C>T* SNPs were determined in 125 LT recipients and their donors. Median follow-up was 5.7 years. CKD developed in 47 patients (36%). No correlation was found between CKD and tacrolimus levels or the investigated SNPs.

In 410 living-donor LT patients, Uesugi (2014) found no significant effect of *CYP3A5* genotype on the rate of acute cellular rejection between postoperative days 14 and 23.[131] However, higher rates of acute cellular rejection were found in patients who received a graft liver with *CYP3A5*1* allele than those with graft liver with the *CYP3A5*3/*3* genotype.

Kato (2016) reported long-term outcomes for 67 donor/recipient couples and their relation to tacrolimus pharmacokinetics and *CYP3A5* genotype.[132] Donor/recipient couples from 2002 to 2009 with tacrolimus administration were included in the study. Recipients who had a **1* allele and/or who had a donor with a **1* allele required significantly higher doses of the drug than those couples without the allele. Additionally, five-year survival rates for recipients with two **1* alleles were significantly worse than for those with a **1*3* or a **3*3* genotype (28.6% vs. 78.8% and 84.3%, respectively).

Section Summary

CYP3A5 genetic variants may be used to predict tacrolimus clearance. One RCT demonstrated that the use of a *CYP3A5* genotype-directed algorithm was associated with improvements in the proportion of patients with target tacrolimus concentration ranges. No differences in morbidity or mortality or graft survival were reported, which the authors attribute to a patient population at low risk of acute rejection or other clinical events. Additional studies of the clinical utility of *CYP3A5* genetic testing-based algorithms in tacrolimus management are needed. There is limited evidence on the impact of genotype on dosing on immunosuppressant medications.

TAMOXIFEN: MANAGING TREATMENT FOR WOMEN AT HIGH RISK FOR OR WITH BREAST CANCER[133]

The CYP450 metabolic enzyme CYP2D6 has a major role in tamoxifen (TAM) metabolism. Variant DNA gene sequences resulting in proteins with reduced or absent enzyme function may be associated with lower plasma levels of active tamoxifen metabolites, which could have an impact on TAM treatment efficacy.

Potential indications for *CYP2D6* pharmacogenomic testing include patients who are to be treated with TAM (alone or prior to treatment with an aromatase inhibitor) for:

- Prevention of breast cancer in high risk women or women with ductal carcinoma in situ (DCIS)
- Adjuvant treatment to prevent breast cancer recurrence

- Treatment of metastatic disease

Post-menopausal patients determined to be *CYP2D6* PMs could avoid TAM therapy and be treated with aromatase inhibitors alone. Pre-menopausal patients might consider ovarian ablation.

Systematic Reviews

In 2010, the Agency for Healthcare Research and Quality (AHRQ) carried out a systematic review of the published evidence of the *CYP2D6* variants and response to tamoxifen therapy in breast cancer.[134] There were 16 publications of *CYP2D6* testing met the eligibility criteria and were included in the review (15 studies in the adjuvant setting and one study in the metastatic setting). However, the meta-analysis was not performed due to extensive heterogeneity in the definition of slow, intermediate, and extreme metabolizers across eligible studies. Instead, the results from individual studies on the strength of the association between *CYP2D6* testing results and clinical outcomes were presented. The assessment concluded the following:

- There were no consistent associations between *CYP2D6* polymorphism status and outcomes in tamoxifen-treated women with breast cancer across 16 studies included in the review.
- The reviewed studies were generally small, followed poor analytic practices, and differed both in the direction and in the formal statistical significance of their results.
- It is questionable whether pharmacogenetic testing of germline variations in *CYP2D6* can predict differential response to adjuvant tamoxifen in women with non-metastatic breast cancer.
- Evidence is severely limited for tamoxifen-treated women with metastatic disease.

A 2008 BlueCross BlueShield Association Technology Evaluation Center Assessment, found that evidence from clinical validity studies of *CYP2D6* for use in tamoxifen management was uncertain.[135] Results from two higher quality trials of adjuvant TAM in relatively homogeneous patient populations suggest that women treated with TAM who are functional PMs or IMs, whether by genotype or by co-medication with *CYP2D6* inhibitors, have significantly reduced time to recurrence and recurrence-free survival (but not overall survival) compared to extensive metabolizers. The significance levels are marginal but might have been stronger and more convincing if PMs alone could have been compared to extensive metabolizers, but numbers of PMs were insufficient. Few variant alleles have been typed in these studies; more extensive genotyping and better categorization might also strengthen results.

The International Tamoxifen Pharmacogenomics Consortium was established to address the controversy regarding *CYP2D6* status and clinical outcomes in tamoxifen therapy. Authors from this consortium performed a meta-analysis on data from 4,973 tamoxifen-treated patients (12 globally distributed sites).[136] Using strict eligibility requirements (postmenopausal women with estrogen receptor-positive breast cancer, receiving 20 mg/day tamoxifen for five years, criterion 1); *CYP2D6* poor metabolizer status was associated with poorer invasive disease-free survival (IDFS HR 1.25, 95% CI 1.06 to 1.47, p=0.009). However, *CYP2D6* status was not statistically significant when tamoxifen duration, menopausal status, and annual follow-up were not specified (criterion 2, n=2,443, p=0.25) or when no exclusions were applied (criterion 3, n=4,935, p=0.38). Authors concluded, although *CYP2D6* is a strong predictor of IDFS using strict inclusion criteria, because the results are not robust to inclusion criteria (these were not

defined a priori), prospective studies are necessary to fully establish the value of *CYP2D6* genotyping in tamoxifen therapy.

Drögemöller (2019) conducted a systematic review of the association between *CYP2D6* genetic variation and survival outcomes after tamoxifen treatment.[137] Included studies showed conflicting conclusions. In multivariate analyses, there was no significant relationship between survival outcomes and the confounders of sample size (p=0.83), ethnicity (p=0.33), or source of DNA (p=0.14). Comprehensive genotyping panels were more likely to report a significant association with *CYP2D6*-survival outcome: 11 of 13 studies that used comprehensive genotyping found a significant association between *CYP2D6* and survival outcomes. Limitations of the studies identified by the review authors included differences in survival outcome definitions, differences in metabolizer group classifications, low consent rates, and not controlling for CYP2D6-inhibitor use. Data in most of these studies were derived from a convenience sample, which was further limited by relatively small numbers of patients and lack of comprehensive genotype data, patient data (e.g., concomitant medications), and detailed clinical outcomes data.

Lu (2017) published a meta-analysis of studies evaluating the role of *CYP2D6 *10* genotype on clinical outcomes for Asian women treated with tamoxifen for breast cancer.[138] The *CYP2D6 *10 T/T* genotype has been linked to low enzyme activity. Fifteen studies with a total of 1,794 patients were included. Pooled analysis of the effect of the *CYP2D6 *10* genotype identified significant associations with disease-free survival in several comparison models (*TT* vs. *CC*: HR 1.79, 95% CI 1.14 to 2.80, p=0.011; *CT* vs. *CC*: HR 2.02, 95% CI 1.04 to 3.19, p=0.037; *TT* vs. *CT*: HR 2.03, 95% CI 1.41 to 2.93, p<0.001; *TT* vs. *CT/CC*: HR 2.19, 95% CI 1.07 to 4.50, p=0.033).

Randomized Controlled Trials

One trial of genotype-directed dosing that assessed outcomes of breast cancer recurrence was identified. The RCT, published by Tamura (2020) was a phase II, proof-of-concept study performed at multiple centers in Japan.[139] A total of 184 patients were included in this study, of which 136 had at least one *CYP2D6* variant-type allele. Only one patient classified as a poor metabolizer with two null alleles was included in this trial. The results of this trial did not find a significant difference in outcomes between increased tamoxifen dosing and standard dosing in patients with *CYP2D6* genotypic variants Nonrandomized Studies.

Nonrandomized studies have reported conflicting findings regarding the role of *CYP2D6* variant status in the selection and dosing of tamoxifen, with some in support[140-153] and others not.[154-163]

Among the most influential studies of the association between *CYP2D6* genotype and tamoxifen effectiveness are three nonconcurrent, prospective studies nested within large RCTs that compared tamoxifen with anastrozole, letrozole, or combination tamoxifen and anastrozole in postmenopausal women with hormone receptor-positive early-stage breast cancer. In the Arimidex, Tamoxifen, Alone or in Combination trial,[155] and Breast International Group 1-98 trial,[154] a subset of patients who received tamoxifen and were genotyped for *CYP2D6* variants (n=588 and n=1,243, respectively) did not show any statistically significant associations between phenotype (patients classified as poor, intermediate, or extensive metabolizer) and breast cancer recurrence. In the Austrian Breast and Colorectal Cancer Study Group trial, a case-control study was done using a subset of patients where cases were defined as those with disease recurrence, contralateral breast cancer, second non-breast cancer, or died and

controls were identified from the same treatment arm of similar age, surgery/radiation, and stage.[164] Results showed that patients with two poor-metabolizer alleles had a higher likelihood of recurrence than women with two extensive-metabolizer alleles. Concerns about the substantial departure from Hardy-Weinberg equilibrium for the *CYP2D6* allele, *4 and analyses not meeting the Simon-Paik-Hayes criteria for nonconcurrent prospective studies have been raised to explain the lack of effect in the Arimidex, Tamoxifen, Alone or in Combination trial and Breast International Group 1-98 trials.[165]

Section Summary

The evidence for *CYP2D6* genotype-guided tamoxifen treatment includes one RCT, several meta-analyses and systematic reviews, multiple nonrandomized studies. Published data on the association between *CYP2D6* genotype and tamoxifen treatment outcomes have yielded inconsistent results. Data in most of these studies were derived from a convenience sample, which was further limited by relatively small numbers of patients and lack of comprehensive genotype data, patient data, and detailed clinical outcomes data. Three influential nonconcurrent prospective studies nested within large RCTs that included postmenopausal women with hormone receptor-positive early-stage breast cancer also reported contradictory results, with two larger studies failing to show statistically significant associations between phenotype (patients classified as poor, intermediate, or extensive metabolizer) and recurrence of breast cancer. The RCT examining genotype-directed dosing found no difference in progression free survival between standard dose and increased dose; however, this trial was limited by its proof-of-concept design. No trials of genotype-directed drug choice that compared health outcomes for patients managed with and without the test were identified. It is not known whether *CYP2D6* genotype-guided tamoxifen treatment results in the selection of a treatment strategy that would reduce the rate of breast cancer recurrence, improve disease-free survival or OS, or reduce adverse events.

TETRABENAZINE FOR HUNTINGTON DISEASE

Tetrabenazine (Xenazine) is a monoamine depleter and reduces the amount of certain chemicals in the brain (e.g., dopamine, norepinephrine, and serotonin) to reduce chorea, or involuntary muscle movements, in Huntington disease. Its primary metabolites are metabolized mainly by *CYP2D6*, and people with *CYP2D6* poor metabolizer genotypes should be treated with lower doses.

Systematic Reviews

No systematic reviews of *CYP2D6* genotyping for tetrabenazine management were identified.

Randomized Controlled Trials

There were no RCTs reported for this indication.

Nonrandomized studies

Mehanna (2013) published results from a study that performed sequential *CYP2D6* genotyping on 127 patients treated with tetrabenazine.[166] The majority of patients (n=100) were categorized as extensive metabolizers, 14 as IMs, 11 as PMs, and two as ultrarapid metabolizers (UMs). UMs needed a longer titration (8 vs. 3.3, 4.4, and 3 weeks, respectively, p<.01) to achieve optimal benefit and required a higher average daily dose than the other patients, but this difference did not reach statistical significance. The treatment response was

less robust in the intermediate metabolizer group when compared with the extensive metabolizer patients (p=.013), but there were no statistically significant differences between the various groups with regard to adverse effects. Therefore, the current recommendation to systematically genotype all patients prescribed more than 50 mg/day of tetrabenazine should be reconsidered.

U.S Food and Drug Administration (FDA) Safety Communication

In 2015, the FDA published a warning labeling for tetrabenazine includes recommendations for genotyping for *CYP2D6* for patients who are being considered for doses above 50 mg per day. The labeling states: "Patients should be genotyped for CY2D6 prior to treatment with daily doses of tetrabenazine over 50 mg."[167]

Section Summary

There is limited published evidence regarding the changes in outcomes associated with genotype-directed therapy for tetrabenazine in Huntington disease; however, given the FDA labeling and high variation in drug exposure based on metabolizer status, *CYP2D6* to determine metabolizer status before the use of tetrabenazine when a dosage greater than 50 mg per day may be considered medically necessary.

SIPONIMOD FOR MULTIPLE SCLEROSIS

The FDA has approved siponimod for the treatment of relapsing forms of multiple sclerosis, to include clinically isolated syndrome, relapsing-remitting disease, and active secondary progressive disease, in adults. The recommended maintenance dosage is 2 mg. The recommended maintenance dosage in patients with a *CYP2C9*1/*3* or **2/*3* genotype is 1 mg. Siponimod is contraindicated in patients with a *CYP2C9*3/*3* genotype.[168]

WARFARIN DOSING AND MANAGEMENT[169]

Warfarin (Coumadin®) is administered for preventing and treating thromboembolic events in high-risk individuals. Dosing of warfarin is a challenging process, due to narrow therapeutic windows, variable response to dosing, and serious bleeding events.

Stable or maintenance warfarin dose varies significantly among individuals. Factors influencing stable dose include body mass index (BMI), age, interacting drugs, and indication for therapy. In addition, genetic variants of *CYP450 2C9* (*CYP2C9*) and vitamin K epoxide reductase subunit C1 (*VKORC1*) genes together account for a substantial proportion of variability:

- Genetic variants of *CYP2C9* result in enzymes with decreased activity, increased serum warfarin concentration at standard doses, and a higher risk of serious bleeding.
- *VKORC1* genetic variants alter the degree of warfarin effect on its molecular target and are associated with differences in maintenance doses.

The purpose of *CYP2C9* and *VKORC1* genetic testing is to predict an individual's likely maintenance warfarin dose by incorporating demographic, clinical, and genotype data. Warfarin is then initiated at that predicted dose to limit over-anticoagulation and increased risk of serious bleeding events.

Regulatory Status

In 2010, the FDA updated labeling for Coumadin® to include information on personalizing initial dose according to genotyping results for *CYP2C9* and *VKORC1*. However, the information on genetic variation is not included in the black box warning and the label indicates that genetic testing is not required.

Systematic Reviews

Wang (2022) completed a SR to analyze the impact of CYP2C19 polymorphisms on warfarin maintenance dose. Nine studies were included in the analysis (1393 patients). Three CYP2C19 SNPs were identified: rs4244285, rs4986893 and rs3814637. Warfarin maintenance dose was significantly reduced by 10% in individuals with the rs4986893 A allele compared with the GG carriers and was 34%, 16% and 18% lower in patients with rs3814637 TT and CT genotypes and T allele, respectively, than that in CC carriers. No significant dose difference was observed among the rs4244285 genotypes. The authors conclude that CYP2C19 rs4986893 and rs3814637 are associated with significantly reduced warfarin dose requirements. These results were largely driven by the Zhu (2020) RCT.[170]

The Washington Health Care Authority completed a technology assessment of pharmacogenetic testing for anticoagulants in 2018, which included 13 RCTs.[171] In the meta-analysis of mortality, thromboembolic events, and major bleeding, no differences between groups were seen in mortality or thromboembolism but there was a reduction in major bleeding seen in the pharmacogenetic testing group. There were no statistically significant differences in the percentage of time in therapeutic range or over-anticoagulation. The authors noted that the evidence for the thromboembolic events was rated as moderate quality, while the evidence for the other outcomes was low quality.

A meta-analysis by Yang (2019) included 15 RCTs (total n=4,852) evaluating genotype-guided warfarin dosing.[172] The primary outcome of the analysis was the percentage time in therapeutic range (PTTR). Within a one-month follow-up period, there was no significant difference in PTTR between genotype-guided and control (fixed initial dosage) groups, based on data from eight trials. Three trials reported on PTTR at three months, which was significantly higher for the genotype-guided patients compared to controls (weighted mean difference 5.62%, 95% CI 2.33% to 8.90%, p=0.001). Genotype-guided patients also had a shorter time to first therapeutic international normalized ratio (INR), shorter time to stable therapeutic dose, and decreased risk of warfarin-related major bleeding events. No differences were seen for thromboembolism risk, bleeding events, and all-cause mortality. The authors completed a risk of bias assessment of included studies. All trials claimed to be randomized, however, the random sequence generation was only explicitly described in nine studies. Only seven studies discussed allocation concealment, and blinding was not implemented in most of the included RCTs.

A network meta-analysis by Sridharan and Sivaramakrishnan (2020) compared three different genotyping strategies for warfarin dosing: *CYP2C9* alone, *CYP2C9* with *VKORC1*, and *CYP2C9* with both *VKORC1* and *CYP4F2*.[173] The analysis included data from 28 RCTs, and the primary outcomes were the time to first therapeutic INR, time to stable INR or warfarin dose, PTTR, and the proportion of patients with supra-therapeutic INR. The results of the meta-analysis indicated that the *CYP2C9*-alone strategy and the *CYP2C9* with *VKORC1* strategy were associated with a shorter time to first therapeutic INR and stable INR/warfarin dose, while only the *CYP2C9* with *VKORC1* strategy was associated with a greater PTTR.

Tse (2018) published a meta-analysis of 18 trials of genotype-guided versus standard warfarin dosing.[174] The analysis included 2,626 patients in the genotype-guided group and 2,604 patients in the control group, and the mean follow-up duration was 64 days. Genotype-guided dosing was associated with a shorter time to therapeutic international normalized ratio (INR) (mean difference 2.6 days, p<0.0001, I^2 0%) and stable INR (mean difference 5.9 days, p<0.01, I^2 94%), but no difference was seen in thromboembolism or mortality. Similar results were seen in a meta-analysis by Kheiri (2018) that included 20 RCTs.[175]

Five systematic reviews with meta-analyses of RCTs were published in 2014 and 2015.[176-181] The included RCTs compared genotype-guided warfarin dosing with other dose selection strategies. The RCTs overlapped across analyses, though not all RCTs were included in all analyses. Meta-analyses used random effects models or fixed effects models when statistical heterogeneity (I^2) was 0%. Most studies were included in all systematic reviews.

Two systematic reviews[176, 177] included the same nine RCTs[71, 182-189] comparing genotype-guided versus clinically-guided warfarin dosing (n=2,812); the RCTs were rated as high quality. Range of follow-up duration was 4 to 24 weeks (median 12 weeks). Publication bias was not detected. With one exception, pooled results from both systematic reviews were consistent. There was no statistical difference between dosing strategies in the percentage of time that the INR was in therapeutic range (I^2=89%), the proportion of INRs that exceeded 4 (I^2=0%), or thromboembolic events (I^2=0%). However, Stergiopoulos (2014) found no difference in major bleeding events (pooled RR 0.60, 95% CI 0.29 to 1.22, I^2=0%), while Franchini (2014) found reduced major bleeding events with genotype-guided warfarin dosing (pooled RR=0.48, 95% CI 0.23 to 0.97, I^2=0%). This inconsistency may be attributed to the exclusion of the EU-PACT trial[183] (n=455) from the analysis of major bleeding in Franchini (2014) systematic review; EU-PACT reported no major bleeding events in either warfarin dosing group.

Goulding (2014) reported improved clinical outcomes with genotype-guided versus other (i.e., fixed or clinically-guided) warfarin dosing.[178] Literature was reviewed through December 2013; nine RCTs were included, seven of which overlapped with the systematic reviews previously described, and six of which were rated high or very high quality. Range of follow-up duration was 2 to 12 weeks. Pooled mean difference in the percentage of time within the therapeutic range (TTR) was 6.67 percentage points (95% CI 1.34 to 12.00, I^2=80%). However, this meta-analysis included one trial[190] that showed benefit of genotype-guided dosing compared with fixed initial warfarin dosing (2.5 mg/day), and excluded two trials[182, 186] that showed no benefit of genotype-guided dosing compared with clinically-guided dosing. Meta-analysis also showed decreased risk of bleeding or thromboembolic events with genotype-guided dosing (pooled risk ratio 0.57, 95% CI 0.33 to 0.99, I^2=60%).

In an analysis of eight RCTs Xu (2014) reported a significantly increased TTR for genotype-guided dosing compared to fixed initial dose, but no significant difference between genotype-guided and clinically-guided dosing. The authors also reported no significant between-group differences in adverse events. The authors noted high between-group participant heterogeneity that hindered pooled estimates.

Liao (2015) reported increased TTR with genotype-guided dosing compared with fixed initial warfarin dosing (three RCTs, I^2=48%) but not compared with clinically-guided dosing (two RCTs, I^2=0%).[179] These authors also found no overall difference between pooled groups in adverse events (major bleeding [defined as a decrease in hemoglobin ≥2 g/dL], clinically relevant non-major bleeding, thromboembolism, myocardial infarction, death from any cause,

or other condition requiring emergency medical management; four RCTs, I^2=0%) or mortality (three RCTs, I^2=10%).

A systematic review by Zhang (2017) evaluated *CYP2C9* polymorphisms and warfarin maintenance dosage in pediatric patients.[191] The review included eight studies with a total of 507 patients. Of these, five studies investigated the role of the *CYP2C9 *1/*2* genotype, and meta-analysis indicated that this genotype was associated with warfarin maintenance dose that was 15% lower than that for patients with *CYP2C9 *1/*1.* In five studies that evaluated the *CYP2C9 *1/*3,* this genotype was associated with 41% lower maintenance dose compared with **1/*1*. However, this study did not evaluate the use of genotyping in pediatric warfarin dose selection.

Prior systematic reviews and meta-analyses focused on analysis of associations between *CYP2C9* and *VKORC1* gene variants and warfarin dosing.

The 2009 Agency for Healthcare Research and Quality (AHRQ) Technology assessment of selected pharmacogenetic tests for non-cancer and cancer conditions included a systematic review of the published evidence of *CYP2C9* and *VKORC1* gene polymorphisms and response to warfarin therapy (29 studies of *CYP2C9* and 19 studies of *VKORC1* polymorphisms).[192] The review concluded the following:

- Carriers of the *CYP2C9* gene variant alleles **2* or **3* require lower mean maintenance warfarin doses than do noncarriers.
- Few studies investigated the relationship between genetic variations in *CYP2C9* or *VKORC1* and warfarin dose requirements in the induction phase. *CYP2C9* variants were associated with an increased rate of bleeding complications during the induction phase of warfarin therapy, but the studies did not report whether affected patients had normal or supratherapeutic INR ranges.
- The clinical utility of genetic testing for *CYP2C9* in everyday clinical practice is not straightforward.
- It is unclear whether dose-prediction algorithms using genetic information improve clinical outcomes over those of standard practice. Only three RCT addressed this question, but all had flaws in design and inclusion criteria, and had inadequate power to reach statistical conclusions.
- Carriers of the three common *VKORC1* variants (alleles *T*, *G*, and *C*) required lower mean maintenance doses of warfarin than did noncarriers. Data were not adequate to address any other questions.

New genetic associations such as *CYP4F2* are under investigation and evaluating interactions among *CYP2C9, VKORC1*, and this new variant along with gene-environmental interactions may result in better risk predictive instruments for clinical use.

A systematic review commissioned by the American College of Medical Genetics (ACMG), evaluated *CYP2C9* and *VKORC1* genetic testing prior to warfarin dosing and concluded that no large study had yet shown this to be acceptable or effective.[193]

Jorgensen (2012) investigated the influence of *CYP2C9* and *VKORC1* on patient response to warfarin in a systematic review and meta-analysis of 117 studies.[194] Authors concluded that genetic associations with warfarin response vary between ethnicities. In addition, authors suggest that a high level of methodological rigor must be maintained and that studies should

report sufficient data to enable inclusion in meta-analyses and achieve unbiased estimates in different populations.

A systematic review and meta-analysis by Liang (2012) suggested a more substantial contribution of *CYP4F2* genetic variants.[195] Compared with wild type patients, carriers of *CYP4F2* variants required warfarin doses 11% and 21% higher for heterozygous and homozygous patients, respectively.

Randomized Controlled Trials

A total of 28 RCTs comparing genotype-guided with clinical dosing of warfarin were identified. Twenty-seven of these RCTs were included in at least one systematic review. We identified one additional RCTs not included in any of the systematic reviews. Zhu (2020) found that INR time in therapeutic range was improved with genotype-guided dosing based on *CYP2C9* and *VKORC1* compared with clinically-guided dosing in elderly Chinese patients with nonvalvular atrial fibrillation.[196] Additionally, bleeding events did not differ between groups, but ischemic stroke occurred less frequently with genotype-guided dosing.

Nonrandomized Studies

A number of nonrandomized and retrospective studies of genotype-based vs. standard warfarin dosing have been published,[197] including preliminary findings in children.[198-212] However, evidence from these studies does not permit conclusions due to methodological limitations such as non-random allocation of dosing management and lack of appropriate comparison groups.[198-209]

Section Summary

Genetic testing may help predict the initial warfarin dose within the first week of warfarin treatment, but the evidence does not support the conclusion that clinically relevant outcomes, such as rates of bleeding or thromboembolism, are improved. Proposed dosing algorithms require evaluation in large, prospective, randomized trials comparing genotype-guided dosing with current standard-of-care approaches to determine net health benefit.

PRACTICE GUIDELINE SUMMARY

ANTI-TUBERCULOSIS MEDICATIONS

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the selection and dosing of anti-tuberculosis medications**.**

BETA BLOCKER SELECTION AND DOSING

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the selection and dosing of beta-blocker medications.

CLOPIDOGREL: DETERMINING RISK OF ATHEROTHROMBOTIC EVENTS AFTER AN ACUTE CORONARY SYNDROME OR A PERCUTANEOUS CORONARY INTERVENTION

American College of Cardiology (ACC) foundation and the American Heart Association (AHA)

A consensus statement by the American College of Cardiology (ACC) foundation and the American Heart Association (AHA) on genetic testing for selection and dosing of clopidogrel was published in 2010.[213] The recommendations for practice included the following statements:

- Adherence to existing ACCF/AHA guidelines for the use of antiplatelet therapy should remain the foundation for therapy. Careful clinical judgment is required to assess the importance of the variability in response to clopidogrel for an individual patient and its associated risk to the patient.
- Clinicians must be aware that genetic variability in CYP enzymes alters clopidogrel metabolism, which in turn can affect its inhibition of platelet function. Diminished responsiveness to clopidogrel has been associated with adverse patient outcomes in registry experiences and clinical trials.
- The specific impact of the individual genetic polymorphisms on clinical outcome remains to be determined.
- Information regarding the predictive value of pharmacogenomic testing is very limited at this time; resolution of this issue is the focus of multiple ongoing studies. Both the selection of the specific test and the issue of reimbursement are important additional considerations.
- The evidence base is insufficient to recommend either routine genetic or platelet function testing at the present time.
- There are several possible therapeutic options for patients who experience an adverse event while taking clopidogrel in the absence of any concern about medication compliance.

SELECTION OR DOSING OF CODEINE

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the selection and dosing of codeine for nursing mothers.

DOSE AND SELECTION OF HIGHLY ACTIVE ANTIRETROVIRAL AGENTS

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the dosing of efavirenz.

ELIGLUSTAT (CERDELGA™) FOR GAUCHER DISEASE TYPE I.

Currently no published clinical practice guidelines recommend *CYP2D6* genotyping for the dosing of eliglustat.

H. PYLORI INFECTION

No evidence-based clinical practice guidelines were identified that recommend *CYP450* (i.e., *CYP2C19*) genotyping to select and dose treatment for *H. pylori* eradication.

IMMUNOSUPPRESSANT DOSING FOR ORGAN TRANSPLANTATION

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the dosing of immunosuppressant medications**.**

TAMOXIFEN: MANAGING TREATMENT FOR WOMEN AT HIGH RISK FOR OR WITH BREAST CANCER

Currently no published clinical practice guidelines recommend *CYP450* genotyping for the selection and dosing of tamoxifen.

National Comprehensive Cancer Network

The National Comprehensive Cancer Network (NCCN) guidelines for breast cancer (v.1.2024) state that, "CYP2D6 genotype testing is not recommended in women who are considering tamoxifen."[214]

American Society of Clinical Oncology

The 2016 guideline on the use of biomarkers to guide adjuvant systemic therapy decisions for women with early-stage invasive breast cancer states that, "The clinician should not use CYP2D6 polymorphisms to guide adjuvant endocrine therapy selection. Type: evidence based. Evidence quality: intermediate. Strength of recommendation: moderate.[215]."

TETRABENAZINE FOR HUNTINGTON DISEASE

Currently no published clinical practice guidelines recommend *CYP2D6* genotyping for chorea in HD.

WARFARIN DOSING AND MANAGEMENT

American College of Chest Physicians

The 2012 American College of Chest Physicians evidence-based clinical practice guidelines on "Antithrombotic Therapy and Prevention of Thrombosis," states, "For patients initiating VKA [vitamin K antagonist] therapy, we recommend against the routine use of pharmacogenetic testing for guiding doses of VKA (Grade 1B)."[216]

American College of Medical Genetics

Per the 2008 statement from the American College of Medical genetics, "there is insufficient evidence at this time to recommend for or against routine *CYP2C9* and *VKORC1* testing in warfarin-naive patients."[217]

SUMMARY

ANTI-TUBERCULOSIS MEDICATIONS:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients taking anti-tuberculosis medications. There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* genotyping for the management of anti-tuberculosis medications is considered investigational.

BETA BLOCKER SELECTION AND DOSING:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients taking beta blockers. There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* (including *CYP2D6*) genotyping for selection or dosing of beta blockers is considered investigational.

CLOPIDOGREL - DETERMINING RISK OF ATHEROTHROMBOTIC EVENTS AFTER AN ACUTE CORONARY SYNDROME OR A PERCUTANEOUS CORONARY INTERVENTION:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients taking anti-tuberculosis medications. Despite this, FDA labeling recommends cytochrome p450 genetic testing for selection and dosing of clopidogrel (Plavix®). Therefore, *CYP450* genotyping may be considered medically necessary to guide selection and dose management of clopidogrel.

CODEINE PRESCRIPTION FOR NURSING MOTHERS:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients taking codeine, including nursing mothers. There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* (including *CYP2D6*) for codeine selection and dosing is considered investigational.

EFAVIRENZ DOSING FOR THE TREATMENT OF HIV INFECTION:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients taking efavirenz to treat HIV infection. There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* genotyping (including CYP2B6) to select or dose efavirenz is considered investigational.

ELIGLUSTAT (CERDELGA™) FOR GAUCHER DISEASE TYPE I:

There is very little research on *CYP450* genetic testing for people with Gaucher disease considering eliglustat. However, FDA labeling recommends cytochrome p450 genetic testing for selection and dosing of eliglustat. Therefore, *CYP450* genotyping may be considered medically necessary to guide selection and dose management of eliglustat.

H. PYLORI INFECTION:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for people with *H. pylori* infections taking proton pump inhibitors (PPIs). There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* genotyping (including *CYP2C19*) to select or dose PPIs is considered investigational.

IMMUNOSUPPRESSANT DOSING FOR ORGAN TRANSPLANTATION:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for organ transplantation patients taking immunosuppressant medications. There are no clinical guidelines based on research that recommend genetic testing for this purpose. Therefore, *CYP450* genotyping (including *CYP3A5*) to select or dose immunosuppressant drugs is considered investigational.

TAMOXIFEN - MANAGING TREATMENT FOR WOMEN AT HIGH RISK FOR OR WITH BREAST CANCER:

There is not enough research to show that genetic testing of *CYP450* genes can improve health outcomes for patients with breast cancer or at high risk for breast cancer that are considering tamoxifen treatment. Additionally, there are clinical guidelines based on research that specifically recommend against genetic testing for this purpose. Therefore, *CYP450* genotyping (e.g., *CYP2D6*) for selection and dosing of tamoxifen is considered investigational.

TETRABENAZINE FOR HUNTINGTON DISEASE

There is very little research showing how genetic testing can help with tetrabenazine dosing decisions. However, because of the FDA labeling for the medication and evidence that genetics can greatly affect the metabolism of the medication, *CYP2D6* testing to determine metabolizer status may be considered medically necessary before the use of tetrabenazine, when a dosage greater than 50mg per day may be considered.

SIPONIMOD FOR MULTIPLE SCEROSIS

There is limited research showing how genetic testing can help with siponimod dosing decisions. However, because of the FDA labeling for the medication and evidence that genetics can greatly affect the metabolism of the medication, *CYP2C9* testing to determine metabolizer status may be considered medically necessary before the use of siponimod for patients with relapsing forms of multiple sclerosis.

WARFARIN DOSING AND MANAGEMENT:

There is research that shows that *CYP2C9* and *VKORC1* genes are related to warfarin dosing, but there is not enough research to show that genetic testing for these genes improves health outcomes for people taking this medication. Therefore, genotyping for variants to predict initial warfarin dose is considered investigational.

OTHER INDICATIONS

CYP2C19 testing may be useful for selecting anti-platelet treatments, and CYP2D6 testing can aid in medication selection for patients with Gaucher or Huntington disease. While testing for various CYP450 genes has been proposed to help with selection of other medications, there is not enough research to show that this testing is helpful for guiding medication selection and improving health outcomes for patients. In addition, there are no clinical guidelines based on research that recommend such testing. Therefore, CYP450 genetic testing that does not meet the policy criteria is considered investigational.

CODES

Codes	Number	Description
CPT	0029U	Drug metabolism (adverse drug reactions and drug response), targeted sequence analysis (ie, *CYP1A2, CYP2C19, CYP2C9, CYP2D6, CYP3A4, CYP3A5, CYP4F2, SLCO1B1, VKORC1* and rs12777823)
	0030U	Drug metabolism (warfarin drug response), targeted sequence analysis (ie, *CYP2C9, CYP4F2, VKORC1*, rs12777823)
	0031U	*CYP1A2* (cytochrome P450 family 1, subfamily A, member 2)(eg, drug metabolism) gene analysis, common variants (ie, *1F, *1K, *6, *7)
	0070U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, common and select rare variants (ie, *2, *3, *4, *4N, *5, *6, *7, *8, *9, *10, *11, *12, *13, *14A, *14B, *15, *17, *29, *35, *36, *41, *57, *61, *63, *68, *83, *xN)

Codes	Number	Description
		CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, full gene sequence (List separately in addition to
	0072U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, CYP2D6-2D7 hybrid gene) (List separately in addition to code for primary procedure)
	0073U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, CYP2D7-2D6 hybrid gene) (List separately in addition to code for primary procedure)
	0074U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, non-duplicated gene when duplication/multiplication is trans) (List separately in addition to code for primary procedure)
	0075U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, 5' gene duplication/multiplication) (List separately in addition to code for primary procedure)
	0076U	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, 3' gene duplication/ multiplication) (List separately in addition to code for primary procedure)
	0347U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 16 gene report, with variant analysis and reported phenotypes
	0348U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 25 gene report, with variant analysis and reported phenotypes
	0349U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis, including reported phenotypes and impacted gene-drug interactions
	0350U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis and reported phenotypes
	~~0380U~~	~~Drug metabolism (adverse drug reactions and drug response), targeted sequence analysis, 20 gene variants and CYP2D6 deletion or duplication analysis with reported genotype and phenotype~~ (Deleted 01/01/2025)
	0434U	Drug metabolism (adverse drug reactions and drug response), genomic analysis panel, variant analysis of 25 genes with reported phenotypes
	0438U	Drug metabolism (adverse drug reactions and drug response), buccal specimen, gene-drug interactions, variant analysis of 33 genes, including deletion/duplication analysis of CYP2D6, including reported phenotypes and impacted genedrug interactions
	0460U	Oncology, whole blood or buccal, DNA single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, with variant analysis and reported phenotypes
	0461U	Oncology, pharmacogenomic analysis of single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, whole blood or buccal swab, with variant analysis, including impacted gene-drug interactions and reported phenotypes
	0516U	Drug metabolism, whole blood, pharmacogenomic genotyping of 40 genes and *CYP2D6* copy number variant analysis, reported as metabolizer status
	0533U	Drug metabolism (adverse drug reactions and drug response), genotyping of 16 genes (ie, ABCG2, CYP2B6, CYP2C9, CYP2C19, CYP2C, CYP2D6, CYP3A5,

Codes	Number	Description
		CYP4F2, DPYD, G6PD, GGCX, NUDT15, SLCO1B1, TPMT, UGT1A1, VKORC1), reported as metabolizer status and transporter function
	81225	*CYP2C19* (cytochrome P450, family 2, subfamily C, polypeptide 19) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *8, *17)
	81226	*CYP2D6* (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *5, *6, *9, *10, *17, *19, *29, *35, *41, *1XN, *2XN, *4XN)
	81227	CYP2C9 (cytochrome P450, family 2, subfamily C, polypeptide 9) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *5, *6)
	81230	CYP3A4 (cytochrome P450 family 3 subfamily A member 4) (eg, drug metabolism), gene analysis, common variant(s) (eg, *2, *22)
	81231	CYP3A5 (cytochrome P450 family 3 subfamily A member 5) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *5, *6, *7)
	81355	*VKORC1* (vitamin K epoxide reductase complex, subunit 1) (eg, warfarin metabolism), gene analysis, common variant(s) (eg, -1639G>A, c.173+1000C>T)
	81401	Molecular pathology procedure, Level 2
	81402	Molecular pathology procedure, Level 3
	81404	Molecular pathology procedure, Level 5
	81405	Molecular pathology procedure, Level 6
	81418	Drug metabolism (eg, pharmacogenomics) genomic sequence analysis panel, must include testing of at least 6 genes, including CYP2C19, CYP2D6, and CYP2D6 duplication/deletion analysis
HCPCS	G9143	Warfarin responsiveness testing by genetic technique using any method, any number of specimen(s)

Genetic Testing for Familial Hypercholesterolemia

Effective: March 1, 2025

Next Review: November 2025
Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Homozygous familial hypercholesterolemia (FH) is a rare disorder that causes extremely high levels of low-density lipoprotein (LDL), leading to very early cardiovascular disease. Heterozygous FH is more common and can also cause elevated LDL levels and premature cardiovascular disease, though with reduced severity and more variable presentation than homozygous FH.

MEDICAL POLICY CRITERIA

I. Genetic testing of *LDLR, APOB, PCSK9,* and/or *LDLRAP1* genes to confirm a diagnosis of familial hypercholesterolemia (FH) may be considered **medically necessary** when there is documentation of an uncertain diagnosis of FH (see Policy Guidelines) and a definitive diagnosis is required for selection of specialty medications (e.g., PCSK9 inhibitors).

II. Genetic testing for known familial FH-causing gene variants may be considered **medically necessary** for children (younger than age 18) when there is an affected first or second-degree relative, to determine future risk of disease.

III. Genetic testing for FH is **investigational** for all other indications, including but not limited to, a diagnosis when Criterion I. or II. is not met, and genetic testing for other genes.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

UNCERTAIN DIAGNOSIS OF FH

There are no standardized definitions of uncertain diagnosis of FH, however there are tools that can be useful for this determination, including but not limited to the Simon Broom Registry Criteria and the Dutch Lipid Clinic Network Criteria (score of 3-8).

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test
    - History and physical exam
    - Conventional testing and outcomes
    - Conservative treatment provided, if any

BACKGROUND

Familial hypercholesterolemia (FH) is an inherited disorder characterized by markedly elevated low-density lipoprotein (LDL) levels, physical exam signs of cholesterol deposition, and premature cardiovascular disease. FH can be categorized as homozygous or heterozygous FH. Homozygous FH is an extremely rare disorder that arises from biallelic homozygous or compound heterozygous variants and has a prevalence of between 1:160,000 and 1:4,000,000. Individuals with homozygous (which includes compound heterozygous) FH have extreme elevations of LDL, and typically develop coronary artery disease (CAD) in the second or third decade of life[1].

Heterozygous FH is relatively common, with an estimated prevalence of 1 in 311 in the general population. Some populations such as Ashkenazi Jews and South Africans have higher prevalence of up to 1 in 100. The prevalence of FH in people with atherosclerotic cardiovascular disease (ASCVD) is 1 in 17. For affected individuals, the burden of illness is high. If untreated, the average age for presentation with CAD is in the fourth decade for males and the fifth decade for females, and there is a 30% to 50% risk of a fatal or nonfatal cardiac event for men and women in the fifth and sixth decades, respectively[2-4].

The diagnosis of FH relies on elevated LDL levels in conjunction with a personal and/or family history of premature CAD and physical exam signs of cholesterol deposition. There is wide variability in cholesterol levels for patients with FH, and considerable overlap in levels between patients with FH and patients with non-FH. Physical exam findings can include tendinous xanthomas, xanthelasma, and corneal arcus. Physical signs of FH are uncommon in children. Xanthelasma and corneal arcus are common in the elderly population and therefore not specific. Tendinous xanthomas are relatively specific for FH but are not sensitive findings. They occur mostly in patients with higher LDL levels and treatment with statins likely delays or prevents the development of xanthomas.

Because of the variable cholesterol levels, and the low sensitivity of physical exam findings, there are a considerable number of patients in whom the diagnosis is uncertain. For these individuals, there are a number of formal diagnostic tools for determining the likelihood of FH, including the Dutch Lipid Clinic Criteria, the Simon Broome Registry Criteria, and the Make Early Diagnosis Prevent Early Deaths Program Diagnostic Criteria.[5] Not all diagnostic tools for FH are appropriate for use in pediatric settings due to their reliance on physical signs of FH.

Treatment for FH in adults is similar to that for non-familial hypercholesterolemia and is based on LDL levels. Treatment for FH differs in that the approach is more aggressive (i.e., treatment may be initiated sooner, and a higher intensity medication regimen may be used). In children with FH, lipid screening and statin therapy are initiated at younger ages than in average risk children.

As with other forms of hypercholesterolemia, statins are the mainstay of treatment for FH. However, because of the degree of elevated LDL in many patients with FH, statins will often not be sufficient to achieve target lipid levels. Additional medications can be used in these patients. Ezetimibe inhibits absorption of cholesterol from the gastrointestinal tract and is effective for reducing LDL levels by up to 25% in patients already on statins. The IMPROVE-IT trial randomized patients with acute coronary syndrome to a combination of ezetimibe plus statins versus statins alone and reported that cardiovascular events were reduced for patients treated with combination therapy.[6]

The PCSK9 inhibitors are the most recently approved drugs for hyperlipidemia. These medications have potent LDL-lowering properties and have been tested in patients with FH. When added to statins, these drugs can result in additional LDL reduction of 30% to 70% and have been reported to reduce the incidence of nonfatal myocardial infarction.[4] Other antilipid medications (e.g., bile acid sequestrants, niacin) are effective at reducing LDL levels but have not demonstrated efficacy in reducing cardiovascular events when added to statins. For patients who continue to have elevated LDL levels despite maximum medical treatment, lipid apheresis is an option.

FH is most often inherited as an autosomal dominant condition. The primary physiologic defect in FH is impaired ability to clear LDL from the circulation, resulting in elevated serum levels. Four genes have been identified as harboring variants associated with FH. The LDL receptor gene (*LDLR*) is the most common gene in which a variant is identified, accounting for between 85-90% of genetically confirmed FH[2] Because the LDL receptor binds LDL and allows removal of LDL from the circulation, a defect in this receptor leads to reduced clearance of LDL. Over 1,500 different pathogenic variants have been identified in this gene.[5]

Other genes associated with FH include the *APOB* and *PCSK9* genes. Changes in the *APOB* gene account for approximately 5%-15% of FH cases. Apolipoprotein B is a cofactor in the

binding of LDL to the LDL receptor, and variants in *APOB* lead to reduced clearance of LDL. Variants in the *PCSK9* gene that increase the levels of PCSK9, impairing the function of LDL receptors, account for approximately 1% of FH. *APOB* and *PCSK9* variants result in increased PCSK9 levels, which impair the function of the LDL receptors leading to reduced clearance of LDL.[2] Recessive FH is caused by homozygous *LDLRAP1* pathogenic (or likely pathogenic) variants.

Penetrance for heterozygous FH varies by gene and in some cases by specific variant but is at least 70%. Variable clinical expressivity may also be mediated by both environmental factors such as diet and exercise, and unknown genetic factors that modify gene expression.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[7] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

- The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
- The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
- The clinical utility of the test, which describes how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

This evidence review is focused on clinical validity and utility.

CLINICAL VALIDITY

The clinical sensitivity is defined as the proportion of patients with FH who have a pathogenic variant for FH, and the clinical specificity is defined as the proportion of patients without FH who do not have a pathogenic variant for FH.

Six of the larger, more recent published studies of clinical validity were identified and are shown in Table 1.[8-13] These cohorts included sample sizes ranging from 254 to 6,015 patients with definite or suspected FH. These studies were conducted in different countries in Western Europe; no similar studies of US individuals were identified. All studies reported clinical sensitivity and two studies reported on clinical specificity. In some cases, the analysis was stratified by the clinical likelihood of FH prior to genetic testing using the Dutch Lipid Clinic Network (DLCN) criteria.

The largest cohort, studied by Abul-Husn (2016), focused on genetic testing through exome sequencing of 46,321 adults from a single health system.[13] The test had low sensitivity (2%)

and high specificity (99%), complicated by reliance on an incomplete electronic medical record for retrospective clinical diagnosis by the Dutch Lipid Clinic Network diagnostic criteria. This study further went on to note that within the 215 patients found to have genetic variants in the *LDR*, *PCSK9*, and *APOB* genes, only 25% met criteria for a clinical diagnosis of FH. Patients with relevant variants had higher LDL-H levels (p<0.001) with an increased risk of both general CAD (OR 2.6, p<0.001) and premature CAD (OR 3.7, p<0.001). Weaknesses of this study include reliance on a partially incomplete electronic medical record, as well as an ascertainment bias due to sampling within a single health care delivery system.

The clinical sensitivity of these studies ranged from 2% to 66.5%, with four studies clustering in the 34.5% to 41.2% range. The study that reported a substantially higher sensitivity of 66.5% included only patients with definite FH, unlike the other studies that included both definite and suspected FH cases. Two studies used the DLCN criteria to categorize individuals as definite, probable or possible FH.[9, 11] The proportion of individuals testing positive for FH varied by category. In the definite FH category, the sensitivity was 56.3% and 70.3%, respectively. This is in the same range as the study by Diakou (2011), which reported a sensitivity of 66.5% in patients with definite FH. In patients with probable or possible FH, the sensitivity was substantially lower (range, 10.8% to 29.5%).

Differences in the methodology of these studies may impact the reported sensitivities. The populations are from different countries and are comprised mostly of patients from tertiary referral centers. Different populations, especially those seen in primary care, may have different rates of variants. The type and number of variants tested for, and the methods of testing, also varied in these studies. For example, for *LDLR* gene variants, some studies used a defined set of known pathogenic variants while other studies searched for any variants and reported both known and unknown variants. There were also differences in the method for making a clinical diagnosis, and different diagnostic criteria may have resulted in different populations. Future studies may report on additional genes associated with FH (i.e., *STAP1*), and on copy number variation. Sensitivity and specificity have not yet been reported in large cohort studies for these tests.[14]

Table 1. Clinical Validity of Genetic Testing for FH

Study (Year)	Location	N	Genes Tested (Variants)	Clinical Sensitivity				Clinical Specificity
				Definite FH	Probable FH	Possible FH	Overall	
Diakou (2011)	Greece	254	*LDLR* (n=10) *APOB* (n=1) *PCSK9* (n=1) *ARH* (n=1)	66.5% (169/254)[a]	–	–	66.5% (169/254)[a]	100% (40/40)

Study (Year)	Location	N	Genes Tested (Variants)	Clinical Sensitivity				Clinical Specificity
				Definite FH	Probable FH	Possible FH	Overall	
Hedegaard (2023)[15]	Denmark	1243	*LDLR* *APOB* *PCSK9*	41.3 (19/46)	31.8 (34/107)	19.0 (97/511)	27.9% (350/1243)	

FH: familial hypercholesterolemia.
a Individuals with a clinical diagnosis of FH based on Williams's clinical criteria.
b Individuals with possible, probable, definite FH but not separated by category.
c Individuals with a high clinical suspicion for FH based on personal history, family history, and low-density lipoprotein levels.

Section Summary: Clinical Validity

Evidence on clinical validity includes cohorts of patients with definite or suspected FH tested for genetic variants, and cohorts of unaffected patients tested for genetic variants. Five moderate-to-large cohorts were reviewed, from the U.S. and Europe. A wide range of clinical sensitivity was reported (range 2% to 66.5%). The sensitivity is higher in patients with definite FH (range 50% to 70%). In patients with probable or possible FH, the sensitivity is low (range 1.2% to 30%). Two studies reported clinical specificity (range 2% to 66.5%).

CLINICAL UTILITY

There is no direct evidence on the clinical utility of genetic testing for FH. However, FH is a disorder with a high burden of illness and potentially preventable morbidity and mortality. Accelerated atherosclerotic disease in the absence of treatment leads to premature CAD and increased morbidity and mortality for affected patients. There are cases in which the diagnosis cannot be made by standard clinical workup without genetic testing. There is an overlap in cholesterol levels between individuals with FH and those with other types of hypercholesterolemia, and family history of premature CAD may or may not be apparent for all individuals, leading to a substantial number of cases in which the diagnosis is uncertain based on family history and cholesterol levels.

For patients with an uncertain diagnosis of FH, genetic testing can confirm the diagnosis in a substantial proportion of patients. Identification of a known pathogenic variant has a high specificity for FH and therefore will confirm the disorder with a high degree of certainty. On the other hand, the sensitivity for identifying a pathogenic variant is suboptimal and therefore a negative genetic test will not rule out FH in the absence of a known pathogenic/likely pathogenic variant in a blood relative. For patients who are in an uncertain category by clinical criteria, a positive genetic test will confirm the diagnosis of FH. These patients will then be eligible for specialty medications (e.g., PCSK9 inhibitors) and these medications will be initiated in patients who have uncontrolled lipid levels despite treatment with statins and/or other agents. In patients who have uncontrolled lipid levels despite treatment with standard medications, these drugs have been demonstrated to improve outcomes.[16, 17]

There is evidence that children with FH benefit from genetic testing in order to confirm their diagnosis. A Cochrane meta-analysis found that statin therapy use in children with FH was safe and effectively lowered cholesterol levels. The meta-analysis included studies involving children treated with statins as young as age 6, which is younger than current population-based cholesterol screening guidelines of age 9. The Cochrane review emphasized the importance of molecular diagnosis of FH in order to identify children who are more likely to need specialty medications.[18]

A long-term follow-up study reported that former participants in a placebo-controlled RCT involving statin therapy in children for genetically confirmed FH had reduced risk for cardiovascular disease 20 years later. The follow-up study compared patients who received statins between age 8 and 18 to their parents who were not treated with statin therapy before adulthood.[19]

Section Summary: Clinical Utility

There is a lack of direct evidence for clinical utility, therefore indirect chains of evidence are used to determine whether testing has clinical utility. For diagnostic genetic testing, when a definitive diagnosis of FH is required to establish eligibility for specialty medications, the links in the chain of indirect evidence are intact and clinical utility is demonstrated. In other situations, there are gaps in the chain of indirect evidence that preclude conclusions on clinical utility. For this indication, genetic testing can confirm the presence of FH in some individuals who have an uncertain clinical diagnosis, but treatment decisions are made primarily on LDL levels and the establishment of definite FH will not change treatment recommendations. It is possible that some types of management changes are undertaken after a diagnosis of FH, such as intensification of medication treatment or referral to a lipid specialist, but these management changes have an uncertain impact on outcomes.

TESTING INDIVIDUALS WITH A CLOSE RELATIVE WITH A DIAGNOSIS OF FH FOR FUTURE RISK OF DISEASE

Genetic testing for children at risk for FH has clinical utility. Targeted testing for a known pathogenic variant has positive and negative predictive values, both approaching 100%. Genetic testing in children is superior to standard risk stratification in determining future disease risk. Genetic testing is used to determine the age to start cholesterol testing in order to enable prompt statin therapy, and to rule out FH in children who have a blood relative with a known FH-causing gene variant. Evidence is sufficient that the technology leads to improvement in net health outcome.

There is no direct evidence on the clinical utility of genetic testing for FH in adults based on known familial variants. Cascade testing for FH in adults is unlikely to lead to changes in clinical management or improved outcomes for adults with FH since cholesterol levels are routinely assessed during adulthood. FH treatment is based on LDL levels and response to therapy. However, some studies have investigated whether FH diagnosis through genetic testing leads to better identification of FH in the family.

Miller (2022) conducted a pragmatic trial in the United States of cascade testing for FH that used direct contact between the investigators and family members.[20] Family members of 52 FH probands with a pathogenic variant in *LDLR*, *APOB*, or *PCSK9* were offered genetic testing. Family members of 73 probands without a pathogenic variant were asked to undergo lipid testing. A total of 111 family members of individuals with a pathogenic variant underwent genetic testing, and 48 new cases were identified (43.2% yield; 0.92 new cases per index case; p=.032 and p<.001, respectively compared to the other group). Among the 63 family members of individuals without a pathogenic variant who underwent lipid testing, 17 new cases were identified (27% yield; 0.23 new cases per index case). The cascade testing uptake rate was 43.9% versus 21.4%, respectively (p<.001). The authors concluded that direct contact and coordinated genetic testing may increase cascade testing uptake and yield. The study did not address whether cascade testing affected medical management or clinical outcomes.

The "Is Family screening Improved by Genetic Testing in FH" ("I FIGhT FH") RCT (2021) conducted in the United States compared cascade screening uptake in adult relatives following proband genetic testing or usual care (lipid testing) for diagnosis of FH.[21] Of 240 enrolled probands, only 43 relatives enrolled in the trial (0.2 relatives per proband). The trial did not find a difference in cascade screening uptake among relatives whether the proband was diagnosed with FH using genetic testing or usual care (0.2 vs. 0.1 relatives per proband; p=.14) nor was there a difference between group in relatives diagnosed with FH as a results of cascade screening (0.1 vs. 0.1 new cases per index case; p=.27). Results of this study may be limited due to the low participation rate by relatives eligible for cascade screening.

There is some evidence regarding the outcomes of familial testing from studies of cascade screening in countries where this method has been used.

A systematic review (2019) of cascade screening included six studies of genetic cascade testing and four studies of biochemical testing.[22] Due to the constraints associated with cascade screening noted below, none of the included studies were conducted in the United States. The review found similar diagnostic yield with genetic (44.3%) and biochemical (45.2%) testing, but the new cases identified per index case by genetic testing was nearly six times larger than cases identified by biochemical testing (2.42 versus 0.42 cases). Results favoring new case identification with genetic testing were consistent when excluding one outlier study (1.37 versus 0.42 cases).

Cascade screening for FH was evaluated by Leren (2004) in a national screening program from the Netherlands in a large study not included in the systematic review.[23] This program was initiated at a time when cholesterol screening was recommended for the general population. The addition of cascade screening for FH led to more than 9000 additional individuals diagnosed with FH. The rate of statin use increased in this population from an estimate of 39% prior to initiation of the program to 85% after full implementation. s While cascade screening is likely to improve outcomes, it requires an infrastructure that allows access to the entire population, and that is not likely to be feasible when only a limited population is available for screening. As a result of these barriers, cascade screening has not been used in the U.S., and the applicability of these studies to a U.S. population is unclear.

SUMMARY OF EVIDENCE

For individuals who have signs and/or symptoms of familial hypercholesterolemia (FH) and who receive genetic testing to confirm the diagnosis of FH, the evidence includes case series and cross-sectional studies. Relevant outcomes are test accuracy and validity, other test performance measures, symptoms, change in disease status, and morbid events. No published empiric evidence on analytic validity was identified; however, there are claims in the literature that the analytic validity approaches 100%. For clinical validity, there are large samples of individuals with FH who have been systematically tested for FH variants. In these cohorts of patients, the clinical sensitivity ranges from 30% to 70% for those with definite FH. For suspected FH, the sensitivity is lower, ranging from 1% to 30%. Clinical specificity ranges from 99% to 100%. False positives are expected to be low for known pathogenic variants, but the false-positive rate is unknown for novel variants or for variants of unknown significance.

Direct evidence of clinical utility is lacking. However, for patients who are in an uncertain diagnostic category, a positive genetic test can confirm the diagnosis of FH and establish eligibility for specialty medications. Specialty medications (e.g., PCSK9 inhibitors) have known

efficacy in patients with FH and uncontrolled lipid levels despite treatment with statins and/or other medications.

There is evidence that children with blood relatives who have known FH-causing gene variants benefit from targeted testing to determine future disease risk. Long-term follow-up data demonstrate reduced disease risk after childhood statin therapy for FH. Because FH causes, on average, earlier onset of symptoms, and there is a long pre-symptomatic phase; identification through genetic testing in order to enable preventative strategies and prompt treatment is warranted. The evidence is sufficient to determine qualitatively that the technology results in a meaningful improvement in the net health outcome.

PRACTICE GUIDELINE SUMMARY

INTERNATIONAL ATHEROSCLEROSIS SOCIETY

A 2023 guideline from the international atherosclerosis society includes recommendations about genetic testing as part of a best practice approach to managing FH.[24] All patients with a phenotypic diagnosis or strong suspicion of FH should be offered genetic testing. Testing should include the following genes: *LDLR*, *APOB*, *PCSK9*, and *LDLRAP1*. Cascade testing (consisting of both phenotype and genotype testing) of all close relatives of an index case is recommended, with a focus on the specific variant(s) identified in the index case. Children should receive genetic testing at the earliest opportunity if an FH-causing variant has been identified in a parent or other first-degree relative. Reverse cascade testing (from child to parent) should be offered after a child is found to be a proband. Any potential index case should be confirmed with genetic testing. In all cases, genetic testing should include genetic counseling.

NATIONAL LIPID ASSOCIATION EXPERT PANEL

Recommendations on the diagnosis and screening for FH were developed by the National Lipid Association Expert Panel on Familial Hypercholesterolemia and published in 2011[25] and built upon by a scientific statement published in 2020.[26] This statement includes the following recommendations:

- Genetic testing is reasonable when heterozygous familial hypercholesterolemia is suspected but not definitively diagnosed based on clinical criteria alone. (Strength of recommendation: IIa, Level of evidence: B-NR [Nonrandomized])
- Cascade screening for FH either by lipid profile or genetic testing is recommended in all first-degree relatives (children and siblings) of an individual who has tested genetically positive for FH. (Strength of recommendation: I; Level of evidence: C-EO [Consensus of expert opinion])

AMERICAN COLLEGE OF CARDIOLOGY

The Journal of the American College of Cardiology (JACC) Scientific Expert Panel published consensus guidelines regarding clinical genetic testing for FH in 2018.[27] These included the following recommendations:

- Genetic testing for FH should be offered to individuals of any age in whom a strong clinical index of suspicion for FH exists based on examination of the patient's clinical and/or family histories. This index of suspicion includes the following:

    - Children with persistent LDL-C levels ≥160 mg/dl or adults with persistent LDL-C levels ≥190 mg/dl without an apparent secondary cause of hypercholesterolemia and with at least 1 first-degree relative similarly affected or with premature CAD or where family history is not available (e.g., adoption)
    - Children with persistent LDL-C levels ≥190 mg/dl or adults with persistent LDL-C levels ≥250 mg/dl without an apparent secondary cause of hypercholesterolemia, even in the absence of a positive family history
- Genetic testing for FH may be considered in the following clinical scenarios:
    - Children with persistent LDL-C levels ≥160 mg/dl (without an apparent secondary cause of hypercholesterolemia) with and LDL-C level ≥190 mg/dl in at least 1 parent or a family history of hypercholesterolemia and premature CAD
    - Adults with no pre-treatment LDL-C levels available but with a personal history of premature CAD and family history of both hypercholesterolemia and premature CAD
    - Adults with persistent LDL-C levels ≥160 mg/dl (without an apparent secondary cause of hypercholesterolemia) in the setting of a family history of hypercholesterolemia and either a personal history or a family history of premature CAD.

In 2017, the American College of Cardiology (ACC) published a focused update to the 2016 ACC Expert Consensus Decision Pathway on the Role of Non-Statin Therapies for LDL-Cholesterol Lowering in the Management of Atherosclerotic Cardiovascular Disease Risk.[28] This guide included definitions of heterozygous and homozygous FH, based on clinical criteria alone or with genetic testing performed. However, no specific recommendations regarding such testing.

AMERICAN HEART ASSOCIATION

According to a scientific statement from the American Heart Association (2021), “Children with a strong clinical suspicion for FH should be offered genetic testing for diagnosis. Furthermore, if a pathogenic/likely pathogenic variant is found in an individual with FH, risk-predictive genetic testing should be performed in the family, including children.”[29]

NATIONAL HEART, LUNG, AND BLOOD INSTITUTE

Recommendations from an expert panel on cardiovascular health and risk reduction in children and adolescents were published in 2011.[30] The report contained the following recommendations:

- “The evidence review supports the concept that early identification and control of dyslipidemia throughout youth and into adulthood will substantially reduce clinical CVD risk beginning in young adult life. Preliminary evidence in children with heterozygous FH with markedly elevated LDL-C indicates that earlier treatment is associated with reduced subclinical evidence of atherosclerosis. (Grade B)
- TC and LDL-C levels fall as much as10-20% or more during puberty. (Grade B) Based on this normal pattern of change in lipid and lipoprotein levels with growth and maturation, age 10 years (range age 9-11 years) is a stable time for lipid assessment in children. (Grade D) For most children, this age range will precede onset of puberty.”

U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

The U.S. Preventive Services Task Force (2023) published an evidence update and recommendation statement on screening for lipid disorders in asymptomatic children and adolescents.[31] The report states the evidence is insufficient to recommend for or against lipid screening in children and adolescents age 20 years and younger. The evidence review for FH is focused on heterozygous FH, with a statement that homozygous FH is beyond the scope of the report. Regarding treatment of lipid disorders, the report states the benefit is strongest for statins in children and adolescents with FH.

The U.S. Preventive Services Task Force (2022) published recommendations on statin use for primary prevention of cardiovascular disease in adults.[32] This publication did not make specific recommendations for genetic testing for FH.

SUMMARY

There is enough research to show that genetic testing to confirm a diagnosis of familial hypercholesterolemia (FH) can help identify patients that may benefit from certain cholesterol-lowering medications. Treatment with these medications can lower the risk of cardiovascular disease and improve health outcomes in patients with FH. Clinical guidelines based on research state that genetic testing may be useful when patients have an uncertain diagnosis of FH. Therefore, genetic testing of the genes *LDLR, APOB, PCSK9,* and *LDLRAP1* to confirm a diagnosis of FH may be considered medically necessary when policy criteria are met.

There is enough research to show that testing in children for known familial FH-causing gene variants in order to determine future disease risk can improve health outcomes. Standard approaches without genetic testing are insufficient to identify and prevent complications from FH in children. Therefore, this testing may be considered medically necessary when policy criteria are met.

There is not enough research to show that genetic testing in other situations can improve health outcomes for patients. This includes testing patients that already have a diagnosis of FH, , and testing genes other than genes *LDLR, APOB, PCSK9,* and *LDLRAP1.* Therefore, testing that does not meet the policy criteria is considered investigational.

KRAS, NRAS, and BRAF Variant Analysis and MicroRNA Expression Testing for Colorectal Cancer

Effective: March 1, 2025

Next Review: December 2025
Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Variants in the *KRAS*, *NRAS*, and *BRAF* genes can substantially reduce the efficacy of certain antibody-based therapies for metastatic colon cancer. Testing for such variants can help to guide treatment decisions.

MEDICAL POLICY CRITERIA

I. *KRAS*, *NRAS*, and *BRAF* variant analysis may be considered **medically necessary** for treatment selection in patients with metastatic, unresectable, or advanced colorectal cancer.

II. *KRAS*, *NRAS*, and *BRAF* variant analysis is considered **investigational** for colorectal cancer that is not metastatic, unresectable, or advanced.

III. MicroRNA expression testing to predict anti-EGFR therapy response, including but not limited to the miR-31now™ test, is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF GENETIC TESTING DOCUMENTATION

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or mutations being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test
    - History and physical exam
    - Conventional testing and outcomes
    - Conservative treatment provided, if any

BACKGROUND

Cetuximab (Erbitux®) and panitumumab (Vectibix®) are monoclonal antibodies that bind to the epidermal growth factor receptor (EGFR), preventing binding and activation of downstream signaling pathways vital for cancer cell proliferation, invasion, metastasis, and stimulation of neovascularization.

The *KRAS* gene can harbor oncogenic variants that may result in tumor resistance to therapies that target the epidermal growth factor receptor (EGFR). *KRAS* variants are found in approximately 30–50% of colorectal cancer tumors and are common in other tumor types.

The *NRAS* gene can harbor variants in codons 12, 13 and 61 that constitutively activate the EGFR-mediated signaling pathway similar to variants in *KRAS*. Thus, the *NRAS* oncogene may also have an impact on outcomes of anti-EGFR treatments for advanced colorectal cancer. Although *NRAS* variants account for some 15% of all *RAS* variants, they are rare compared to *KRAS* variants and are found in perhaps 2-7% % of all CRC. As a consequence of the low prevalence of *NRAS* variants, it is difficult to assess their effect on cancer behavior or therapy.

BRAF encodes a protein kinase and is involved in intracellular signaling and cell growth and is

a principal downstream effector of *KRAS*. *BRAF* variants occur in less than 10-15% of colorectal cancers.

It has been shown that patients with a *KRAS* mutant tumor do not respond to cetuximab or panitumumab. However, there are still patients with *KRAS* wild-type tumors that do not respond to these agents, suggesting that other factors, such as alterations in other EGFR effectors could drive resistance to anti-EGFR therapy, and therefore, *BRAF* variants are now increasingly being investigated in metastatic colorectal cancer. *KRAS* and *BRAF* variants are considered to be mutually exclusive.

REGULATORY STATUS

Most *KRAS*, *NRAS*, and *BRAF* variant and microRNA tests using PCR methodology are commercially available as laboratory-developed tests. Such tests are regulated under the Clinical Laboratory Improvement Amendments (CLIA). Premarket approval from the U.S. Food and Drug Administration (FDA) is not required when the assay is performed in a laboratory that is licensed by CLIA for high-complexity testing.

Two companion diagnostic tests for KRAS variant analysis have been premarket approval from the FDA:

- "The cobas® KRAS Mutation Test, for use with the cobas® 4800 System, [which] is a real-time PCR [polymerase chain reaction] test for the detection of seven somatic mutations in codons 12 and 13 of the KRAS gene in DNA derived from formalin-fixed paraffin-embedded human colorectal cancer (CRC) tumor tissue. The test is intended to be used as an aid in the identification of CRC patients for whom treatment with Erbitux® (cetuximab) or with Vectibix® (panitumumab) may be indicated based on a no mutation detected result."[1]

- "The therascreen® KRAS RGQ PCR Kit is a real-time qualitative PCR assay used on the Rotor-Gene Q MDx instrument for the detection of seven somatic mutations in the human KRAS oncogene, using DNA extracted from formalin-fixed paraffin-embedded (FFPE), colorectal cancer (CRC) tissue. The therascreen® KRAS RGQ PCR Kit is intended to aid in the identification of CRC patients for treatment with Erbitux (cetuximab) and Vectibix (panitumumab) based on a KRAS no mutation detected test result."[1]

In 2015, the FDA prescribing information for panitumumab was updated to indicate that panitumumab was not indicated for treatment in colorectal cancer patients with variants in exon 2, 3, or 4 of either *KRAS* or *NRAS* in combination with oxaliplatin-based chemotherapy.

In June 2022, FDA granted accelerated approval to dabrafenib (Tafinlar) in combination with trametinib (Mekinist) for the treatment of adult and pediatric patients six years of age and older with unresectable or metastatic solid tumors with *BRAF* V600E mutation who have progressed following prior treatment and have no satisfactory alternative treatment options. However, dabrafenib in combination with trametinib is not indicated for patients with colorectal cancer because of known intrinsic resistance to BRAF inhibition

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[2] is used to describe variants found

in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

The focus of the scientific evidence is on evidence related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and
- Improve health outcomes as a result of those decisions.

For *KRAS, NRAS,* and *BRAF* testing in individuals with metastatic, unresectable, or advanced colorectal cancer, the evidence includes FDA-approved therapeutics with National Comprehensive Cancer Network (NCCN) recommendations of 2A or higher, and evidence reviews below for these genes will not be updated.

KRAS

Agency for Healthcare Research and Quality (AHRQ) Technology Assessment[3]

In 2010, AHRQ conducted a systematic review of the published evidence on *KRAS* variant testing and its ability to predict patient response to treatment with the anti-EGFR antibodies cetuximab and panitumumab. Forty-seven publications of *KRAS* variant testing met the eligibility criteria and were included in the review (45 in metastatic setting and two in neo-adjuvant setting). The review of evidence identified both small, retrospective studies and randomized controlled trials (RCTs). The assessment concluded that there is substantial and consistent evidence that *KRAS* testing can predict response to anti-EGFR therapy in colorectal cancer patients, and that,

> "For all outcomes assessed, patients with *KRAS* mutations were less likely to experience benefit with anti-EGFR antibody treatment, compared to patients whose tumors were wild-type for *KRAS* mutations. The direction of the association is consistent for overall mortality, disease progression and treatment failure by radiologic imaging."

BlueCross BlueShield Association Technology Evaluation Center (TEC) Assessment

The 2008 BlueCross BlueShield Association TEC Assessment concluded that the data are sufficient to demonstrate both the analytical and clinical validity of *KRAS* variant testing.[4] The evidence from five randomized trials and five single-arm studies is sufficient to indicate that metastatic colorectal cancer patients with mutated *KRAS* tumors do not respond to anti-EGFR monoclonal antibody therapy (either as monotherapy or in combination with other treatment regimens), do not derive survival benefit, and may experience decreased progression-free survival. Identifying patients whose tumors express mutated *KRAS* avoids exposing them to ineffective drugs, avoids exposure to unnecessary drug toxicities, and expedites the use of the best available alternative therapy.

Several studies published after the TEC and AHRQ assessments, including a meta-analysis and systematic review, continue to support the above findings.[5-12]

NRAS

A 2014 meta-analysis evaluated the predictive value of *NRAS* variants on clinical outcomes of anti-EGFR therapy in CRC[13] and included data from three nonrandomized studies.[14-16] The investigators suggest that the pooled analyses showed a trend towards poor objective response based on 17 events, but with significant effects on progression free survival (PFS) (hazard ratio [HR] 2.30, 95% CI 1.30 to 4.07) and overall survival (OS) (HR 1.85, 95% CI 1.23 to 2.78) among patients with wild-type *KRAS*. These results are limited by the small pool of variants, with studies reporting a prevalence of 2.2-5%.

Sorich (2015) published a systematic review and meta-analysis of nine RCTs that included 5948 metastatic colorectal cancer patients evaluated for *KRAS* exon 2 variants and new *RAS* variants, which were defined as variants in exons 3 and 4 of *KRAS* and exons 2, 3, and 4 of *NRAS*.[17] The prevalence of *NRAS* exon 2, 3, and 4 variants ranged from 0.5% to 4.8% and was similar to the prevalence of *KRAS* exon 3 and 4 variants, which ranged from 4.3% to 6.7% of tumors. Pooled data indicated that tumors without *KRAS* exon 2 variants or new *RAS* variants were found to have significantly superior PFS ($p<0.001$) and OS ($p=0.008$) with anti-EGFR monoclonal antibody (mAb) treatment compared to tumors with these variants. In addition, there were no differences noted in the PFS or OS of tumors with *KRAS* exon 2 variants when compared to new *RAS* variants. These results were consistent between different anti-EGFR mAb agents, lines of therapy, and chemotherapy. No PFS or OS benefit was observed with the use of anti-EGFR mAb agents in tumors with *KRAS* exon 2 variants or new *RAS* variants ($p>0.05$). Based on these results, authors concluded that approximately 53% of metastatic colorectal tumors (~42% with *KRAS* exon 2 and ~11% with new *RAS* variants) are unlikely to have a positive response to anti-EGFR mAb therapy. Results from this pooled data analysis suggest *NRAS* variant results may be used to guide treatment decisions in patients with metastatic colorectal tumors, as patients with *NRAS* variants are unlikely to benefit from anti-EGFR mAb therapy.

A systematic review and meta-analysis by Lin (2016) evaluated the efficacy of cetuximab-based chemotherapy according to *RAS* and *BRAF* variant subgroups in nine studies.[12] Cetuximab was associated with longer overall survival in tumors that had no variants in exon 2 of *KRAS* ($p=0.004$), tumors with wild-type (exons 2, 3, and 4) *KRAS*/*NRAS* ($p=0.0002$). There were no significant differences in OS or PFS between tumors with *KRAS* exon 2 variants and other exon 2, 3, or 4 *KRAS* or *NRAS* variants.

Additional studies published since the systematic reviews have shown similar differences in response to EGFR inhibitors according to *RAS* variant status.[18]

BRAF

Systematic Reviews

Pietrantonio (2015) published a systematic review and meta-analysis of randomized trials that compared cetuximab or panitumumab plus chemotherapy compared to standard therapy or best supportive care in patients with advanced colorectal cancer that have a *BRAF* variant.[19] Pooled results were reported for the efficacy of anti-EGFR-based therapy according to variant status as a first-line, second-line or refractory setting. Nine phase III trials and one phase II trial with a total of 463 patients with metastatic colon cancer were analyzed. Treatment with cetuximab or panitumumab did not significantly improve PFS (HR 0.88, 95% CI 0.67 to 1.14), OS (HR 0.91, 95% CI 0.62 to 1.34), or overall response rates (RR 1.31, 95% CI 0.83 to 2.08) compared to the control groups.

Rowland (2015) also published a systematic review and meta-analysis RCTs which evaluated the impact of *BRAF* variant status upon anti-EGFR mAb treatment outcomes in patients with metastatic colorectal cancer.[20] Seven RCTs met inclusion criteria for OS and eight studies met inclusion criteria for PFS. Pooled data indicated that cetuximab and panitumumab did not improve PFS (HR 0.86, 95% CI 0.61 to 1.21) or OS (HR 0.97, 95% CI 0.67 to 1.41) in patients with *BRAF* variants.

Other Studies

An updated analysis of the CRYSTAL trial reported increased follow-up time and an increased number of patients evaluable for tumor *KRAS* status and considered the clinical significance of the tumor variant status of *BRAF* in the expanded population of patients with *KRAS* wild-type tumors.[8] The impact of *BRAF* tumor variant status in relation to the efficacy of the chemotherapy regimen consisting of cetuximab plus folinic acid (leucovorin), 5-FU, and irinotecan (FOLFIRI) was examined in the population of patients with *KRAS* wild-type disease (n=625). There was no evidence of an independent treatment interaction by tumor *BRAF* variant status. The authors concluded that *BRAF* variant status was not predictive of treatment effects of cetuximab plus FOLFIRI but that *BRAF* tumor variant was a strong indicator of poor prognosis for all efficacy end points compared with those whose tumors were wild-type. Other studies have been published that report mixed results.[8, 21-29]

The data regarding the utility of variant testing as a predictive marker which informs the use of anti-EGFR mAb is less substantial for *BRAF* testing than for *KRAS* or *NRAS* testing. However, the evidence suggests that *BRAF* variant testing may be useful in directing treatment decisions, as anti-EGFR therapies do not improve PFS or OS in metastatic colorectal cancer patients with *BRAF* variants.

MICRORNA

Several studies have evaluated the association between the expression of the miR-31-3p microRNA and colorectal cancer progression in patients treated with anti-EGFR therapies.[30-34] For example, an industry-sponsored study published by Laurent-Puig (2018) reported that individuals with low miR-31-3p expression derived more benefit from cetuximab than bevacizumab (PFS HR 0.74, 95% CI 0.55 to 1.00, p=0.05; OS HR 0.61, 95% CI 0.41 to 0.88, p<0.01).[30] However, no studies have assessed the use of microRNA expression test results to guide treatment decisions or impact health outcomes.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN)[35] guidelines (v.6.2024) on the treatment of colon cancer make the following recommendation regarding *KRAS*, *NRAS*, and *BRAF* variant testing:

> "All patients with metastatic colorectal cancer should have tumor genotyped for *RAS* (*KRAS* and *NRAS*) and *BRAF* mutations individually or as part of an NGS panel. Patients with any known *KRAS* mutation (exons 2, 3, and 4) or *NRAS* mutation (exons 2, 3, and 4) should not be treated with either cetuximab or panitumumab, unless given as part of a regimen targeting a *KRAS* G12C mutation. *BRAF* V600E mutation makes

response to panitumumab or cetuximab highly unlikely unless given with a *BRAF* inhibitor."

The guidelines did not discuss microRNA testing.

SUMMARY

There is enough evidence to show that cetuximab and panitumumab are not effective treatments for colorectal cancers with *KRAS*, *NRAS* or *BRAF* variants. Clinical guidelines based on research recommend testing patients with metastatic colorectal cancer for variants in the *KRAS*, *NRAS*, and *BRAF* genes to help with treatment decisions. Therefore, *KRAS*, *NRAS* and *BRAF* variant analysis may be considered medically necessary to predict nonresponse to anti-EGFR monoclonal antibodies in the treatment of metastatic colorectal cancer.

Anti-EGFR monoclonal antibodies are approved to treat advanced forms of colorectal cancer. These therapies are not approved for patients with non-metastatic, resectable colorectal cancer. Therefore, *KRAS*, *NRAS*, and *BRAF* variant analysis is considered investigational for colorectal cancer that is not metastatic, unresectable, or advanced.

There is not enough research to show that testing for microRNA expression can improve treatment decisions or health outcomes for patients with colorectal cancer. In addition, there are no clinical guidelines based on research that recommend microRNA testing for these patients. Therefore, microRNA expression testing to predict anti-EGFR therapy response, including but not limited to the miR-31now™ test, is considered investigational.

Medical Policy Manual Genetic Testing, Policy No. 18

Preimplantation Genetic Testing of Embryos

Effective: October 1, 2024

Next Review: March 2025
Last Review: September 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Preimplantation genetic testing (PGT) involves analysis of biopsied cells as part of an assisted reproductive procedure. It is generally considered to be divided into two categories: 1) Preimplantation genetic testing for monogenic conditions (PGT-M) or for structural rearrangements (PGT-SR), are used to detect a specific inherited disorder, and aim to prevent the birth of affected children in people at high risk of transmitting a disorder. 2) Preimplantation genetic testing for aneuploidy (PGT-A) uses similar techniques to screen for potential genetic abnormalities in conjunction with in vitro fertilization for people without a specific known inherited disorder.

MEDICAL POLICY CRITERIA

Notes:

- Preimplantation genetic testing is an associated service, an adjunct to in vitro fertilization. Member contracts for covered services vary. Member contract language takes precedent over medical policy.
- This policy does not address whole exome sequencing (WES), whole genome sequencing (WGS), or carrier screening (see Cross References section).

I. Preimplantation genetic testing for monogenic conditions (PGT-M) or structural rearrangements (PGT-SR) may be considered **medically necessary** as an adjunct to

in vitro fertilization (IVF) in people who meet at least one of the following criteria, subject to careful consideration of the technical and ethical issues involved:

A. For evaluation of an embryo at an identified elevated risk of a genetic disorder such as when:
   1. Both partners are known carriers of a single-gene autosomal recessive disorder
   2. One partner is a known carrier of a single-gene autosomal recessive disorder, and the partners have one offspring that has been diagnosed with that recessive disorder
   3. One partner is a known carrier of a single-gene autosomal dominant disorder
   4. One partner is a known carrier of a single X-linked disorder

B. For evaluation of an embryo at an identified elevated risk of structural chromosomal abnormality, such as for a parent with balanced or unbalanced chromosomal translocation.

II. Preimplantation genetic testing for monogenic conditions (PGT-M) or structural rearrangements (PGT-SR) as an adjunct to IVF is considered **investigational** in people who are undergoing IVF in all situations other than those specified above.

III. Preimplantation genetic testing for aneuploidy (PGT-A), as an adjunct to IVF is considered **investigational** in people who are undergoing IVF in all situations.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
   - History and physical exam including any relevant diagnoses related to the genetic testing
   - Conventional testing and outcomes
   - Conservative treatments, if any

BACKGROUND

Preimplantation genetic testing (PGT) describes a variety of adjuncts to an assisted reproductive procedure, in which either maternal or embryonic DNA is sampled and genetically analyzed, thus permitting deselection of embryos harboring a pathogenic gene abnormality prior to implantation of the embryo into the uterus. The ability to identify preimplantation embryos with pathogenic gene variants before the initiation of pregnancy provides an attractive alternative to amniocentesis or chorionic villous sampling (CVS) with selective pregnancy termination of affected fetuses. Preimplantation genetic testing can be viewed as either diagnostic, including (PGT-M, formerly known as preimplantation genetic diagnosis; PGD) and preimplantation genetic testing for structural chromosomal rearrangements (PGT-SR); or screening for aneuploidy (PGT-A, formerly known as preimplantation genetic screening; PGS). PGT-M and PGM-SR are used to detect genetic evidence of a specific inherited disorder in the oocyte or embryo derived from biologic mother or reproductive partner that has a high risk of transmission. PGT-A is not used to detect a specific abnormality but instead uses similar techniques to identify genetic abnormalities to identify embryos at risk. This terminology, however, is not used consistently (e.g., some authors use the term preimplantation genetic diagnosis when testing for a number of possible abnormalities in the absence of a known disorder).

Biopsy for PGT-M can take place at three stages; the oocyte, the cleavage stage embryo or the blastocyst. In the earliest stage, the first and second polar bodies are extruded from the oocyte as it completes meiotic division after ovulation (first polar body) and fertilization (second polar body). This strategy thus focuses on maternal chromosomal abnormalities. If the biologic mother is a known carrier of a pathogenic gene variant, and genetic analysis of the polar body is normal, then it is assumed that the variant was transferred to the oocyte during meiosis.

Biopsy of cleavage stage embryos or blastocysts can detect genetic abnormalities arising from either the maternal or paternal genetic material. Cleavage stage biopsy takes place after the first few cleavage divisions when the embryo is composed of six to eight cells (i.e., blastomeres). Sampling involves aspiration of one and sometimes two blastomeres from the embryo. Analysis of two cells may improve diagnosis but may also affect the implantation of the embryo. In addition, a potential disadvantage of testing at this phase is that mosaicism might be present. Mosaicism refers to genetic differences among the cells of the embryo that could result in an incorrect interpretation if the chromosomes of only a single cell are examined.

The third option is sampling the embryo at the blastocyst stage when there are about 100 cells. Blastocysts form five to six days after insemination. Three to 10 trophectoderm cells (outer layer of the blastocyst) are sampled. A disadvantage is that not all embryos develop to the blastocyst phase in vitro and, if they do, there is a short time before embryo transfer needs to

take place. Blastocyst biopsy has been combined with embryonic vitrification to allow time for test results to be obtained before the embryo is transferred.

The biopsied material can be analyzed in a variety of ways. Polymerase chain reaction or other amplification techniques can be used to amplify the harvested DNA with subsequent analysis for single genetic variants. This technique is most commonly used when the embryo is at risk for a specific genetic disorder such as Tay-Sachs disease or cystic fibrosis. Fluorescent in situ hybridization (FISH) is a technique that allows direct visualization of specific (but not all) chromosomes to determine the number or absence of chromosomes. This technique is most commonly used to screen for aneuploidy, sex determination, or to identify chromosomal translocations. Fluorescent in situ hybridization cannot be used to diagnose single gene variant disorders. However, molecular techniques can be applied with FISH, and thus single-gene variants (eg, microdeletions, duplications) can be recognized with this technique.

A more recent approach for preimplantation genetic testing is with comprehensive chromosome screening using techniques such as array comparative genome hybridization and next generation sequencing.

Three general categories of embryos have undergone PGT:

1. Embryos at risk for a specific inherited single gene abnormality (PGT-M and PGT-SR)

Inherited single-gene pathogenic variants fall into three general categories: autosomal recessive, autosomal dominant, and X-linked. When either or both biologic parents are a known carrier of a pathogenic gene variant, PGT-M testing can be used to deselect embryos harboring the variant. Gender selection of a female embryo is another strategy when the biologic mother is a known carrier of an X-linked disorder for which there is not yet a specific molecular diagnosis. The most common example is female carriers of fragile X syndrome. In this scenario, PGT-M is used to deselect male embryos, half of which would be affected. PGT-M could also be used to deselect affected male embryos. While there is a growing list of single gene variants for which molecular diagnosis is possible, the most common indications include cystic fibrosis, beta thalassemia, muscular dystrophy, Huntington's disease, hemophilia, and fragile X disease. It should be noted that when PGT-M is used to deselect affected embryos, the treated reproductive partners are not technically infertile but are undergoing an assisted reproductive procedure for the sole purpose of PGT-M. In this setting, PGT-M may be considered an alternative to selective termination of an established pregnancy after diagnosis by amniocentesis or chorionic villus sampling.

Inherited chromosomal structural rearrangements may be either balanced, with no loss or gain of genetic material, or unbalanced, with some deletion or duplication. The risk of passing such a rearrangement on to offspring varies but can be as high as 50%. PGT-SR is testing to detect these rearrangements.

2. Identification of aneuploid embryos

Implantation failure of fertilized embryos is a common cause for failure of assisted reproductive procedures. Aneuploidy of embryos is thought to contribute to implantation failure and may also be the cause of recurrent spontaneous abortion. The prevalence of aneuploid oocytes increases in older women. These age-related aneuploidies are mainly due to nondisjunction of chromosomes during maternal meiosis. Therefore, PGT-A of the extruded polar bodies from the oocyte has been explored as a technique to deselect aneuploid oocytes in older women. In

addition to advanced maternal age, PGT-A has been proposed for people with repeated implantation failure.

3. Embryos at a higher risk of translocations

Balanced translocations occur in 0.2% of the neonatal population but at a higher rate in people with infertility or recurrent spontaneous abortions. PGT-SR for structural rearrangements (translocations or inversions) can be used to deselect those embryos carrying the translocations, thus leading to an increase in fecundity or a decrease in the rate of spontaneous abortion.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[1] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Promotion of greater diversity and inclusion in clinical research of historically marginalized groups (e.g., People of Color [African-American, Asian, Black, Latino and Native American]; LGBTQIA (Lesbian, Gay, Bisexual, Transgender, Queer, Intersex, Asexual); Women; and People with Disabilities [Physical and Invisible]) allows policy populations to be more reflective of and findings more applicable to our diverse members. While we also strive to use inclusive language related to these groups in our policies, use of gender-specific nouns (e.g., women, men, sisters, etc.) will continue when reflective of language used in publications describing study populations.

TECHNICAL FEASIBILITY

Preimplantation genetic diagnosis (PGT-M) has been shown to be a feasible technique to detect pathogenic genetic variants and to deselect affected embryos. Recent reviews continue to state that PGT-M using either polymerase chain reaction (PCR) or FISH can be used to identify numerous single gene disorders and unbalanced chromosomal translocation.[2, 3] According to a PGT-M registry initiated by the European Society of Hormone Reproduction and Embryology (ESHRE), the most common indications for PGT-M were thalassemia, sickle cell syndromes, cystic fibrosis (CF), spinal muscular disease, and Huntington’s disease.[4]

In 2007 the ESHRE PGT-M registry reported PGT-M testing on 3,753 oocyte retrievals, resulting in 729 with chromosomal abnormalities, 110 with X-linked diseases, 1,203 with monogenic diseases, and 92 for social sexing.[4] These registry data suggest that PGT-M, using either PCR or FISH, can be used to deselect affected embryos.

Several studies have suggested that the role of preimplantation genetic testing (PGT) has expanded to a broader variety of conditions that have not been considered as an indication for genetic testing via amniocentesis or chorionic villus sampling. The report of PGT used to deselect embryos at risk for early-onset Alzheimer’s disease prompted considerable controversy, both in lay and scientific publications.[5-7] Other reports focus on other applications

of PGT for *predispositions* to late-onset disorders.[8] This contrasts with the initial use of PGT-M in deselecting embryos with genetic variants highly predictive of lethal diseases. PGT-M has also been used for gender selection and "family balancing."[9-11] A representative sample of case series and reports on the technical feasibility of PGT to deselect embryos for different indications follows.

Several smaller case series reported on individual diseases. For example, Goossens (2000) reported on 48 cycles of PGT-M in 24 couples at risk for cystic fibrosis (CF). Thirteen patients became pregnant, and 12 healthy babies were born.[12] In an additional 2013 study on cystic fibrosis, there were 44 PGT-M cycles performed for 25 CF-affected homozygous or double-heterozygous CF patients (18 male and seven female partners), which involved testing simultaneously for three variants, resulting in the birth of 13 healthy CF-free children and no misdiagnosis. PGT-M was also performed for six couples at a combined risk of producing offspring with CF and another genetic disorder. Concomitant testing for CF and other variants resulted in birth of six healthy children, free of both CF and another genetic disorder in all but one cycle.[13] Other anecdotal studies have reported successful PGT-M in patients with osteogenesis imperfecta,[14] Lesch-Nyhan syndrome,[15] bulbar muscular atrophy,[16] and phenylketonuria.[17]

EFFICACY AND SAFETY

An area of clinical concern is the impact of PGT on overall IVF success rates. The available evidence is largely focused on people undergoing IVF due to infertility, and not specifically for PGT-M**.** The Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review on infertility management.[18] The AHRQ reviewed studies compared all types of PGT cycles with non-PGT cycles and found that for women younger than 35 years live birth per embryo transfer was lower for PGT cycles compared to non-PGT cycles.

An important general clinical issue is whether PGT-M is associated with adverse obstetric outcomes, specifically fetal malformations related to the biopsy procedure. Strom (2000) addressed this issue in an analysis of 102 pregnant women who had undergone PGT with genetic material from the polar body.[19] All preimplantation genetic diagnoses were confirmed postnatally; there were no diagnostic errors. The incidence of multiple gestations was similar to that seen with IVF. PGT-M did not appear to be associated with an increased risk of obstetric complications compared to data reported for obstetric outcomes for in vitro fertilization. However, it should be noted that biopsy of the polar body is extra-embryonic material, and thus one might not expect an impact on obstetric outcomes. The patients in this study had undergone PGT for both unspecified chromosomal disorders and various disorders associated with a single gene variant (e.g., CF, sickle cell disease, and others).

Preimplantation Genetic Testing for Monogenic Conditions

Systematic Reviews

Li (2022) published a systematic review and meta-analysis that included eleven studies to compare pregnancy outcomes in couples with recurrent pregnancy loss (RPL) and abnormal karyotypes to couples with RPL and normal karyotypes.[20] First pregnancy live birth rate (LBR) after RPL was lower in couples with abnormal karyotypes than in couples with normal karyotype (9 studies, OR, 0.55; 95% CI 0.46-0.65; I^2=27%; p<0.00001). Accumulated LBR was not significantly different between couples with abnormal vs. normal karyotype after RPL (4 studies; OR, 0.96; 95% CI, 0.90-1.03; I^2=0; p=0.26) However, miscarriages were more

common in couples with an abnormal karyotype (4 studies; OR, 2.21; 95% CI, 1.69-2.89; I^2=0; p<0.00001). A second analysis reported pregnancy outcomes of couples with RPL and abnormal karyotype that had expectant management compared to those that had PGD. While limited by the availability of only two non-randomized studies, the meta-analysis found the difference in accumulated LBR was not significant (2 studies; OR 0.55; 95% CI, 0.11-2.62; I^2=71%; 0=0.45) but PGD was associated with a lower miscarriage rate (2 studies; OR 0.15; 95% CI, 0.04-0.51; I^2=45%; p=0.002). The findings suggest that while miscarriages and unsuccessful first pregnancy are more common in people with chromosomal abnormalities, their overall LBR was the same as for people with normal karyotypes. However, the evidence also suggests repeated attempts are required after unsuccessful first pregnancy to achieve similar outcomes.

A systematic review by Iews (2018) evaluated reproductive outcomes with PGD among patients who had recurrent pregnancy losses due to structural chromosomal rearrangements.[21] There were 20 studies included in the review. There was significant heterogeneity between these studies, precluding meta-analysis. Among the 847 couples who conceived naturally, the live birth rate ranged from 25% to 71%, while among the 526 couples who underwent IVF with PDG the live birth rate ranged from 27% to 87%. The authors noted that the review was limited by the lack of large comparative or randomized studies.

Hasson (2017) published a systematic review of studies comparing obstetric and neonatal outcomes after intracytoplasmic sperm injection (ICSI) without PGD compared with ICSI with PGD.[22] Studies focused on cases in which there were known parental genetic aberrations. Reviewers identified six studies, including data published by the investigators in the same article. Pooled analysis found no significant differences between the two groups for four of the five reported outcomes, mean gestational age at birth, the rate of preterm delivery, and the rate of malformations. There was a significantly lower rate of low birth weight neonates (<2500 g) in the PGD group compared with the non-PGD group (relative risk [RR] 0.84, 95% confidence interval [CI] 0.72 to 1.00, p=0.04).

Randomized Controlled Trials

No randomized controlled trials (RCTs) of PGT-M were identified.

Nonrandomized Studies

A study by Heijligers (2018) evaluated perinatal outcomes following PGD between 1995 and 2014 in the Netherlands.[23] The study included 439 pregnancies in 381 women leading to 366 live born children. Of these, two were lost to follow-up. Nine of the remaining 364 children (2.5%) had major congenital malformations, which was consistent with other PGD cohorts, and five had a minor malformation. One misdiagnosis resulted in the spontaneous abortion of a fetus with an unbalanced 47,XX,+der(5)t(X;5)(q13;p14)mat karyotype. Seventy-one (20%) of the children were premature, including eight, all from twin pregnancies, that were very premature (<32 weeks). The authors concluded that there was no evidence that PGD was associated with an increased risk of adverse perinatal outcomes or congenital malformations.

Won (2018) reported clinical outcomes for patients who underwent PGD or PGS at a single center in Korea from January 2014 through December 2015.[24] This included samples from 116 PGD cycles for 76 couples. Of these PGD cases, there were 24 Robertsonian translocations, 60 reciprocal translocations, 23 with mosaicism, three inversions, four additions, and two deletions. Implantation and clinical pregnancy rates with PGD were higher

when testing was performed at the blastocyst stage (n=26) as compared with the cleavage stage (n=90) (27.5% vs. 17.8% and 38.5% vs. 18.9, respectively).

Maithripala (2017) performed a retrospective chart review of 36 couples with recurrent pregnancy loss due to structural chromosomal rearrangements.[25] Couples were more likely to choose natural conception than IVF with PGD, and no significant differences in live birth rate were seen between treatment groups.

A study by Kato (2016) included 52 couples with a reciprocal translocation (n=46) or Robertsonian translocation (n=6) in at least one partner.[26] All couples had a history of at least two miscarriages. The average live birth rate was 76.9% over 4.6 oocyte retrieval cycles. In the subgroups of young (<38 years) female carriers, young male carriers, older (≥38 years) female carriers, and older male carriers, live birth rates were 77.8%, 72.7%, 66.7%, and 50.0%, respectively.

Chow (2015) reported on 124 cycles of PGD in 76 couples with monogenetic diseases (X-linked recessive, autosomal recessive, autosomal dominant).[27] The most common genetic conditions were α-thalassemia (64 cycles) and β-thalassemia (23 cycles). Patients were not required to have a history of miscarriage. A total of 92 PGD cycles resulted in embryo transfer, with an ongoing pregnancy rate (beyond 8 to 10 weeks of gestation) in 28.2% of initiated cycles and an implantation rate of 35%. The live birth rate was not reported.

A study by Scriven (2013) evaluated PGD for couples carrying reciprocal translocations.[28] This prospective analysis included the first 59 consecutive couples who completed treatment at a single center. Thirty-two out of the 59 couples (54%) had a history of recurrent miscarriages. The 59 couples underwent a total of 132 cycles. Twenty-eight couples (47%) had at least one pregnancy, 21 couples (36%) had at least one live birth and 10 couples (36%) had at least one pregnancy loss. The estimated live birth rate per couple was 30 of 59 (51%) after three to six cycles. The live birth rate estimate assumed that couples who were unsuccessful and did not return for additional treatment would have had the same success rate as couples who did return.

Keymolen (2012) reported clinical outcomes of 312 cycles performed for 142 couples with reciprocal translocations.[29] Data were collected at one center over 11 years. Seventy-five of 142 couples (53%) had PGD due to infertility, 40 couples (28%) due to a history of miscarriage, and the remainder due to a variety of other reasons. Embryo transfer was feasible in 150 of 312 cycles and 40 women had a successful singleton or twin pregnancy. The live birth rate per cycle was thus 12.8% (40 of 312), and the live birth rate per cycle with embryo transfer was 26.7% (40 of 150).

No studies were identified that specifically addressed PGT-M for evaluation of embryos in people with a history of aneuploidy in a previous pregnancy.

Section Summary

Studies have shown that PGT-M for evaluation of an embryo at identified risk of a genetic disorder or structural chromosomal abnormality is feasible and does not appear to increase the risk of obstetric complications.

Preimplantation Genetic Screening for Aneuploidy

Technology Assessments

A 2008 technology assessment published by the Agency for Healthcare Research and Quality (AHRQ) found two randomized controlled trials that assessed the use of PGT-A for embryo selection in women 35 years or older.[30] The first study reported lower pregnancy and live birth rates in the PGS group compared with the control group which did not undergo PGS, though this difference was not statistically significant (p=0.09).[31] About 25% of the embryos biopsied were genetically abnormal; therefore, fewer embryos were transferred in the PGT-A group. In the second study, which also studied women 35 years or older, Mastenbroek (2007) reported significantly lower pregnancy and live birth rates in the PGS group.[32] In this study, all women had two embryos transferred; thus, the between-group difference could not be attributed to differences in the number of transferred embryos. A 2019 comparative review by the Agency for Healthcare Research and Quality (AHRQ) states that available evidence on PGS screening for unexplained fertility is too dated to be applicable to current clinical practice.[18]

Systematic Reviews

Vitagliano (2023) published a systematic review and meta-analysis of seven studies involving 11,335 transfers of euploid embryos that compared maternal age <35 years to maternal age ≥35 years.[33] Maternal age <35 years was associated with a higher ongoing pregnancy rate or live birth rate (OR 1.29; 95% CI, 1.07-1.54; I^2 = 40%), and higher implantation rate (OR 1.22; 95% CI, 1.12-1.32; I^2=0%). The authors concluded that maternal age >35 years is associated with lower success rates for assisted reproductive technology independent of embryo ploidy.

Liang (2023) conducted a systematic review and meta-analysis focused on PGT-A outcomes after recurrent pregnancy failure (RPF).[34] RPF includes recurrent spontaneous abortion (RSA) and recurrent implantation failure (RIF). Thirteen studies were included in the analysis.

The analysis divided the overall outcomes into five groups:

- Six studies of implantation rate showed a significantly higher implantation rate after PGT-A compared to in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) (p<0.00001).
- The analysis of clinical pregnancy rate (CPR) involved 12 studies and found PGT-A was associated with higher CPR than IVF/ICSI (p<0.0001).
- Clinical miscarriage rate (CMR) was analyzed in 11 studies that found CMR was significantly lower in the PGT-A group compared to IVF/ICSI (p=0.0047).
- Four studies were included in the analysis of ongoing pregnancy rate (OPR) which found that OPR was higher in the PGT-A group than in the IVF/ICSI group (p<0.0001).
- Nine studies were included in the analysis of live birth rate (LBR) which found LBR was significantly higher in the PGT-A group compared to the IVF/ICSI group (p<0.0001).

Subgroup analysis found that when outcomes were stratified by maternal age, for both women younger than 35 years and women aged 35 and older, CPR and LBR were significantly higher in the PGT-A groups but there was no difference in clinical miscarriage rates (CMR) in either maternal age group when comparing PGT-A to IVF/ICSI.

The authors conclude that for patients with RPF, PGT-A may improve outcomes, but note that PGT-A by itself is inadequate to address RPF. The authors also note the analysis was limited

by the small number of studies, and particularly the small number of studies included in sub-group analyses.

Kasaven (2023) published a systematic review and meta-analysis comparing PGT-A to conventional morphologic assessment.[35] The primary outcomes were live birth rate (LBR) and ongoing pregnancy rate (OPR) per embryo transfer. The analysis included 16 studies of which six were randomized controlled trials (RCTs) and 10 were cohort studies. LBR was higher in both the RCTs (p=0.03) and the cohort studies (p<0.001). The OPR per embryo transfer was also higher in the PGT-A group in the RCTs (p=0.04) and in the cohort studies (p<0.001). The authors conclude that PGT-A results in higher rates of LBR and OPR than conventional morphologic assessment but acknowledge that studies comparing PGT-A to other strategies, e.g., FISH and the use of cleavage-stage biopsies, have not found that PGT-A is superior. The authors also note that PGT-A in most of the included studies was not performed for a specific indication and some studies excluded women with risk factors for unsuccessful pregnancy outcomes (e.g., diminished ovarian reserve, history of implantation failure).

Cheng (2022) published a systematic review and meta-analysis to assess whether preimplantation genetic screening for aneuploidy (PGT-A) leads to higher live-birth rates than IVF without PGT-A.[36] Nine RCTs with 3,334 participants were included. The overall live-birth rate was not significantly different (RR 1.13, 95% CI 0.96-1.34, I^2=50%). However, when stratified by maternal age, PGT-A was associated with a higher rate of live births to woman of advanced maternal age (RR 1.34, 95% CI 1.02-1.77, I^2=50), but not women of nonadvanced maternal age (RR 0.94, 95% CI 0,89-0.99, I^2=0%). Miscarriage rates were compared in eight studies. The PGT-A group experienced significantly fewer miscarriages than the control group (RR 0.53%, 95% CI 0.35-0.81, I^2=50). Other secondary outcomes; clinical pregnancy, ongoing pregnancy, multiple pregnancy, and birth weight were not significantly different. Funnel plot showed low risk of publication bias, but four of the nine studies had unclear risk of bias. The authors note the main limitation of the study is high heterogeneity (;<0.001, I^2=79%). The quality of the evidence for live births was deemed moderate.

Chromosomal mosaicism occurs when two or more distinct cell populations are present in the same embryo. Mosaicism is common, occurring in up to 80% of embryos using next generation sequencing (NGS) for PGT.[37] There have been conflicting reports of the impact of mosaicism on pregnancy outcomes, and some people have no embryos without mosaicism available for transfer. Further, healthy babies have been born after mosaic embryo transfer. [37, 38] Wang (2023) published a systematic review and meta-analysis of transfer outcomes of aneuploid mosaicism after PGT-A between 2016 and 2021 in China. [37] The authors reported institutional data from 448 women and meta-analysis was performed with data from five other studies. The focus was on the effects of aneuploid mosaicism, especially single chromosome abnormality subtypes, on reproductive outcomes. Outcomes of interest were implantation, ongoing pregnancy, and miscarriage. Implantation and clinical pregnancy rates were lower in single aneuploid embryos compared to euploid embryos for all single aneuploidy subtypes (implantation: whole chromosome loss (WCL), p<0.00001; whole chromosome gain (WCG), p=0.002; chromosome segment gain (CSG), p=0.001; chromosome segment loss (CSL), p=0.002; clinical pregnancy: WCL, p<0.00001**;** WCG, p=0.0007; CSG, p=0.0001; CSL p<0.0001). Miscarriage rates were higher with WCL (p=0.0007) and SCL (p=0.03) compared to euploid embryos, but differences in WSG (p=0.27) and CSG (p=0.22) were not significant. Maternal age >35 years was associated with lower rates of implantation and clinical pregnancy for every subtype of single aneuploid abnormality compared to euploid. However, for miscarriage, WCL was the only aneuploid subtype associated with maternal age >35 years

(p=0.0001). Maternal age ≤35 years was varied in its associations of implantation, clinical pregnancy, and miscarriage rates by single aneuploid subtype. Comparisons of mosaic ratio to euploid embryos found that higher level mosaic ratio (>30% to 60%) was associated with reduced implantation and clinical pregnancy in all aneuploid subtypes (implantation: WCG (p=0.005), WCL (p<0.00001), CSG (p=0.03) and CSL (p=0.002; clinical pregnancy: WCG (p=0.001), WCL (p<0.00001), CSG (p=0.009), and CSL (p<0.0001). WCL was associated with increased miscarriage rates at both lower-level (≤30%) and higher-level mosaic ratios (higher level, p=0.04; lower level, p=0.007). Bias was not addressed in the meta-analysis. The authors did not address limitations of the study.

Using three of the same studies as Wang (2023), Ma (2022) performed a systematic review and meta-analysis focused on pregnancy outcomes after mosaic embryo transfers.[38]. Twelve studies were included in the systematic review and six of those were included in the meta-analysis. The six studies involved 1106 transfer cycles. Three studies used NGS platforms for PGT, two used array comparative genome hybridization (cCGH), and one reported on a combination of NGS and cCGH data. Comparison of mosaicism level <50% to ≥50% found improved rates of implementation and fewer miscarriages at mosaicism levels <50% [Implementation: OR 1.42, 95% CI (1.06, 1.89); Miscarriage: OR 0.45, 95% CI (027, 0.75)]. There was no significant difference between embryos with one mosaic chromosome compared to two, but embryos with three or more mosaic chromosomes had worse outcomes than embryos with single chromosome mosaicism [Implementation rate: OR 1.76, 95% CI (1.23, 2.52) Miscarriage rate: OR 0.78, 95% CI (0.40, 1.54)]. The authors suggest a 50% mosaicism threshold for embryo transfer. Strengths of the study include low heterogeneity (I^2>50%). The authors note limitations of the study include the lack of prospective studies, and variety of genetic screening platforms involved. Importantly, they point out that there is little information on the children that result from mosaic chromosome transfer. Neither Wang (2023) nor Ma (2022) compare universal screening for PGT-A to no screening, or to screening based on risk factors, such as advanced maternal age.

A number of RCTs evaluating PGS (PGT-A) have been published, and these findings have been summarized in a several systematic reviews and meta-analyses.[39-44] One of the most recent and comprehensive meta-analysis was a Cochrane review published by Cornelisse (2020), which included 13 RCTs involving 2,794 women.[39] The quality of the included trials ranged from low to moderate, and the main limitations were reported to be imprecision, inconsistency, and risk of publication bias. One study by Verpoest (2018, described below) compared PGT-A with the use of aCGH to no PGT-A,[45] while another, by Munné (2019, described below) compared PGT-A with the use of NGS–based genome-wide analyses to no PGT-A.[46] The other studies compared PGT-A with FISH to no PGT-A. The review concluded that there was “insufficient good-quality evidence of a difference in cumulative live birth rate, live birth rate after the first embryo transfer, or miscarriage rate between IVF with and IVF without PGT-A as currently performed.” The authors noted that the use of FISH for the PGT-A genetic analysis is outdated and probably harmful.

A systematic review and meta-analysis by Shi (2021) evaluated PGS specifically in the setting of advanced maternal age, with a comparison between FISH and newer technologies. The meta-analysis included nine RCTs, six of which had high or unclear risk of bias in at least one domain. These studies had differing definitions of advanced maternal age, which generally ranged from 35 to 44 years of age. The pooled analysis of all nine trials showed no difference in live birth rate (risk ratio [RR] 1.01, 95% CI 0.75 to 1.35), though an analysis restricted to the three studies that used comprehensive chromosome screening technology, including real-time

qPCR, aCGH, and NGS, found a higher birth rate in those randomized to PGS (RR 1.30, 95% CI 1.03 to 1.65).

In meta-analysis limited to PGT-A with comprehensive chromosomal screening conducted on day 3 or day 5, Simopoulou (2021) identified 11 RCTs.[47] In the overall population PGT-A did not improve live birth rates (RR 1.11; 95% CI, 0.87 to 1.42; 6 trials; n=1513; I^2=75%). However, in a subgroup of patients over 35 years of age, live birth rates improved with PGT-A (RR 1.29; 95% CI, 1.05 to 1.60; 4 trials; n=629). Clinical pregnancy rates were also not significantly improved in the overall population (RR 1.14; 95% CI, 0.95 to 1.37; 9 trials; n=1824); however, miscarriage rates were improved with PGT-A (RR 0.36; 95% CI, 0.17 to 0.73; 7 trials; n=912). The authors concluded that PGT-A with comprehensive chromosomal screening did not generally improve outcomes, but when performed on blastocyst stage embryos in women over 35 years of age live birth rates were improved.

Randomized Controlled Trials

A randomized trial by Yan (2021) evaluated the impact of PGT-A on live birth rate in subfertile women between 20 and 37 years of age.[48] The trial included 1,212 patients who were considered to have a “good prognosis for a live birth,” were planning to undergo their first IVF cycle, and had at least three good-quality blastocysts. The patients were randomized 1:1 to receive PGS or standard IVF, and the primary outcome was live births within one year of randomization from up to three embryo transfers. The proportion of patients with the primary outcome was 77.2% (468) in the PGS group and 81.8% (496) in the control group, which met the prespecified noninferiority margin of a 7% difference.

Munné (2019) published the results of a multi-center RCT called the Single Embryo Transfer of Euploid Embryo (STAR) study.[46] The study reported similar (50.0% versus 45.7%) ongoing pregnancy rates (≥ 20 weeks gestation) for NGS-based PGS versus morphology in good-prognosis patients aged 25 to 40 years. In the subgroup of 267 women aged 35 to 40 years, NGS-based PGS improved ongoing pregnancy rates (50.8% versus 37.2%, p=0.0349).

A multi-center trial by Verpoest (2018) evaluated prenatal screening for aneuploidy for women between 36 and 40 years of age.[45] A total of 396 women undergoing ICSI treatment were randomized to either receive PGS or conventional ICSI without screening. There were no significant differences between groups for clinical pregnancy or live birth rates. However, the PGS group had reduced rates of transfer (RR 0.81, 95% CI 0.74 to 0.89, p<0.001) and miscarriage (RR 0.48, 95% CI 0.26 to 0.90, p=0.02).

Rubio (2017) published a randomized trial comparing outcomes in women of advanced maternal age who underwent PGS for aneuploidy prior to blastocyst transfer compared with blastocyst transfer without PGS.[49] The trial included women between 38 and 41 years of age with normal karyotypes who were on their first or second cycle of ICSI. A total of 138 patients were randomized to the PGS group and 140 to the non-PGS control group. Of these, 100 patients in the PGS group and 105 in the non-PGS group completed the intervention. In an intention-to-treat analysis, there was a significantly higher live birth rate in the PGS group (31.9%) than in the control group (18.6%, odds ratio [OR] 2.4, 95% CI 1.3 to 4.2, p=0.003). In the per-protocol analysis, there was a significantly higher rate of live birth in the PGS group than in the control group, both in the per transfer and per patient analyses. Per transfer, there were live births in 65% of the PGS group and 27% of the control group (OR 4.86, 95% CI 2.49 to 9.53, p<0.001). Per patient, there were live births in 44% of the PGS group and 25% of the control group (OR 2.39, 95% CI 1.32 to 4.32, p=0.005). In addition, the implantation was

significantly higher in the PGS group (53%) than in the control group (43%, p<0.001) and the miscarriage rate was significantly lower in the PGS group (3%) than in the control group (39%, p=0.007).

Yang (2015) performed a two-phase pilot study that randomly compared next-generation sequencing (NGS) and aCGH for preimplantation genetic screening.[50] Phase I retrospectively evaluated the accuracy of NGS for aneuploidy screening in comparison to aCGH from previous IVF-PGS cycles (n=38). Phase II compared clinical pregnancy and implantation outcomes between NGS and aCGH for 172 IVF-PGS patients randomized into two groups: 1) NGS (Group A): patients (n=86) had embryos screened with NGS and 2) aCGH (Group B): patients (n=86) had embryos screened with aCGH. The investigators reported that in phase I, NGS detected all types of aneuploidies of human blastocysts accurately and provided a 100 % 24-chromosome diagnosis consistency with the highly validated aCGH method. In phase II, NGS screening resulted in similarly high ongoing pregnancy rates for PGS patients compared to aCGH screening (74.7% vs. 69.2%, respectively, p=0.56). The observed implantation rates were also comparable between the NGS and aCGH groups (70.5% vs. 66.2%, respectively, p=0.564). The investigators acknowledged that the improved pregnancy rates achieved in this study may not be applied to all IVF-PGS patients, especially those at advanced maternal age or with diminished ovarian reserve.

An RCT by Scott (2013) compared sustained implantation and delivery rates in pregnant females between the ages of 21 and 42 years who had blastocysts tested by real-time polymerase chain reaction-based comprehensive chromosome screening (CCS) versus no screening (routine care group).[51] In the CCS intervention group (n=72 patients) 134 blastocysts were transferred, while in the routine care group (n=83), 163 blastocysts were transferred. Sustained implantation rates (probability that an embryo will implant and progress to delivery) were statistically significantly higher in the CCS group compared with those from the routine care group (89/134, 66.4% vs. 78/163, 47.9%, p=0.002). However, the embryologists were not blinded to the CCS results, potentially inflating the implantation rates in the CCS group. Delivery rates per cycle were also statistically significantly higher in the CCS group (61/72, [84.7%] vs. 56/83 [67.5%], p=0.001).

Forman (2013) performed a randomized trial to compare ongoing pregnant and multiple gestation rates in in pregnant women under the age of 43 who had blastocysts tested by qPCR-based comprehensive chromosome screening (CCS) versus no screening.[52] The intervention group (n=89) had all viable blastocysts biopsied for CCS and single euploid blastocyst transfer, while the control group (n=86) had their two best-quality, untested blastocysts transferred. Implantation rates were 60.7% in the intervention group and 65.1% in the control group. The rate appeared lower in the intervention group, but this was considered “noninferior.” The authors used a 20% noninferiority margin which may not be the most appropriate approach to evaluating the impact of PGS-v2 on health outcomes. The investigators noted that this study only focused on patients with good prognoses, meaning good responders with normal markers of ovarian reserve and large oocyte yields and an abundance of embryos to evaluate. Further prospective studies will be required to validate the best way to apply CCS in women who are low responders or who have other abnormal markers of ovarian reserve.

Schendelaar (2013) reported on outcomes when children were four years old. Data were available on 49 children (31 singletons, nine sets of twins) born after IVF with PGS and 64 children (42 singletons, 11 sets of twins) born after IVF without PGS.[53] The primary outcome

of this analysis was the child's neurological condition, as assessed by the fluency of motor behavior. The fluency score ranged from 0 to 15 and is a sub-scale of the neurological optimality score. In the sample as a whole, and among singletons, the fluency score did not differ among children in the PGS and non-PGS groups. However, among twins, the fluency score was significantly lower among those in the PGS group (mean score 10.6, 95% CI 9.8 to 11.3) than those in the non-PGS group (mean score: 12.3, 95% CI 11.5 to 13.1). Cognitive development as measured by IQ score and behavioral development as measured by the total problem score were similar between non-PGS and PGS groups.

Rubio (2013) published findings of two RCTs evaluating PGS.[54] Studies designs were similar but one included women of advanced maternal age (41 to 44 years old) and the other included couples under 40 years old with repetitive implantation failure (RIF), defined as failing three or more previous attempts at implantation. All couples were infertile and did not have a history of pregnancy or miscarriage with chromosomal abnormality. In all cases, blastocysts were transferred at day five. In the groups receiving PGS, single-cell biopsies were done at the cleavage stage. A total of 91 patients enrolled in the RIF study (48 in the PGS group and 43 in the non-PGS group) and 183 patients in the advanced maternal age study (93 patients in the PGS group and 90 patients in the non-PGS group). Among RIF patients, the live birth rate did not differ significantly between groups. Twenty-three of 48 patients (48%) in the PGS group and 12 of 43 patients (28%) in the non-PGS groups had live births. (The exact p-value was not provided). However, the live birth rate was significantly higher with PGS in the advanced maternal age study. Thirty of 93 patients (32%) in the PGS group and 14 of 90 patients (16%) in the non-PGS group had live births: The difference between groups was statistically significant (p=0.001).

Yang (2012) performed a pilot study to assess embryos selected on the basis of morphology and comprehensive chromosomal screening via aCGH compared to embryos selected by morphology only.[55] Fifty five patients (n=425 blastocysts) were biopsied and analyzed via aCGH, and 48 patients (n=389 blastocysts) were examined by microscopy only. Clinical pregnancy rate and ongoing pregnancy rate were significantly higher in the aCGH group compared to the morphology-only group (70.9% vs. 45.8%, p=0.017) and (69.1% vs. 41.7%, p=0.009), respectively. Aneuploidy was detected in 191/425 (44.9%) of blastocysts in the aCGH group, highlighting the imprecision of the morphology-only group.

Nonrandomized Studies

There have been many nonrandomized studies of PGS, however, the conclusions that can be drawn from these are limited by study design and they are not discussed in detail.[24, 32, 56-61]

Section Summary

Most RCTs and meta-analyses of RCTs of initial techniques used for PGT-A found similar or lower ongoing pregnancy and/or live birth rates after IVF with PGT-A compared with IVF without PGT-A. These initial PGT-A tests were not found to improve the net health outcome. Three RCTs evaluating newer PGT-A methods have been published, as well as systematic reviews of these trials. Recent studies of newer methods have found some benefit in subgroups of patients (e.g., advanced maternal age); however, the evidence is limited because the studies tended to include good prognosis patients and study methods had potential biases. Well-conducted RCTs evaluating PGT-A in the target population (e.g., women of advanced maternal age) are needed before conclusions can be drawn about the impact on the net health outcome.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS

In 2020, the American College of Obstetricians and Gynecologists (ACOG) issued Committee Opinion #799 on Preimplantation Genetic Testing.[62] Recommendations are as follows:

- "Preimplantation genetic testing comprises a group of genetic assays used to evaluate embryos before transfer to the uterus. Preimplantation genetic testing-monogenic (known as PGT-M) is targeted to single gene disorders. Preimplantation genetic testing-monogenic uses only a few cells from the early embryo, usually at the blastocyst stage, and misdiagnosis is possible but rare with modern techniques. Confirmation of preimplantation genetic testing-monogenic results with chorionic villus sampling (CVS) or amniocentesis should be offered."
- "To detect structural chromosomal abnormalities such as translocations, preimplantation genetic testing-structural rearrangements (known as PGT-SR) is used. Confirmation of preimplantation genetic testing-structural rearrangements results with CVS or amniocentesis should be offered."
- "The main purpose of preimplantation genetic testing-aneuploidy (known as PGT-A) is to screen embryos for whole chromosome abnormalities. Traditional diagnostic testing or screening for aneuploidy should be offered to all patients who have had preimplantation genetic testing-aneuploidy, in accordance with recommendations for all pregnant patients."

In 2015 (reaffirmed in 2017), ACOG issued an opinion statement that recommends “[p]atients with established causative mutations for a genetic condition” who are undergoing in vitro fertilization and desire prenatal genetic testing should be offered the testing, either preimplantation or once pregnancy is established.[63]

AMERICAN SOCIETY FOR REPRODUCTIVE MEDICINE

In 2023, the American Society for Reproductive Medicine published a joint practice committee opinion with the Genetic Counseling Professional Group on the clinical management of mosaic results from preimplantation genetic testing for aneuploidy of blastocysts, which states:[64]

> The value of preimplantation genetic testing for aneuploidy (PGT-A) as a universal screening test for all patients undergoing in vitro fertilization (IVF) has not been established. Indeed, two randomized controlled trials have shown no benefit of PGT-A in improving live birth rates, particularly in women <38 years of age. Nonetheless, the use of PGT-A has continued to increase in the US. In particular, the significance of suspected chromosomal mosaicism in embryos has been a widely discussed and controversial topic since the first known live births from these embryos were documented in 2015. Although previous interpretations of mosaic results and patient counseling relied heavily on prenatal and pediatric literature about mosaicism, a growing body of evidence suggests that these data may not apply to preimplantation embryos.

The committee opinion also states:

> True embryonic mosaicism has long been recognized as a potential limiting factor in the interpretation of PGT-A and as a contributing factor in misdiagnosis related to biopsy

sample size. Suspected mosaicism has typically gone undetected or unreported with prior methods of PGT-A, such as fluorescent in situ hybridization, which tested single cells, and array comparative genomic hybridization, as well as the single nucleotide polymorphism microarray (currently in use). With more recent and sensitive assays, such as NGS, it has become increasingly common to identify and report results consistent with an intermediate copy number. Further, the opinion states, "The frequency and clinical relevance of mosaicism have been the subject of much debate."

Also in 2023, the American Society of Reproductive Medicine published a committee opinion; The Indications and Management of Preimplantation Genetic Testing for Monogenic Conditions:[65]

- Preimplantation genetic testing for monogenic conditions should be offered if a significant reproductive risk is identified. Acceptance of PGT-M by patients should be optional.
- Preimplantation genetic testing should not be offered for autosomal recessive carrier status without manifestations of symptoms, combination of variants not associated with disease, pseudodeficiency alleles, or somatic-only variants.
- Patients should have genetic counseling about the condition and all reproductive options before PGT-M is performed.
- Patients may also benefit from genetic counseling about PGT-M results, particularly when making embryo transfer decisions.
- Given technical limitations that may result in embryo misdiagnosis, prenatal testing should be offered for pregnancies conceived using PGT-M to confirm the embryo testing results and screen for other fetal anomalies unrelated to the indication for PGT-M.
- Although PGT laboratory genetic counselors support providers and patients in the PGT-M process, IVF clinics should consider employing genetic counselors to result in smoother case management, more efficient workflows, and improved patient experiences.

A 2018 practice committee opinion on preimplantation screening for aneuploidy issued by the American Society for Reproductive Medicine concluded the following:[66]

> The value of PGT-A as a universal screening test for all IVF patients has yet to be determined. While research suggests improved outcomes from PGT-A screening, the available evidence has important limitations. Participants in RCTs likely do not accurately represent the patient population that would be affected by broadly applied PGT-A screening. Large, prospective, well-controlled trials are needed to determine the effectiveness and safety of universal PGT-A screening.

SUMMARY

There is enough research to show that preimplantation genetic testing for monogenic disorders (PGT-M) and structural chromosomal rearrangements (PGT-SR) leads to improved health outcomes (e.g., birth of unaffected fetuses) when used for evaluation of an

embryo that is known to be at elevated risk of a genetic disorder or structural chromosomal abnormality. Therefore, PGT-M and PGT-SR may be considered medically necessary when the evaluation is focused on an elevated risk for a known disease or disorder and the policy criteria are met.

There is not enough research to show that preimplantation genetic testing for monogenic disorders (PGT-M) or structural rearrangements (PGT-SR) leads to improved health outcomes for the evaluation of an embryo without an elevated risk or in all other situations not outlined in the medically necessary policy criteria. More research is needed to know if or how well PGT-M and PGT-SR will impact outcomes in these situations. Therefore, PGT-M and PGT-SR are considered investigational when the policy criteria are not met.

There is not enough research to show that preimplantation genetic testing for aneuploidy (PGT-A) improves health outcomes, including pregnancy and live birth rates. Recent studies of newer methods have found some benefit in subgroups of patients (e.g., advanced maternal age); however, the evidence is limited, and larger trials are needed to understand how to use the information on ploidy PGT-A provides to improve patient outcomes. Therefore, preimplantation genetic testing for aneuploidy as a part of the in vitro fertilization process is considered investigational in all situations.

CODES

Codes	Number	Description
		Reproductive medicine (preimplantation genetic assessment), analysis of 24 chromosomes using embryonic DNA genomic sequence analysis for aneuploidy, and a mitochondrial DNA score in euploid embryos, results reported as normal (euploidy), monosomy, trisomy, or partial deletion/duplications, mosaicism, and segmental aneuploidy, per embryo
	~~0396U~~	~~Obstetrics (pre-implantation genetic testing), evaluation of 300000 DNA single-nucleotide polymorphisms (SNPs) by microarray, embryonic tissue, algorithm reported as a probability for single-gene germline conditions~~ (Deleted 10/01/2024)
	81228	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number variants, comparative genomic hybridization [CGH] microarray analysis
	81229	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number and single nucleotide polymorphism (SNP) variants, comparative genomic hybridization (CGH) microarray analysis

Codes	Number	Description
	81479	Unlisted molecular pathology procedure
	88271 – 88275	Molecular cytogenetics (i.e., FISH), code range
	89290	Biopsy, oocyte polar body or embryo blastomere, microtechnique (for preimplantation genetic diagnosis), less than or equal to 5 embryo(s)
	89291	;greater than 5 embryo(s)
HCPCS	None	

Date of Origin: *August 2010*

Regence

Medical Policy Manual Genetic Testing, Policy No. 19

IDH1 and IDH2 Genetic Testing for Conditions Other Than Myeloid Neoplasms or Leukemia

Effective: April 1, 2024

Next Review: January 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Isocitrate dehydrogenase genes, *IDH1* and *IDH2*, are involved in cellular metabolism and epigenetic regulation. These genes are defining features in classifying primary brain tumors and are proposed as diagnostic and prognostic indicators for a number of other cancers.

MEDICAL POLICY CRITERIA

Notes:

- This policy does *not* address *IDH1* and *IDH2* testing for myeloid neoplasms or leukemia which is addressed in a separate policy.
- Please refer to the Cross References section below for genetic testing not addressed in this policy.

I. Genetic testing for *IDH1* and *IDH2* variants may be considered **medically necessary** for patients with gliomas of any grade (Note: gliomas include, but are not limited to astrocytoma, ependymoma, and oligodendroglioma).

II. Genetic testing for *IDH1* variants may be considered **medically necessary** for patients with cholangiocarcinoma who are considering treatment with ivosidenib (Tibsovo®).

III. Genetic testing for *IDH1* and *IDH2* variants is considered **investigational** for all other circumstances, including but not limited to chondrosarcoma and colorectal cancer.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

GLIOMAS

Gliomas are the most common types of brain tumors, and are named for their origin (i.e., the tumor begins in cells called glial cells, which surround nerve cells). The three major types of glioma include:

- Astrocytoma,
- Ependymomas, and
- Oligodendrogliomas.

Initial workup will include radiologic evaluation, wherein a tumor may be initially stratified as a high- or low-grade glioma. Further workup, including genetic molecular studies will further classify the tumor.

GENETIC TESTING

Strategies for testing may include testing for individual genes or in combination, such as in a panel.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or mutation(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
   - History and physical exam including any relevant diagnoses related to the genetic testing
   - Conventional testing and outcomes
   - Conservative treatments, if any
   - Sample collection date

BACKGROUND

ISOCITRATE DEHYDROGENASE

Isocitrate dehydrogenase (IDH) genes encode IDH proteins which are homodimeric enzymes involved in numerous cellular processes, including adaptation to hypoxia, histone demethylation and DNA modification. In humans, IDH exists in three isoforms. IDH3 is a catalyst in the citric acid cycle, converting NAD^+ to NADH in mitochondria. IDH1 and IDH2 catalyze the same reaction outside the citric acid cycle and are associated with the formation of (D)-2-hydroxyglutarate. High concentrations of (D)-2-hydroxyglutarate inhibits the function of other enzymes, causing differentiated gene expression which ultimately may lead to activated oncogenes and inactivated tumor-suppressor genes. This cascade effect may ultimately develop into cancer.

TUMORS OF THE CENTRAL NERVOUS SYSTEM

The 2016 World Health Organization Classification of Tumors of the Central Nervous System presented a major restructuring of CNS tumor categorization.[1] Specifically, diffuse gliomas, medulloblastomas and other embryonal tumors were better defined by a combination of histologic and molecular features. As of this update, diagnostic criteria heavily rely on IDH gene status. The combined genotypic and phenotypic approach improves the diagnostic process compared to previous versions by inclusion of the objective utilization of genotyping. Potential for discordance is increased with this approach, e.g., tumors that histologically appear astrocytic are proven to have an IDH mutation, however, according to the criteria, genotype trumps phenotype in these situations. Tumors of the CNS are hence designated by their histological name followed by a comma, and the genetic features as adjectives, as in: *Diffuse astrocytoma, IDH-wildtype*.

REGULATORY STATUS

More than a dozen commercial laboratories currently offer a wide variety of diagnostic procedures for genetic testing related to *IDH1* and *IDH2*. These tests are available as laboratory developed procedures under the U.S. Food and Drug Administration (FDA) enforcement discretion policy for laboratory developed tests (LDTs). Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; LDTs must meet the general regulatory standards of Clinical Laboratory Improvement Act (CLIA) and laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, FDA does not require regulatory review of LDTs.

For *IDH1* and *IDH2* testing related to treatment with Tibsovo® (ivosidenib) and Idhifa® (enasidenib) for hematologic disorders, please refer to Genetic Testing for Myeloid Neoplasms and Leukemia in the Cross References section, above.

EVIDENCE SUMMARY

GENETICS NOMENCLATURE UPDATE

Human Genome Variation Society (HGVS) nomenclature is used to describe variants found in DNA and serves as an international standard.[2] It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used

terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

SCOPE OF THIS REVIEW

The clinical utility of testing for variants in the *IDH1* and *IDH2* genes to inform the combined process of phenotypic and genotypic classification for the diagnosis of glioma brain tumors has been unequivocally demonstrated. These molecular markers also inform prognosis and treatment selection for the management of gliomas. Therefore, the scientific evidence for the clinical utility of *IDH1* and *IDH2* related to gliomas will not be included, as testing may be considered medically necessary.

Validation of the clinical use of any genetic test focuses on three main principles: 1) The analytic validity of the test, which refers to the technical accuracy of the test in detecting a mutation that is present or in excluding a mutation that is absent; 2) The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and 3) The clinical utility of the test, i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

The focus of this review is on evidence related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and
- Improve health outcomes as a result of those decisions.

SYSTEMATIC REVIEWS

No systematic reviews regarding IDH genes within the scope of this review were identified.

RANDOMIZED CONTROLLED TRIALS

No randomized controlled trials regarding IDH genes within the scope of this review were identified.

NONRANDOMIZED STUDIES

Associations between *IDH1* and *IDH2* variants are being investigated for potential diagnostic and prognostic significance in several other cancers, including but not limited to: chondrosarcoma[3-8], and colorectal cancer[9]. Although *IDH1* and *IDH2* variants may be present in approximately half of chondrosarcoma cases, the evidence for clinical utility regarding these markers for the many conditions is uncertain. Reported associations are typically in small case series or cohorts, demonstrating potential targets for additional investigation in larger, well-designed studies.

PRACTICE GUIDELINE SUMMARY

National Comprehensive Cancer Network

National Comprehensive Cancer Network (NCCN) guidelines for central nervous system cancers (v.1.2023) are consistent with World Health Organization diagnostic criteria, and

recommend ivosidenib for certain gliomas with an *IDH1* variant.[10]

NCCN guidelines for bone cancers (v.1.2024) list ivosidenib as a treatment option for *IDH1*-mutated chondrosarcoma,[11] however this medication is only FDA approved for acute myeloid leukemia and cholangiocarcinoma. Other guidelines based on research regarding *IDH1* and *IDH2* genetic testing were not identified.

SUMMARY

There is enough research to show that genetic testing for *IDH1* and *IDH2* contributes to diagnoses and risk stratification in people with gliomas, which contributes to improved overall health outcomes. Therefore, genetic testing for *IDH1* and *IDH2* variants may be considered medically necessary for gliomas of any grade (including but not limited to astrocytoma and glioblastoma).

There is enough research to show that genetic testing for *IDH1* can be used to identify patients with cholangiocarcinoma that may be eligible for treatment with ivosidenib, has been FDA-approved for the treatment of this disease. Therefore, genetic testing for *IDH1* variants may be considered medically necessary for patients with cholangiocarcinoma considering this treatment.

There is not enough research to show that genetic testing for *IDH1* and *IDH2* variants improves overall health outcomes in any other condition. Therefore, genetic testing for *IDH1* and *IDH2* variants is considered investigational for all other circumstances, including but not limited evaluation for chondrosarcoma and colorectal cancers.

Medical Policy Manual Genetic Testing, Policy No. 20

Genetic and Molecular Diagnostic Testing

Effective: May 1, 2024

Next Review: February 2025
Last Review: March 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genetic testing, which detects changes in DNA, RNA, and chromosomes, may be performed to diagnose or determine susceptibility to inherited conditions, screen for potential genetic risk factors for common conditions, and aid in the selection of medications or other treatments.

MEDICAL POLICY CRITERIA

Note: This policy only applies when there is not a more specific medical policy available (see the Genetic Testing Section of the Medical Policy Manual). This policy is not intended to address asymptomatic carrier screening, which is addressed in the Carrier Screening for Genetic Diseases policy (Genetic Testing, Policy No. 81).

The following general criteria are applied to genetic and molecular diagnostic testing.

I. Genetic testing to establish a diagnosis or susceptibility for an inherited disease may be considered **medically necessary** when *all* of the following criteria are met:

   A. The genetic test is not a panel test listed in Genetic Testing Policy No. 64, *Evaluating the Utility of Genetic Panels*, as these tests are always investigational. Genetic panel tests that are not listed in GT64 or addressed by another specific policy will be reviewed by the criteria below.

B. There must be a reasonable expectation based on family history (pedigree analysis), risk factors, and symptomatology that a genetically inherited condition exists.

C. Diagnostic results from physical examination, pedigree analysis, and conventional testing are inconclusive and a definitive diagnosis is uncertain.

D. The clinical utility of all requested genes and gene variants must be established (including all genes and gene variants in a panel test, as applicable). The clinical records must document:

1. How test results will guide decisions regarding: disease treatment, prevention, or management, such as averting treatment for other possible diagnoses, and
2. These treatment decisions would not otherwise be made in the absence of the genetic test results.

II. Genetic testing to establish a diagnosis or susceptibility for an inherited disease is considered **not medically necessary** if Criterion I. above is not met.

III. Genetic testing of children to predict adult-onset diseases is considered **not medically necessary** unless test results will guide current decisions concerning prevention and this benefit would be lost by waiting until the child has reached adulthood.

IV. Genetic testing for indications *other than* determining risk or establishing a diagnosis for a genetically inherited disease (e.g., genotyping for drug selection and dosing) may be considered **medically necessary** when *all* of the following criteria are met:

A. The genetic test is not a panel test listed in Genetic Testing Policy No. 64, *Evaluating the Utility of Genetic Panels*, as these tests are always investigational. Genetic panel tests that are not listed in GT64 or addressed by another specific policy will be reviewed by the criteria below.

B. Diagnostic results from physical examination and conventional testing are inconclusive; and

C. The clinical records document how results of genetic testing are necessary to guide treatment decisions; and

D. There is reliable evidence in the peer-reviewed scientific literature that health outcomes are improved as a result of treatment decisions based on molecular genetic test results.

V. Genetic testing for indications other than determining risk or establishing a diagnosis for a genetically inherited disease is considered **not medically necessary** if any of criteria IV. A.-D. above are not met.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), <u>all of the following information must be submitted for review</u>:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)

3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence of testing
6. Medical records related to this genetic test
    - History and physical exam
    - Date of sample collection (e.g., blood draw)
    - Conventional testing and outcomes
    - Conservative treatment provided, if any

CROSS REFERENCES

2. Investigational Gene Expression, Biomarker, and Multianalyte Testing, Laboratory, Policy No. 77

BACKGROUND

GENETIC TESTING

Genetic testing may be performed for several different purposes, including:

- Diagnosing or predicting susceptibility for inherited conditions[1]
- Screening for common disorders
- Selecting appropriate treatments (also known as pharmacogenetic testing)

GENETIC PANEL TESTING

New genetic technology, such as next generation sequencing and chromosomal microarray, has led to the ability to examine many genes simultaneously.[2] This in turn has resulted in a proliferation of genetic panels. Panels using next generation technology are intuitively attractive to use in clinical care because they can screen for numerous variants within a single gene or multiple genes quickly and may lead to greater efficiency in the work-up of genetic disorders. One potential challenge of genetic panel testing is the identification of genetic variants of unknown significance and variants for which the clinical management is uncertain and may lead to unnecessary follow-up testing and procedures.

GENETIC COUNSELING

Due to the complexity of interpreting genetic test results, patients should receive pre- and post-test genetic counseling from a qualified professional when testing is performed to diagnose or predict susceptibility for inherited diseases. The benefits and risks of genetic testing should be fully disclosed to individuals prior to testing, and counseling concerning the test results should be provided.

REGULATORY STATUS

The majority of genetic tests and genetic panel tests are laboratory derived tests that are not subject to U.S. Food and Drug Administration (FDA) approval.[3] The degree of oversight by the FDA depends on the intended use of the test and risk of inaccurate results. Clinical laboratories may develop and validate tests in-house (“lab-developed tests”) and market them as a laboratory service; such tests must meet the general regulatory standards of the Clinical

Laboratory Improvement Act (CLIA). The laboratory offering the service must be licensed by CLIA for high-complexity testing.

Note: Separate Medical Policies may apply to some specific genetic tests and panels. See the Genetic Testing Section of the Medical Policy Manual Table of Contents for additional genetic testing policies.

CODES

NOTE: If the specific analyte (gene or gene variant) is listed with a CPT code, the specific CPT code should be reported. If the specific analyte is not listed with a specific CPT code, unlisted code 81479 should be reported.

Codes	Number	Description
	0232U	CSTB (cystatin B) (eg, progressive myoclonic epilepsy type 1A, Unverricht-Lundborg disease), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, short tandem repeat (STR) expansions, mobile element insertions, and variants in non-uniquely mappable regions
	0234U	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions
	0235U	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions
	0236U	SMN1 (survival of motor neuron 1, telomeric) and SMN2 (survival of motor neuron 2, centromeric) (eg, spinal muscular atrophy) full gene analysis, including small sequence changes in exonic and intronic regions, duplications and deletions, and mobile element insertions
	0238U	Oncology (Lynch syndrome), genomic DNA sequence analysis of MLH1, MSH2, MSH6, PMS2, and EPCAM, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions
	0244U	Oncology (solid organ), DNA, comprehensive genomic profiling, 257 genes, interrogation for single-nucleotide variants, insertions/deletions, copy number alterations, gene rearrangements, tumor-mutational burden and microsatellite instability, utilizing formalin-fixed paraffin embedded tumor tissue

Codes	Number	Description
	81105 – 81112	HPA genotyping code range
	81170	ABL1 (ABL proto-oncogene 1, non-receptor tyrosine kinase) (eg, acquired imatinib tyrosine kinase inhibitor resistance), gene analysis, variants in the kinase domain
	81200 – 81257	Molecular pathology code range
	81260 – 81268	Molecular pathology code range
	81270 – 81276	Molecular pathology code range
	81287	MGMT (O-6-methylguanine-DNA methyltransferase) (eg, glioblastoma multiforme) promoter methylation analysis
	81290 – 81300	Molecular pathology code range
	81302 – 81304	Molecular pathology code range
	81310 – 81332	Molecular pathology code range
	81336 – 81355	Molecular pathology code range
	81370 - 81408	Molecular pathology code range
	81413	Cardiac ion channelopathies (eg, Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia); genomic sequence analysis panel, must include sequencing of at least 10 genes, including ANK2, CASQ2, CAV3, KCNE1, KCNE2, KCNH2, KCNJ2, KCNQ1, RYR2, and SCN5A
	81419	Epilepsy genomic sequence analysis panel, must include analyses for ALDH7A1, CACNA1A, CDKL5, CHD2, GABRG2, GRIN2A, KCNQ2, MECP2, PCDH19, POLG, PRRT2, SCN1A, SCN1B, SCN2A, SCN8A, SLC2A1, SLC9A6, STXBP1, SYNGAP1, TCF4, TPP1, TSC1, TSC2, and ZEB2
	81441	Inherited bone marrow failure syndromes (IBMFS) (eg, Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan anemia, Shwachman-Diamond syndrome, GATA2 deficiency syndrome, congenital amegakaryocytic thrombocytopenia) sequence analysis panel, must include sequencing of at least 30 genes, including BRCA2, BRIP1, DKC1, FANCA, FANCB, FANCC, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCL, GATA1, GATA2, MPL, NHP2, NOP10, PALB2, RAD51C, RPL11, RPL35A, RPL5, RPS10, RPS19, RPS24, RPS26, RPS7, SBDS, TERT, and TINF2
	81470	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromicXLID); genomic sequence analysis panel, must include sequencing of at least60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1,IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3,and SLC16A2
	81471	;duplication/deletion gene analysis, must include analysis of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3, and SLC16A2
	81479	Unlisted molecular pathology procedure
HCPCS	G0452	Molecular pathology procedure; physician interpretation and report
	S3800	Genetic testing for amyotrophic lateral sclerosis (ALS)

Codes	Number	Description
	S3840	DNA analysis for germline mutations of the RET proto-oncogene for susceptibility to multiple endocrine neoplasia type 2
	S3841	Genetic testing for retinoblastoma
	S3842	Genetic testing for Von Hippel-Lindau disease
	S3844	DNA analysis of the connexin 26 gene (GJB2) for susceptibility to congenital, profound deafness
	S3845	Genetic testing for alpha thalassemia
	S3846	Genetic testing for hemoglobin E beta-thalassemia
	S3849	Genetic testing for Niemann-Pick disease
	S3850	Genetic testing for sickle cell anemia
	S3853	Genetic testing for muscular dystrophy
	S3861	Genetic testing, sodium channel, voltage-gated, type V, alpha subunit (SCN5A) and variants for suspected Brugada syndrome
	S3865	Comprehensive gene sequence analysis for hypertrophic cardiomyopathy
	S3866	Genetic analysis for a specific gene mutation for hypertrophic cardiomyopathy (HCM) in an individual with a known HCM mutation in the family

Medical Policy Manual Genetic Testing, Policy No. 21

Genetic Testing for Biallelic RPE65 Variant-Associated Retinal Dystrophy

Effective: June 1, 2024

Next Review: February 2025
Last Review: April 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

RPE65 genetic testing can be used to predict treatment response to targeted therapy in patients with biallelic RPE65 variant-associated retinal dystrophy.

MEDICAL POLICY CRITERIA

I. Genetic testing for the *RPE65* variant may be considered **medically necessary** to confirm a diagnosis of biallelic *RPE65* variant-associated retinal dystrophy when Luxturna (voretigene neparvovec-rzyl) is being considered as a treatment option.

II. Genetic testing for the *RPE65* variant is considered **investigational** for all other indications.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Strategies for testing may include testing for individual genes or in combination, such as in a panel.

Diagnosis of Biallelic *RPE65*-Mediated Inherited Retinal Dystrophies

Genetic testing is required to detect the presence of pathogenic(s) variants in the *RPE65* gene. By definition, pathogenic variant(s) must be present in both copies of the *RPE65* gene to establish a diagnosis of biallelic *RPE65*-mediated inherited retinal dystrophy.

A single *RPE65* pathogenic variant found in the homozygous state (e.g., the presence of the same pathogenic variant in both copies alleles of the *RPE65* gene) establishes a diagnosis of biallelic *RPE65*-mediated dystrophinopathy.

However, if two different *RPE65* pathogenic variants are detected (e.g., compound heterozygous state), confirmatory testing such as linkage analysis by family studies may be required to determine the *trans* vs *cis* configuration (e.g., whether the two different pathogenic variants are found in different copies or in the same copy of the *RPE65* gene). The presence of two different *RPE65* pathogenic variants in separate copies of the *RPE65* gene (*trans* configuration) establishes a diagnosis of biallelic *RPE65*-mediated dystrophinopathy. The presence of two different *RPE65* pathogenic variants in only one copy of the *RPE65* gene (*cis* configuration) is not considered a biallelic *RPE65*-mediated dystrophinopathy.

Next-generation sequencing and Sanger sequencing typically cannot resolve the phase (e.g., *trans* vs *cis* configuration) when two *RPE65* pathogenic variants are detected. In this scenario, additional documentation of the *trans* configuration is required to establish a diagnosis of biallelic *RPE65*-mediated inherited retinal dystrophy.

REGULATORY STATUS

On December 19, 2017, the AAV2 gene therapy vector voretigene neparvovec-rzyl (Luxturna™; Spark Therapeutics) was approved by the U.S. Food and Drug Administration (FDA) for use in patients with vision loss due to confirmed biallelic *RPE65* variant-associated retinal dystrophy. Spark Therapeutics received breakthrough therapy designation, rare pediatric disease designation, and orphan drug designation.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF DOCUMENTATION:

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or mutation(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
    - o History and physical exam including any relevant diagnoses related to the genetic testing
    - o Conventional testing and outcomes
    - o Conservative treatments, if any

CROSS REFERENCES

None

BACKGROUND

INHERITED RETINAL DYSTROPHIES

Inherited retinal dystrophies (IRDs) are a diverse group of disorders with overlapping phenotypes characterized by progressive degeneration and dysfunction of the retina[1]. The most common subgroup is retinitis pigmentosa, which is characterized by a loss of retinal photoreceptors, both cones and rods. The hallmark of the condition is night blindness (nyctalopia) and loss of peripheral vision. These losses lead to difficulties in performing visually dependent activities of daily living such as orientation and navigation in dimly lit areas. Visual acuity may be maintained longer than peripheral vision, though eventually most individuals progress to vision loss.

RPE65 Gene

Retinitis pigmentosa (RP) and Leber congenital amaurosis (LCA) both have subtypes related to pathogenic variants in *RPE65*. *RPE65* (retinal pigment epithelium–specific protein 65-kD) gene encodes the RPE54 protein is an all-*trans* retinal isomerase, a key enzyme expressed in the retinal pigment epithelium (RPE) that is responsible for regeneration of 11-*cis*-retinol in the visual cycle[2]. The *RPE65* gene is located on the short (p) arm of chromosome 1 at position 31.3 (1p31.3). Individuals with biallelic variations in *RPE65* lack the RPE65 enzyme; this lack leads to build-up of toxic precursors and damage to RPE cells, loss of photoreceptors, and eventually complete blindness[3].

Epidemiology

RPE65-associated IRD is rare. The prevalence of LCA has been estimated to be between 1 in 33,000 and 1 in 81,000 individuals in the United States[4, 5]. LCA subtype 2 (*RPE65*-associated LCA) accounts for between 5% and 16% of cases of LCA4[6-8]. The prevalence of RP in the United States is approximately 1 in 3500 to 1 in 4000 with approximately 1% of patients with RP having *RPE65* variants[9, 10]. Assuming a U.S. population of approximately 326.4 million at the end of 2017, the prevalence of *RPE65*-associated retinal dystrophies in the United States would therefore be roughly 1000 to 3000 individuals[11].

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[12] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

LITERATURE REVIEWS AND SUMMARY OF THE EVIDENCE TO SUPPORT OUR POSITION

Systematic Reviews

There are no systematic reviews for this indication.

Randomized Controlled Trials

One gene therapy (voretigene neparvovec) for patients with biallelic *RPE65* variant-associated retinal dystrophy has RCT evidence. The pivotal RCT (NCT00999609) for voretigene neparvovec was an open-label trial of patients ages three or older with biallelic *RPE65* variants, VA worse than 20/60, and/or a VF less than 20o in any meridian, with sufficient viable retinal cells[13, 14]. Those patients meeting these criteria were randomized 2:1 to intervention (n=21) or control (n=10). The trial was conducted at a children's hospital and university medical center. Patients were enrolled between 2012 and 2013. The intervention treatment group received sequential injections of 1.5E11 vg AAV2-hRPE65v2 (voretigene neparvovec) to each eye no more than 18 days apart (target, 12 days; standard deviation [SD], 6 days). The injections were delivered in a total subretinal volume of 0.3 mL under general anesthesia. The control treatment group received voretigene neparvovec one year after the baseline evaluation. Patients received prednisone 1 mg/kg/d (max, 40 mg/d) for seven days starting three days before injection in the first eye and tapered until three days before injection of the second eye at which point the steroid regimen was repeated. During the first year, follow-up visits occurred at 30, 90, 180 days, and one year. Extended follow-up is planned for 15 years. The efficacy outcomes were compared at 1 year. The primary outcome was the difference in mean bilateral MLMT score change. MLMT graders were masked to treatment group. The trial was powered to have greater than 90% power to detect a difference of one light level in the MLMT score at a two-sided type I error rate of 5%. Secondary outcomes were hierarchically ranked: (1) difference in change in full-field light sensitivity threshold (FST) testing averaged over both eyes for white light; (2) difference in change in monocular (first eye) MLMT score change; (3) difference in change in VA averaged over both eyes. Patient-reported vision-related activities of daily living (ADLs) using a Visual Function Questionnaire (VFQ) and VF testing (Humphrey and Goldmann) were also reported. The VFQ has not been validated.

At baseline, the mean age was about 15 years old (range, 4-44 years) and approximately 42% of the participants were male. The MLMT passing level differed between the groups at baseline; about 60% passed at less than 125 lux in the intervention group vs 40% in the control group. The mean baseline VA was not reported but appears to have been between approximately 20/200 and 20/250 based on a figure in the manufacturer briefing document. One patient in each treatment group withdrew before the year one visit; neither received voretigene neparvovec. The remaining 20 patients in the intervention treatment and nine patients in the control treatment groups completed the year one study visit. The intention-to-treat (ITT) population included all randomized patients. The efficacy outcome results at year one for the ITT population are shown in Table 3. In summary, the differences in change in MLMT and FST scores were statistically significant. No patients in the intervention group had worsening MLMT scores at one year compared with three patients in the control group. Almost two-thirds of the intervention arm showed maximal improvement in MLMT scores (passing at one lux) while no participants in the control arm were able to do so. Significant improvements were also observed in Goldmann III4e and Humphrey static perimetry macular threshold VF exams. The difference in change in VA was not statistically significant although the changes correspond to an improvement of about eight letters in the intervention group and a loss of one letter in the control group. The original VA analysis used the Holladay method to assign values to off-chart results. Using, instead the Lange method for off-chart results, the treatment effect estimate was similar but variability estimates were reduced (difference in change, 7.4 letters; 95% confidence interval [CI], 0.1 to 14.6 letters). No control patients experienced a gain of 15

or more letters (≤0.3 logMAR) at year one while 6 of 20 patients in the intervention group gained 15 or more letters in the first eye and four patients also experienced this improvement in the second eye. Contrast sensitivity data were collected but were not reported.

The manufacturer briefing document reports results out to two years of follow-up21. In the intervention group, both functional vision and visual function improvements were observed for at least two years. At year one, all 9 control patients received bilateral injections of voretigene neparvovec. After receiving treatment, the control group experienced improvement in MLMT (change score, 2.1, SD=1.6) and FST (change, -2.86, SD=1.49). VA in the control group improved an average of 4.5 letters between years 1 and 2. Overall, 72% (21/29) of all treated patients achieved the maximum possible MLMT improvement at one year following injection.

Two patients (one in each group) experienced serious adverse events, both were unrelated to study participation. The most common ocular adverse events in the 20 patients treated with voretigene neparvovec were mild to moderate: elevated intraocular pressure, four (20%) patients; cataract, three (15%) patients; retinal tear, two (10%) patients; and eye inflammation, two (10%) patients. Several ocular adverse events occurred only in one patient each: conjunctival cyst, conjunctivitis, eye irritation, eye pain, eye pruritus, eye swelling, foreign body sensation, iritis, macular hold, maculopathy, pseudopapilledema, and retinal hemorrhage. One patient experienced a loss of VA (2.05 logMAR) in the first eye injected with voretigene neparvovec; the eye was profoundly impaired at 1.95 logMAR (approximately 20/1783 on a Snellen chart) at baseline.

Maguire (2019) recently published the results of the open-label follow-on phase 1 study at year four and the phase 3 study at year two.[15] Mean (SD) MLMT lux score change was 2.4 (1.3) at four years compared with 2.6 (1.6) at one year after administration in phase 1 follow-on subjects (n=8). Mean (SD) MLMT lux score change was 1.9 (1.0) at two years and 1.9 (1.0) at one year post-administration in the original intervention group (n=20). The mean (SD) MLMT lux score change was 2.1 (1.6) at one year post-administration in control subjects (n=9). Therefore, durability for up to four years has been reported, with observation ongoing.

Evidence Summary

In the pivotal RCT, patients in the voretigene neparvovec group demonstrated greater improvements on the MLMT, which measures the ability to navigate in dim lighting conditions, compared with patients in the control group. The difference in mean improvement was both statistically significant and larger than the a priori defined clinically meaningful difference. Most other measures of visual function were also significantly improved in the voretigene neparvovec group compared with the control group, with the exception of VA. Improvements seemed durable over a period of two years. The adverse events were mostly mild to moderate; however, one patient lost 2.05 logMAR in the first eye treated with voretigene neparvovec by the one year visit. There are limitations in the evidence. There is limited follow-up available, therefore, long-term efficacy and safety are unknown. The primary outcome measure has not been used previously in RCTs and has limited data to support its use. Only the MLMT assessors were blinded to treatment assignment, which could have introduced bias assessment of other outcomes. The modified VFQ is not validated, so effects on quality of life remain uncertain.

PRACTICE GUIDELINE SUMMARY

There are no evidence-based clinical practice guidelines that recommend RPE65 variant

testing to confirm a diagnosis of biallelic RPE65 variant-associated retinal dystrophy.

SUMMARY

There is enough research to show that testing for RPE65 variants can help to identify patients with biallelic RPE65 variant-associated retinal dystrophy who are likely to benefit from certain gene therapies. Therefore, RPE65 genetic variant testing may be considered medically necessary for patients that meet the policy criteria.

There is not enough research to show that this testing improves health outcomes for patients who do not meet policy criteria, and therefore, RPE65 variant testing is considered investigational for all other indications.

Medical Policy Manual Genetic Testing, Policy No. 29

Gene Expression Profiling for Melanoma

Effective: August 1, 2024

Next Review: April 2025
Last Review: June 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Gene expression assays have been created to aid risk stratification in patients with melanoma or pigmented lesions suspected of being melanoma.

MEDICAL POLICY CRITERIA

I. The DecisionDx-UM™ gene expression assay may be considered **medically necessary** in patients with primary, localized uveal melanoma.

II. The DecisionDx-UM™ gene expression assay is considered **investigational** for patients that do not meet criterion I.

III. All other gene expression assays for melanoma are considered **investigational**, including but not limited to DecisionDX-Melanoma™, Pigmented Lesion Assay, PLAplus™, AMBLor®, and myPath Melanoma™.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision

outcome.

- Name of the genetic test(s) or panel test
- Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
- The exact gene(s) and/or mutations being tested
- Relevant billing codes
- Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
- Medical records related to this genetic test
    - History and physical exam
    - Date of blood draw for test
    - Conventional testing and outcomes
    - Conservative treatment provided, if any

BACKGROUND

CUTANEOUS MELANOMA

Cutaneous melanoma represents less than 5% of skin malignancies but results in the most skin cancer deaths. The incidence of cutaneous melanoma continues to increase, and it is currently the sixth most common cancer in the United States. Standard treatment for stage 1 and 2 melanoma is excision with or without sentinel lymph node examination. Current risk factors to predict localized tumor aggression include Breslow tumor thickness, tumor ulceration, and mitotic rate of the tumor cells. Regional lymph node involvement, the likelihood of which increases with increasing tumor thickness, significantly negatively impacts the rate of survival.

UVEAL MELANOMA

Uveal melanoma, also referred to as ocular or choroidal melanoma, is the most common, but rare, primary ocular malignancy in adults and shows a strong tendency for metastases to the liver. Approximately four million cases of uveal melanoma occur each year.[1] Even with successful treatment of the primary tumor, up to 50% of individuals subsequently develop systemic metastases, with liver involvement in up to 90% of these individuals. Despite aggressive systemic treatments, metastatic liver disease remains the most common cause of tumor-related mortality in choroidal malignant melanoma, with a median survival time of two to seven months and a one-year survival rate of less than 10%. The primary clinical issue in the management of uveal melanoma is accurately predicting risk of metastasis.

Identifying patients at high risk for metastatic disease might assist in selecting patients for adjuvant treatment and more intensive surveillance for metastatic disease, if such changes lead to improved outcomes. The optimal method and interval for surveillance are not well-

defined, and it has not been established in prospective trials whether surveillance identifies metastatic disease earlier. Potential methods for metastases include magnetic resonance imaging, ultrasound, liver function testing, and positron emission tomography scans.

COMMERCIALLY AVAILABLE TESTING

The DermTech Pigmented Lesion Assay (PLA) test measures expression of six genes (*PRAME*, *LINC00518*, *CMIP*, *B2M*, *ACTB*, *PPIA*). The test is performed on skin samples of lesions at least 5 mm in diameter obtained via noninvasive, proprietary adhesive patch biopsies of a stratum corneum specimen. The test does not work on the palms of hands, soles of feet, nails, or mucous membranes and should not be used on bleeding or ulcerated lesions. The PLA test report includes two results. The first is the PLA MAGE (Melanoma Associated Gene Expression), which indicates low risk (neither *PRAME* nor *LINC00518* expression was detected), moderate risk (expression of either *PRAME* or *LINC00518* was detected), or high risk (expression of both *PRAME* and *LINC00518* was detected). The second result is as an algorithmic PLA score that ranges from 0 to 100, with higher scores indicating higher suspicion of malignant disease. It is not clear whether the PLA test is meant to be used as a replacement, triage, or add-on test with respect to dermoscopy. The PLAplus™ test additionally includes testing for *TERT* variants.

The Myriad myPath test measures expression of 23 genes. Fourteen genes are involved in melanoma pathogenesis and are grouped into three components related to cell differentiation, cell signaling, and the immune response, and nine housekeeper genes are also included. The test is performed on five standard tissue sections from an existing formalin-fixed, paraffin-embedded biopsy specimen, and the test report includes an algorithmic myPath score ranging from -16.7 to 11.1, with higher, positive scores indicating higher suspicion of malignant disease. The myPath report classifies these scores: -16.7 to -2.1 are “benign”; -2.0 to -0.1 are “indeterminate”; and 0.0 to +11.1 are “malignant”.

The DecisionDx-Melanoma™ is a gene expression profile test that is a signature of 31 genes, 28 discriminating genes, and three control genes. The test is used to measure risk of metastasis in patients with stage 1 and 2 cutaneous melanoma and classifies tumors into two groups of risk of metastasis, high or low (Class 1 and 2, respectively). The test purports to give an independent prediction of risk of tumor metastatic risk, independent of currently used metrics of risk assessment (e.g., Breslow’s thickness, ulceration status, and mitotic rate; American Joint Committee on Cancer stage, sentinel lymph node biopsy [SLNB] status), so that patients with high-risk stage 1 or 2 disease can possibly undergo more aggressive surveillance treatment than they would have otherwise received.

The Clinicopathological and Gene Expression Profile (CP-GEP, Skyline Dx), also known as the Merlin Assay, uses a combination of gene expression profiling, age, and Breslow thickness to classify patients as either low risk or high risk for metastasis. Eight genes are included in the GEP: *ITGB3*, *PLAT*, *SERPINE2*, *GDF15*, *TGFBR1*, *LOXL4*, *CXCL8* and *MLANA*. This assay has been proposed to identify which patients at low risk that do not need to undergo SLNB.

The DecisionDx-UM™ test (Castle Biosciences Inc.) is a commercially marketed gene expression profiling test intended for use in assessing metastatic risk in individuals with this condition. It consists of a 15-gene polymerase chain reaction (PCR)-based assay that stratifies individuals with uveal melanoma into two classes based on the molecular signature of tumor tissue. Uveal melanomas cluster into two molecular groups based on their gene expression profile. Tumors with the Class 1 signature rarely metastasize, whereas those with the Class 2

signature metastasize at a high rate. Class 1 tumors have been further distinguished into Class 1a (lowest metastatic risk) and Class 1b (moderate long-term metastatic risk).

According to Castle Biosciences Inc., the DecisionDx-UM™ test results are used for the following:

- To initiate referral to a medical oncologist for treatment planning which may include adjuvant treatment.
- To develop specific monitoring or surveillance plans:
    - More frequent monitoring with advanced imaging procedures may be recommended for those individuals identified as having a high risk of developing metastasis.
    - For individuals at a low risk of developing metastasis, a less intensive surveillance plan may balance the risks of radiation exposure associated with less frequent imaging.
- To improve life-planning.

REGULATORY STATUS

The DecisionDx tests are performed in a Clinical Laboratory Improvement Amendment (CLIA)-certified laboratory and do not require U.S. Food and Drug Administration (FDA) clearance.

Note: Microarray-based gene expression analysis of prostate cancer and breast cancer are addressed in separate medical policies (see Cross References).

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[2] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

1. Analytic validity, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
2. Clinical validity, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. Clinical utility, i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

Review of the literature focused on identifying evidence related to clinical validity and clinical utility, particularly whether the tests can be used to improve treatment planning compared with the standard of care, and whether their use results in improved health outcomes.

EVALUATION OF SUSPICIOUS PIGMENTED LESIONS

DermTech PLA

Primary care providers evaluate suspicious pigmented lesions to determine who should be referred to dermatology. Factors considered include both a patient's risk for melanoma as well as a visual examination of the lesion. The visual examination assesses whether the lesion has features suggestive of melanoma. Criteria for features suggestive of melanoma have been developed. One checklist is the ABCDE checklist:[3]

- Asymmetry;
- Border irregularities;
- Color variegation;
- Diameter ≥6 mm;
- Evolution.

Another criterion commonly used is the "ugly duckling" sign.[4] An ugly duckling is a nevus that is obviously different from others in a given patient. Primary care providers generally have a low threshold for referral to dermatology.

Melanoma is difficult to diagnose based on visual examination, and the criterion standard for diagnosis is histopathology. There is a low threshold for excisional biopsy of suspicious lesions for histopathologic examination due to the procedure's ease and low risk as well as the high probability of missing melanoma. However, the yield of biopsy is fairly low. The number of biopsies performed to yield one melanoma diagnosis has been estimated to be about 15 for U.S. dermatologists.[5] Therefore a test that could accurately identify those lesions not needing a biopsy (i.e., a rule-out test for biopsy) could be clinically useful. The purpose of gene expression profiling (GEP) in patients who have suspicious pigmented lesions being considered for biopsy is to inform a decision about whether to biopsy.

Clinical Validity

Studies were excluded from the evaluation of the clinical validity of the DermTech PLA test because they reported results of the development cohort,[6] they did not use the marketed version of the test,[6, 7] did not include the reference standard test on PLA-negative patients,[8] did not adequately describe the patient characteristics,[9] or did not adequately describe patient selection criteria.[9]

The validation cohort from the Gerami (2017) publication was included.[10] This was a retrospective study that included lesions that were selected by dermatologists experienced in pigmented lesion management from 28 sites in the United States, Europe, and Australia; therefore, the samples were likely not consecutive or random. Information regarding the previous testing was not provided. The flow of potential and included samples was not clear, and neither was whether the samples were all independent or if multiple samples from the same patient were included. Diagnosis of melanoma was based on consensus among a primary reader and three expert dermatopathologists. The report did not state whether the histopathologic diagnosis was blinded to the results of the PLA test but did state the diagnosis was "routinely" assessed. Interpretation of the PLA result does not depend on a reader, so it is blinded to histopathologic results. In 11% of cases originally selected, a consensus diagnosis was not reached, and these samples were not included in the training or validation cohorts. Dates of data collection were not reported. Sex and anatomic location of biopsy were reported, but other clinical characteristics (e.g., risk factors for melanoma, presenting symptoms) were not. The study training cohort included 157 samples with 80 melanomas and 77 nonmelanomas. The study validation cohort included 398 samples with 87 melanomas (22%) and 311 non-melanomas. The sensitivity and specificity of the test in this group was 91% (95%

confidence interval [CI] 83% to 96%) and 69% (95% CI 64% to 74%), respectively, yielding a positive predictive value (PPV) of 45% (95% CI 38% to 53%) and a negative predictive value (NPV) of 96% (95% CI 93% to 98%).

Clinical Utility

Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from randomized controlled trials. No direct evidence of clinical utility was identified.

A decision-impact study by Ferris (2017) assessed the potential impact of the PLA on physicians' biopsy decisions for patients.[9] Forty-five dermatologists evaluated 60 clinical and dermoscopic images of atypical pigmented lesions (8 melanoma, 52 nonmelanoma). In the first round, dermatologists did not have PLA test results, and in the second round, dermatologists had access to PLA test results with the order of cases being scrambled. The dermatologists were asked whether the lesions should be biopsied after each round. Therefore, the corresponding number of biopsy decisions should be 45×60×2=5,400. Data were collected in 2014 and 2015. Results were reported for 4,680 decisions with no description of the disposition of the remaining decisions. Of the 4,680 reported decisions, 750 correct biopsy decisions were made without PLA results while 1,331 were made with PLA results and 1,590 incorrect biopsy decisions were made without PLA results while 1,009 incorrect biopsy decisions were made with PLA results.

GEP FOR DIAGNOSING LESIONS WITH INDETERMINATE HISTOPATHOLOGY

MyPath

The purpose of GEP testing in patients whose melanocytic lesion is indeterminate after histopathology is to aid in the diagnosis of melanoma and decisions regarding treatment and surveillance. In cases of indeterminate histopathology, long-term follow-up is needed to determine evaluate the clinical outcome, specifically metastasis.

Development of the myPath test was described by Clarke (2015).[11] The myPath test is meant to be used as an add-on test to standard histopathology. Studies have evaluated the performance characteristics of the test when histopathology is used as the reference standard,[11-13] but are not the focus of this evidence review given that the test's potential usefulness is in evaluation of indeterminate lesions.

Studies were excluded from the evaluation of the clinical validity of the myPath test because authors did not use the specified reference standard of long-term (at least five years) follow-up[11-16] and/or did not adequately describe patient characteristics.

The clinical validity study by Ko (2017) met selection criteria.[17] For this study, archived melanocytic neoplasms were submitted for myPath testing from university clinics in the United States and United Kingdom with additional samples acquired from Avaden BioSciences. Stage 1, 2, and 3 primary cutaneous melanomas that produced distant metastases subsequent to the diagnosis and benign lesions with clinical follow-up and no evidence of recurrence of metastases were included. For benign samples, a disease-free time of at least five years was recommended. Information on the previous testing was not provided. It is not clear if any of the samples originally had indeterminate histopathology results. Dates of data collection were not reported. Sex, age, Breslow depth, and anatomic location were described; presenting

symptoms were not reported. A total of 293 samples were submitted; of these 53 did not meet inclusion criteria and 58 (24% of those tested) failed to produce a valid test score. An additional seven samples with indeterminate results were excluded from the calculations of performance characteristics. Of the remaining 175 samples, 54 were diagnosed as melanoma with metastases. The sensitivity and specificity of the test in this group was 94% (95% CI 87% to 98%) and 96% (95% CI 89% to 99%), respectively, with a PPV of 97% (95% CI 91% to 99%) and an NPV of 93% (95% CI 85% to 97%). A limitation of the study is that it was not limited to lesions that were indeterminate following histopathology. In addition, the samples were not consecutive or random, and it is unclear how much time elapsed between the biopsy and the myPath test. A follow-up analysis by Clarke (2020) was limited to lesions with "diagnostic uncertainty" from this study.[18] Of the 125 lesions that met diagnostic uncertainty criteria, 54 were determined to be malignant based on clinical outcomes and 47 (87%) of these had a "likely malignant" test result.

Clinical Utility

Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from randomized controlled trials. No direct evidence of clinical utility was identified.

Two decision-impact studies assessed the potential impact of myPath on physicians' treatment decisions in patients with diagnostically challenging lesions.[19, 20] Given the lack of established clinical validity and no reported long-term health outcomes, it is not known whether any treatment changes were clinically appropriate.

CUTANEOUS MELANOMA

Many treatments and surveillance decisions are determined by a patient's prognostic stage group based the American Joint Committee on Cancer tumor, node, metastasis staging system. The prognostic groups are as follows: stage 1, T1a through T2a primary melanomas without evidence of regional or distant metastases; stage 2, T2b through T4b primary melanomas without evidence of lymphatic disease or distant metastases; stage 3: pathologically documented involvement of regional lymph nodes or in transit or satellite metastases (N1 to N3); stage 4: distant metastases. Patients may also SLNB to gain more definitive information about the status of the regional nodes. Wide local excision is the definitive surgical treatment of melanoma. Following surgery, patients with American Joint Committee on Cancer stage 1 or 2 (node-negative) melanoma do not generally receive adjuvant therapy. Patients with higher risk melanoma receive adjuvant immunotherapy or targeted therapy. Patients with stage I and IIA disease should undergo an annual routine physical and dermatologic examination. These patients typically do not receive surveillance imaging. Patients with stage 2B – stage 3 melanoma may be managed with more frequent follow-up and imaging surveillance following therapy. However, follow-up strategies and intervals are not based on rigorous data, and opinions vary regarding appropriate strategies.

The purpose of GEP in patients with melanoma is to identify low and high-risk patients classified as stage 1 or 2 according to the American Joint Committee on Cancer (AJCC) criteria. Current guidelines do not recommend adjuvant therapy or imaging surveillance for AJCC stage 1 or 2 patients following surgery. Patients initially staged as 1 or 2 who have positive lymph nodes following SLNB are then eligible to be treated with adjuvant therapy as stage 3 patients.

DecisionDX-Melanoma

Clinical Validity

Several papers were excluded from the evaluation of clinical validity of the DecisionDx test. Hsueh (2017), Podlipnik (2019), Hsueh (2021), and Bailey (2023) were excluded from the evaluation because they did not report five-year outcomes.[21-24] Samples used in Gerami (2015)[25] and Ferris (2017)[26] appear to overlap with the samples from Gerami (2015)[27] and each other and will not be considered independent validation studies for inclusion in the table. They are described briefly following the clinical validity tables. Samples used in both papers by Gastman (2019) are stated to overlap previous validation studies.[28, 29] Vetto (2019) included a retrospective cohort that was used to develop the model and is thus not eligible for inclusion, as well a prospective cohort with some overlapping samples and without report of five-year outcomes.[30] A publication by Marks (2019) describes the development of a cutpoint.[31]

Four independent clinical validity studies meeting eligibility criteria have been conducted. Characteristics and results are summarized in Tables 1 and 2 and briefly in the paragraphs that follow.

Table 1. Clinical Validity Study Characteristics of the DecisionDx-Melanoma Test for Diagnosing Melanoma

Study	Study Population	Design	Outcome Measure	Threshold for Positive Test	Timing	Assessor Blinding
Gerami (2015);[27] Validation subset	Adults Stage I-IV cutaneous melanoma (87% stage I/II) At least 5 y of FU (median, 7.0 y) Median Breslow thickness, 0.8 mm (nonmetastasis) and 3.99 mm (metastasis) SLN positivity NR	Retrospective Not consecutive or randomly selected	5-y RFS	Class 2 is high-risk Risk threshold not provided	Patient diagnosed between 1998 and 2009 Timing of DecisionDx not described	Yes
Zager (2018)[32]	Stage I-III cutaneous melanoma (68% stage I/II) At least 5 y of FU (median, 7.5 y) Median Breslow thickness, 1.2 mm 30% SLN positive	Retrospective Not consecutive or randomly selected	5-y RFS	Class 2 = high risk Class 1 probability score 0-0.49 Class 2 probability score 0.5-1	Patients diagnosed between 2000 and 2014 Timing of DecisionDx not described	Yes

Study	Study Population	Design	Outcome Measure	Threshold for Positive Test	Timing	Assessor Blinding
Greenhaw (2018)[33]	Patients who were treated for primary invasive CM of any Breslow depth within the last 5 years and had had GEP testing (86% stage I, 14% stage II) Mean follow-up of 23 months; only 20 patients had 5-year follow-up	Retrospective Consecutive	5-y MFS	Commercial test cutoffs used	Institution offered DecisionDx testing to newly diagnosed and those treated within the previous five years	Yes
Keller (2019)[34]	Patients had CM (91% stage I/II), opted for GEP testing and underwent SNB and wide excision of primary tumor. Median follow-up time, 3.5 years Median Breslow thickness, 1.4 mm 9% SLN positive	Prospective	3-y MFS	Commercial test cutoffs used	Patients diagnosed between 2013 and 2015 GEP reported to be performed concurrently with SNB	Yes

FU: follow-up; RFS: recurrence-free survival; MFS: metastasis-free survival; GEP: gene expression profiling; CM: cutaneous melanoma; SLN: sentinel lymph node; SNB: sentinel node biopsy

Table 2. Clinical Validity Study Results of the DecisionDx-Melanoma Test for Diagnosing Melanoma

Study	Initial / Final N	Excluded Samples	Sensitivity, % (95% CI)	Specificity, % (95% CI)	PPV, % (95% CI)	NPV, % (95% CI)
Gerami (2015);[27] Validation subset		Samples excluded if melanoma dx not confirmed, dissectible area not acceptable				
Overall	Unclear / 104		89 (73 to 97)[a]	83 (72 to 91)[a]	72 (56 to 85)[a]	93 (84 to 98)[a]
AJCC stage 1 and 2	Unclear / 78		86 (64 to 97)[a]	84 (72 to 93)[a]	67 (46 to 83)[a]	94 (84 to 99)[a]

Study	Initial / Final N	Excluded Samples	Sensitivity, % (95% CI)	Specificity, % (95% CI)	PPV, % (95% CI)	NPV, % (95% CI)
Zager (2018)[32]		Did not meet analytic quality control thresholds				
Overall	601 / 523		70 (62 to 78)	71 (67 to 76)	48 (41 to 55)	87 (82 to 90)
AJCC stage 1	Unclear / 264		35 (14 to 62)[a]	87 (82 to 91)[a]	15 (6 to 31)[a]	95 (91 to 98)[a]
AJCC stage 2	Unclear / 93		77 (61 to 89)[a]	43 (29 to 57)[a]	49 (36 to 62)[a]	72 (53 to 86)[a]
Greenhaw (2018)[33]	256 / 256	None excluded but only 20 had 5-year follow-up	77 (46 to 94)	87 (82 to 91)	24 (13 to 40)	99 (96 to 100)
Keller (2019)[34]	159 / 174	15 patients had insufficient tumor for GEP testing	NR	NR	NR	NR

AJCC: American Joint Committee on Cancer; Dx: diagnosis; NPV: negative predictive value; NR: not reported; PPV: positive predictive value; RFS: recurrence-free survival; MFS: metastasis-free survival

[a] Confidence intervals not provided in the report; calculated from data provided.

The validation cohort in Gerami (2015) included patients with stage 0, 1, 2, 3, or 4 disease from six U.S. centers (n=104).[27] A complete disposition of samples received from the institutions and those included in the analysis was not provided. For 78 patients in the validation cohort with AJCC stage 1 or 2 cutaneous melanoma who had either a metastatic event or had more than five years of follow-up without metastasis, five-year disease-free survival was 98% (CIs not reported) for DecisionDx class 1 patients and 37% for DecisionDx class 2 patients. The PPV and NPV were 67% and 94%, respectively. CIs for performance characteristics were calculated in Table 2 based on data provided

Zager (2018) reported results of a second clinical validity study including AJCC stage 1, 2, or 3 primary melanoma tumors from 16 U.S. sites.[32] The samples were independent of the other validation studies. Of the 601 cases submitted from the institutions, 523 were included in the analysis (357 stage 1 and 2). The excluded samples did not meet pre- and post-analytic quality control thresholds. SLNB status was untested in 36% of the patients, negative in 34%, and positive in 30%. The report did not describe any adjuvant therapy that the patients received. Overall, 42 (13%) recurrence events occurred in DecisionDx class 1 patients and 100 (48%) recurrence events occurred in DecisionDx class 2 patients. The five-year recurrence free survival (RFS) estimated by Kaplan-Meier was 88% (95% CI 85% to 92%) in class 1 and 52% (95% CI, 46% to 60%) in class 2. The reported sensitivity and specificity were 70% (95% CI 62% to 78%) and 71% (95% CI 67% to 76%), respectively, with a PPV of 48% (95% CI 41% to 55%) and a NPV of 87% (95% CI 82% to 90%). For comparison, the performance characteristics for five-year RFS for sentinel lymph node status among those with SLNB were: sensitivity 66% (95% CI 57% to 74%); specificity 65% (95% CI 58% to 71%); PPV 52% (95% CI 44% to 60%); and NPV 76% (95% CI 69% to 82%). Estimates stratified by AJCC stage I or II are shown in Table 2. If DecisionDx were used as a triage test such that only class 2

received SLNB, then 159 class 1 patients would not have undergone SLNB. Of the 159 patients in class 1, 56 were SLNB-positive and were therefore eligible for adjuvant therapy. It is not clear if the SLNB-positive patients in this study received adjuvant therapy. Of the 56 patients who were DecisionDx class 1 and SLNB-positive, 22 recurrence events occurred by five years.

Greenhaw (2018) reported results of an independent study of the DecisionDx test using their institution's melanoma registry and including patients who had been treated for cutaneous melanoma within the last five years and undergone DecisionDx testing.[33] Study characteristics and results were reported in the preceeding Tables 1 and 2. Two-hundred fifty-six patients were tested; 84% were categorized as DecisionDx class 1 (low-risk) and 16% were DecisionDx class 2 (high-risk). Of these, 219 (86%) tumors were AJCC stage I and 37 (14%) were AJCC stage II. None of the 18 stage 1/class 2 tumors metastasized but 1 (0.5%) of 201 stage I/class 1 tumors metastasized. Ten (42%) of the stage 2/class 2 tumors metastasized and 2 (15%) of the 13 stage 2/class 1 tumors metastasized.

Keller (2019) reported results of a validity study including 159 patients (ages 26 to 88) diagnosed with melanoma between 2013 and 2015 who underwent SNB and concurrent GEP testing.[34] Study characteristics and results were reported in the preceding Tables 1 and 2. There were 117 patients classified as class 1 (91 subclass 1A and 26 subclass 1B) and 42 classified as Class 2 (12 subclass 2A and 30 subclass 2B); and 78% of the tumors were AJCC stage 1, 13% were stage 2, and 9% were stage 3. Five-year RFS was reported only in a figure and sample sizes at year five and precision estimates were not included. There were six recurrent events (n=117) in class 1 patients by three years (three-year RFS 97%, 95% CI 93% to 100%). There were 23 recurrent events (n=42) in class 2 patients (three-year RFS 47%, 95% CI 34% to 65%). GEP class was significantly associated with RFS in multivariate analysis controlling for age, Breslow thickness, ulceration and SNB results.

In a subsequent analysis of patients with melanoma who had undergone SLNB, Gerami (2015) compared the prognostic accuracy of GEP and biopsy .[25] Patients who had undergone SLNB appear to overlap with patients in Gerami (2015)[27], discussed previously. Most (73%) patients had a negative SLNB, and 27% had a positive SLNB. DecisionDx-Melanoma classified 76 (35%) tumors as low-risk (class 1) and 141 (65%) tumors as high-risk (class 2). Within the group of SLNB-negative patients, the five-year OS rate was 91% in class 1 patients and 55% in class 2 patients. Within the group of SLNB-positive patients, the five-year OS rate was 77% in class 1 patients and 57% in class 2 patients.

A systematic review and meta-analysis by Marchetti (2020) evaluated the performance of GEP tests for prognosis in patients with localized melanoma.[35] Five studies of the DecisionDX-Melanoma were included in the review: the four studies in Tables 1 and 2 as well as the study by Hsueh (2017) that was not included. The review also included two studies of the MelaGenix test, which is not available in the U.S. All studies of DecisionDx-Melanoma were determined to have a high risk of bias. The results of the meta-analysis indicated that there was significant heterogeneity in the performance of the DecisionDX-Melanoma test between patients with stage 1 and stage 2 cancers, with poorer classification seen for stage 1. Limitations of the analysis included heterogeneity in recurrence definitions and lack of individual patient data. The authors also noted that censoring and lack of follow-up could substantially impact the recurrence outcome, with the proportion of recurrences in a mixed stage 1-3 cohort that were correctly classified as high-risk by the DecisionDx test decreasing from 80% at a median event-free follow-up time of 1.5 years to 60% at 3.2 years. Another meta-analysis of the

DecisionDx-Melanoma test was published by Greenhaw (2020).[36] This industry-sponsored analysis reported a sensitivity of 76% (95% CI 71% to 80%) and a specificity of 76% (95% CI 73% to 78%) for five-year RFS, and a sensitivity of 76% (95% CI 72% to 80%) and specificity of 69% (95% CI 66% to 72%) for distant metastasis-free survival. The analysis did not include clinicopathologic factors such as sex, anatomic site, and mitotic index.

Clinical Utility

Several decision-impact studies have been published reporting on the impact of DecisionDx-Melanoma on physicians' management decisions.[37-43] Given the lack of established clinical validity and no reported long-term outcomes of the test used to select patients for active surveillance, it is not known whether any management changes were clinically appropriate.

For the proposed use of the test as a triage for SLNB (to identify patients who can avoid SLNB), performance characteristics are not well-characterized. For the proposed use of the test as a replacement for SLNB (identify patients who are AJCC stage 1 or 2 who should receive adjuvant therapy), performance characteristics are also not well-characterized. In addition, an evidence-based management pathway would be needed to support the chain of evidence. The existing RCTs demonstrating that adjuvant therapy reduces recurrence included node-positive patients.

For the proposed use of the test to identify patients who are AJCC stage 1 or 2 who should receive enhanced surveillance, there is also a lack of evidence that imaging surveillance or increased frequency of surveillance improves outcomes in stage 1 and 2 patients. The National Comprehensive Cancer Network guidelines state that imaging surveillance is not recommended for stage 1-2A and can be 'considered' for 2B-4, but that there is an absence of meaningful data on the association of rigorous routine surveillance imaging with improved long-term outcome for stage 2B-2C and the recommendations regarding consideration of imaging surveillance remain controversial. While earlier detection of recurrence is thought to be beneficial because lower tumor burden and younger age are associated with improved treatment response and survival, this has not been proven and RCTs are needed to assess whether enhanced surveillance improves survival. The optimal frequency and duration of follow-up surveillance are not standardized and how the surveillance would be altered for DecisionDx class 2 patients has not be defined.

No evidence was identified that demonstrated that adjuvant therapy or increased surveillance improves net health outcomes in AJCC stage 1 or 2 patients who are DecisionDx class 2.

Clinicopathological and Gene Expression Profile (CP-GEP)

Clinical Validity

One study of the CP-GEP (also known as the Merlin Assay) was identified that met inclusion criteria. Other studies of this assay were not included because they compared the test to SLNB results and did not assess long-term outcomes.[44, 45]

Eggermont (2020) published a validation study of the CP-GEP that included samples from 580 stage 1-2A cutaneous melanoma patients who had a SLNB within 90 days of their diagnosis.[46] Among this group, 47% were classified as high risk based on the assay. The five-year RFS was 89% (95% CI 84% to 93%) for the CP-GEP low-risk group and 74% (95% CI 67% to 80%) for the CP-GEP high-risk group. Melanoma-specific survival was 97% and 91% for these groups, respectively.

Clinical Utility

Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. No direct evidence of clinical utility was identified.

UVEAL MELANOMA

DecisionDX-UM

Clinical Validity

Roelofs (2022) performed a retrospective analysis of 343 patients with uveal melanoma who underwent GEP classification, including 255 patients with class 1 and 88 patients with class 2 results.[47] Patients were classified as being at low (GEP class 1 and tumor thickness <8 mm) or high risk of metastasis (GEP class 2 or tumor thickness ≥8mm); low-risk patients underwent annual surveillance abdominal ultrasound, while high-risk patients underwent alternating surveillance liver ultrasound and abdominal magnetic resonance imaging every six months according to institutional protocol. The mean follow-up was 40 ± 26 months. In univariate Cox proportional hazard regression, enucleation, ciliary body involvement, extraocular extension, tumor thickness, largest basal tumor diameter (as a continuous and categorical [>12mm] variable), and GEP class 2 were associated with future metastasis. Multivariate Cox proportional hazards regression indicated GEP class 2 and longest basal diameter >12mm remained independently predictive of metastasis-free survival, and stratified analysis further indicated longest basal diameter >12mm remained predictive of metastasis-free survival in both GEP class 1 and 2 tumors.

Singh (2022) performed a retrospective analysis of metastasis-free survival in patients with uveal melanoma, with a focused analysis comparing predicted (according to DecisionDx-UM metastasis-free survival prediction for GEP class 2 [i.e., 50% at three years, 28% at five years]), observed (via analysis of a cohort of consecutive patients with uveal melanoma treated at the authors' two institutions), and published (via a meta-analysis of patients with uveal melanoma from seven retrospective or prospective studies utilizing GEP published between 2012 and 2021) metastasis-free survival in GEP class 2 subgroups.[48] The overall retrospective cohort consisted of 343 patients, of whom 121 were GEP class 2, while the meta-analysis pooled data from 667 GEP class 2 patients. In the analysis of GEP class 2 patients, both observed and meta-analysis-derived published metastasis-free survival at three and five years were longer than the corresponding DecisionDx-UM-predicted survival, with point estimate differences ranging from 12% to 19%. The predicted metastasis-free survival estimate was below the lower limit of the 95% confidence interval for both observed and published survival estimates at both time points.

Davanzo (2019) conducted a retrospective review of 107 consecutive uveal melanoma patients, including 39, 31, and 37 patients with unknown, low-, and high-risk GEP results.[49] Low-risk patients were followed with hepatic ultrasonography every six months, whereas high-risk patients were managed with more frequent hepatic imaging. High-risk patients (8/37) were significantly more likely to develop metastasis ($p<0.001$) compared to patients in the low/unknown risk group (0/70) (see Table 3).

Cai (2018) retrospectively evaluated a cohort of 240 patients with uveal melanoma arising from the choroid and/or ciliary body.[50] The study sought to determine whether the prognostic accuracy of combined GEP and PRAME (preferentially expressed antigen in melanoma) status was noninferior to the AJCC tumor-node-metastasis (TNM) staging system for uveal

melanoma. Patients were followed for a median duration of 29 months with metastasis as the primary endpoint. GEP class was the most significant predictor of metastasis ($p=1.5x10^{-8}$). The prognostic accuracy of an optimized GEP/PRAME model ($p=8.6x10^{-14}$) was superior to an optimized TNM model ($p=1.3x10^{-5}$).

Augsburger (2015) reported on the correlation between GEP classifications when samples from two sites from the same tumor were tested.[51] This prospective, single-center study enrolled 80 patients who had uveal melanoma resection. Tumor samples were taken from two different sites and GEP testing was performed independently on both samples. The primary measure reported was the rate of discordance between the two samples on GEP Class. Nine (11.3%) cases were definitely discordant (95% CI 9.0% to 13.6%), and 13 (16.3%) cases were definitely or possibly discordant (95% CI 13.0% to 19.6%). Thus, the heterogeneity of tumor and limitations to sampling may explain cases of misclassification where GEP results do not accurately predict prognosis.

Onken (2010) revalidated the GEP assay when it was migrated from a microarray platform to a polymerase chain reaction–based 15-gene assay comprised of 12 discriminating genes and three endogenous control genes from previously published data sets collected from the same group.[52, 53] Technical performance of the assay was assessed in 609 tumor samples, including 553 fine needle aspiration biopsies and 56 enucleation specimens from the authors' laboratory (n=188) and 11 collaborating sites (n=421). According to the study protocol, sample failure rate due to incorrect specimen handling was low, occurring in 32 of 609 (5.3%) of samples ($p<0.0001$). Preliminary data suggested the potential for increased sensitivity of gene expression profiling compared with cytologic diagnosis, as the assay failed in only one of 51 (2%) of samples with insufficient material for cytological diagnosis; however, point estimates of overall test accuracy (e.g., sensitivity, specificity, or both) were not provided. In a subset of 172 individuals with UM, the relationship between tumor class and metastasis was studied with available clinical data and a median follow-up time of 16 months. Within this group, the assay was reported to correctly identify individuals who went on to develop metastatic disease. Kaplan-Meier analysis showed approximately 24% Class 2 individuals with uveal melanoma surviving at 48 months and close to 100% survival in the Class 1 group, although more specific data was not provided. This study evaluated primarily fine needle aspiration biopsy specimens (553 of 609, or 90.8%) rather than enucleation specimens; however, the data reported on the relationship between tumor class and metastasis are limited, and median follow-up time was reported as a relatively short duration (16 months).

In a prospective, multicenter study by Onken (2012), the prognostic performance of the 15-gene GEP assay was evaluated in 459 patients with posterior uveal melanoma from 12 independent centers.[54] Tumors were classified by GEP as Class 1 or Class 2. The first 260 samples were also analyzed for chromosome 3 status using a single nucleotide polymorphism assay. Net reclassification improvement analysis was performed to compare the prognostic accuracy of GEP with the 7th edition clinical Tumor-Node-Metastasis (TNM) classification and chromosome 3 status. Patients were managed for their primary tumor and monitored for metastasis. The GEP assay successfully classified 446 of 459 cases (97.2%). Metastasis was detected in three Class 1 cases (1.1%) and 44 Class 2 cases (25.9%) (log-rank test, P<10(-14)). At three years follow-up, the net reclassification improvement of GEP over TNM classification was 0.43 (p=0.001) and 0.38 (p=0.004) over chromosome 3 status. The GEP provided a highly significant improvement in prognostic accuracy over clinical TNM classification and chromosome 3 status. The impact of the test results on health outcomes were not identified in the study.

Walter (2016) evaluated two cohorts of patients at two clinical centers who underwent resection for uveal melanoma.[55] This study had similar methodology to Onken (2012) study described above. The primary cohort included 339 patients, of which 132 patients were also included in the Onken study, along with a validation cohort of 241 patients, of which 132 were also included in the Onken study, the latter group of which was used to test a prediction model using the GEP plus pretreatment largest basal diameter. Cox proportional hazards analysis was used in the primary cohort to examine GEP classification and other clinicopathologic factors (tumor diameter, tumor thickness, age, sex, ciliary body involvement, pathologic class). GEP Class 2 was the strongest predictor of metastases and mortality. Tumor diameter was also an independent predictor of outcomes, using a diameter of 12 mm as the cutoff value. In the validation cohort, GEP results were Class 1 (61.4%) in 148 patients and Class 2 (38.6%) in 93 patients.

Similar outcomes were reported by Demirci (2018) in a retrospective review of 293 patients with choroidal melanoma.[56] Class 2 tumors with largest basal diameter ≥ 12 mm and class 2 and 1B tumors with American Joint Committee on Cancer (AJCC) stage III showed significantly worse prognosis. At a median follow-up of 26 months, the probability of metastasis-free survival was lowest in patients with class 2 tumors (HR 0.60, 95% CI 0.44 to 0.72) compared to patients with class 1A (HR 0.99, 95% CI 0.94 to 0.99) or class 1B (HR 0.90, 95% CI 0.77 to 0.96) tumors. The authors subsequently analyzed a scoring system combining AJCC stage and GEP in the same dataset (including three additional patients since the 2018 publication), with results indicating better estimate of prognosis with the combined score than with use of AJCC stage or GEP alone.[57]

Decatur (2016) published a smaller, retrospective study of 81 patients who had tumor samples available from resections occurring between 1998 and 2014.[58] GEP was Class 1 in 35 (43%) patients, Class 2 in 42 (52%) patients, and unknown in four (5%) patients. GEP Class 2 was strongly associated with BAP1 variants (r=0.70, p<0.001). On Cox proportional hazards analysis, GEP Class 2 was the strongest predictor of metastases and melanoma mortality.

Corrêa (2016) performed a single-institution prospective intervention case series to compare the prognostic value of the 15-gene GEP test with other conventional prognostic factors for metastasis and metastatic death, including 299 patients with posterior uveal melanoma evaluated by fine-needle aspiration biopsy at the time of or shortly prior to initial treatment.[59] The cohort in this study had a substantial proportion of patients with smaller tumors compared to previous studies, and this was reflected in the higher proportion of Class 1 to Class 2 cases in this cohort; 211 (70.6%) Class 1 patients and 88 (29.4%) Class 2 patients. Stepwise multivariant analysis determined that although GEP class was the strongest prognostic factor for metastatic death in this series; that tumor large basal diameter was also a significant prognostic indicator of metastatic death. Kaplan-Meier survival curves demonstrated lower survival in GEP Class 2 patients compared with Class 1 patients, but survival and metastasis rates by class were not reported.

Field (2016) published a follow-up study of the Onken (2010) validation cohort, looking at additional biomarkers to complement the DecisionDx-UM GEP test results in 389 consecutive patients.[60] This study analyzed 64 tumor samples previously determined as Class 1 in an effort to find independent markers of metastasis in these samples. The investigators reported that Class 2 GEP was associated with significantly greater metastatic risk than Class 1 GEP, with metastatic disease being detected in 12/216 (6%) Class 1 cases versus 63/173 (36%) Class 2 cases (p<0.0001).

Table 3. Studies of Clinical Validity

Study	Patient Populations	Rates of Metastases		Melanoma Mortality Rates	
		GEP Class 1	GEP Class 2	GEP Class 1	GEP Class 2
Onken (2012)[54]	459 pts with UM from 12 clinical centers	1.1%	25.9%	NR	NR
Walter (2016)[55]	Primary cohort: 339 pts from one clinical center with UM arising in ciliary body or choroid	5.8%	39.6%	3.7%	29.5%
	Validation cohort: 241 pts from one (different) clinical center with UM arising in ciliary body or choroid	2.7%	31.2%	0.7%	17.2%
Decatur (2016)[58]	81 pts from a single center with available tumor samples of UM arising in ciliary body or choroid		9.4 (3.1 to 28.5)		15.7% (3.6 to 69.1)
Field (2016)[60]	389 pts from two clinical centers with UM arising in ciliary body or choroid	6%	36%	NR	NR
Demirci (2018)[56]	293 patients from 2 clinical centers with UM arising from the choroid	3.6%	26.5%	NR	NR
Cai (2018)[50]	240 patients from a single center with UM arising from the choroid and/or ciliary body	10.2% 3.9% (*PRAME*-) 6.3% (*PRAME*+)	41.1% 19.6% (*PRAME*-) 21.4% (*PRAME*+)	NR	NR
Davanzo (2019)[49]	107 consecutive patients from a single-center with UM	0%	21.6%	NR	NR
Roelofs (2022)[47]	343 patients from a single center with non-metastatic UM	4.3%	34%	NR	NR
Singh (2022)[48]	• Observed survival cohort: 343 consecutive patients from two centers with UM, including 121 GEP class 2 patients • Published survival pooled cohort: 667 GEP class 2 patients	• Observed 3-year MFS: 93% (95% CI 89% to 97%) • Observed 5-year MFS: 87% (95% CI 81% to 93%	3-year MFS: • Predicted:[c] 50% • Observed: 67% (95% CI 59% to 77%) • Published: 62% (95% CI 57% to 66%) 5-year MFS: • Predicted:[c] 28% • Observed: 47% (95% CI 37% to 61%) • Published: 40% (95% CI 34% to 46%)	NR	NR

CI: confidence interval; GEP: gene expression profile; MFS: metastasis-free survival; NR: not reported; *PRAME*: preferentially expressed antigen in melanoma; UM: uveal melanoma

Clinical Utility

To date, there are no published studies that address the specificity, sensitivity, or positive- and negative-predictive values, and no studies that compare patient health outcomes as a result of patient management with versus without this testing. However, a chain of evidence based on the clinical validity of the test can be developed.

Khan (2022) conducted a multicenter, single-arm study of crizotinib as adjuvant therapy in adults with localized high-risk uveal melanoma (defined as GEP class 2 and longest basal tumor diameter >12mm).[61] This was the first published clinical trial of crizotinib in uveal melanoma. Patients received crizotinib 250 mg by mouth twice daily for a total of 48 weeks, beginning within 90 days of primary enucleation or radiotherapy. The primary outcome was 32-month relapse-free survival (RFS) rate; planned enrollment was 30 patients to provide 90% power to detect a 75% RFS rate at 32 months relative to a 50% RFS rate based on historical data. The analysis included a comparison of the primary outcome in the study cohort to a 2:1 propensity score-matched historical control. Among the 34 patients enrolled, the median age was 60 years, and all patients had an Eastern Cooperative Oncology Group performance status of 0 or 1. The mean relative dose intensity per cycle was 84%; four patients did not complete 48 weeks of treatment with crizotinib due to toxicity despite dose reduction. In 32 evaluable patients, at a median follow-up of 47.1 months, the estimated 32-month RFS rate was 50% (95% CI 23% to 67%). There was no difference in the primary outcome between the study cohort and the propensity score-matched historical control cohort, in whom the estimated 32-month RFS rate was 57% (95% CI 40% to 73%). All patients experienced at least one treatment-related adverse event, the most common of which were nausea, transaminase elevation, diarrhea, fatigue, and sinus bradycardia.

Schefler (2020) reported on risk-appropriate changes in management following testing with DecisionDx-UM in a prospective, multicenter cohort (n=93) enrolled in the Clinical Application of DecisionDx-UM Gene Expression Assay Results (CLEAR II) registry study.[62] Following testing, 44 (98%) of class 2 patients received a referral to another provider, of which 42 (93%) received referrals to medical oncology. For class 1 patients, 55 (59%) received a referral to another provider, of which 47 (51%) were referred to medical oncology. Medical oncology referral was more common for high-risk class 2 patients compared to class 1 ($p<0.001$). Class 2 patients were more 3.3 times more likely to receive high-frequency chest imaging ($p<0.001$) and 4.3 times more likely to received high-frequency abdominal imaging ($p<0.001$). Health outcomes resulting from changes in management were not reported.

Plasseraud (2016) reported metastasis surveillance practices and patient outcomes using data from a prospective observational registry study of DecisionDx-UM conducted at four centers, which included 70 patients at the time of reporting.[63] Surveillance regimens were documented by participating physicians as part of registry data entry. “High-intensity” surveillance was defined as imaging and/or liver function testing (LFTs) every three to six months and “low-intensity” surveillance was defined as annual imaging and/or LFTs. The method for following patients for clinical outcomes was not specified. Of the 70 enrolled patients, 37 (53%) were Class 1. Over a median follow up of 2.38 years, more Class 2 patients (36%) than Class 1 patients (5%; $p=0.002$) experienced a metastasis. The three-year metastasis-free survival rate was lower for Class 2 patients (63%; 95% CI 43% to 83%) than Class 1 patients (100%, $p=0.003$). Most Class 1 patients (n=30) had low-intensity surveillance and all (n=33) Class 2 patients had high-intensity surveillance. Aaberg (2020) published updated five-year outcomes for 89 patients.[64] Of these 89 patients, 49 (55%) were class 1, of which 39 (80%) received low-intensity management. The five-year metastasis-free survival rate was 90% for class 1 patients compared to 40.7% for class 2 patients ($p<0.0001$). The five-year melanoma-specific survival was 94.3% for class 1 patients compared to 63.4% for class 2 patients ($p=0.0007$). Strengths of this study included a relatively large population given the rarity of the condition, and an association between management strategies and clinical outcomes. However, it is not clear which outcome measures were prespecified or how data was collected, making the risk of bias high.

Aaberg (2014) reported on changes in management associated with GEP risk classification.[1] They analyzed Medicare claims data submitted to Castle BioSciences by 37 ocular oncologists in the United States. Data were abstracted from charts on demographics, tumor pathology and diagnosis, and clinical surveillance patterns. High-intensity surveillance was defined as a frequency of every three to six months and low-intensity surveillance was a frequency of every 6 to 12 months. Of 195 patients with GEP test results, 88 (45.1%) patients had evaluable tests and adequate information on follow-up surveillance, 36 (18.5%) had evaluable tests and adequate information on referrals, and 8 (4.1%) had evaluable tests and adequate information on adjunctive treatment recommendations. Of the 191 evaluable GEP tests, 110 (58%) were Class 1 and 81 (42%) were Class 2. For patients with surveillance data available (n=88), all patients in GEP Class 1 had low-intensity surveillance and all patients in GEP Class 2 had high-intensity surveillance ($p<0.001$ vs. Class 1).

PRACTICE GUIDELINE SUMMARY

There are no evidence-based clinical practice guidelines which specifically recommend the use of gene expression assays, specifically the DecisionDx assays, to guide the clinical management of patients with malignant tumors.

NATIONAL COMPREHENSIVE CANCER NETWORK

Cutaneous Melanoma

The National Comprehensive Cancer Network guidelines (v.2.2024) for cutaneous melanoma state the following the use of GEP to evaluate lesions of uncertain malignancy following histology:[65]

> "Ancillary tests to differentiate benign from malignant melanocytic neoplasms include immunohistochemistry (IHC) and molecular testing via comparative genomic hybridization (CGH), fluorescence in situ hybridization (FISH), gene expression profiling (GEP), single-nucleotide polymorphism (SNP) array, and next generation sequencing (NGS). These tests may facilitate a more definitive diagnosis and guide therapy in cases that are diagnostically uncertain or controversial by histopathology. Ancillary tests should be used as adjuncts to clinical and expert dermatopathologic examination and therefore be interpreted within the context of these findings."

The guidelines state the following regarding prognostic testing:

> “Despite commercially available GEP tests being marketed to risk stratify cutaneous melanoma, current GEP platforms do not provide clinically actionable prognostic information when combined or compared with known clinicopathologic (CP) factors (eg, sex, age, primary tumor location, thickness, ulceration, mitotic rate, lymphovascular invasion, microsatellites, and/or SLNB status) or multivariable nomograms/risk location, thickness, ulceration, mitotic rate, lymphovascular invasion, microsatellites, and/or SLNB status). Furthermore, the clinical utility of these tests to inform treatment recommendations and improve health outcomes by prompting an intervention has not been established.”
>
> Various studies of prognostic GEP tests suggest their role as an independent predictor of worse outcome. However, GEP studies to date have not demonstrated added benefit beyond comprehensive CP variables, and it remains unclear whether available GEP tests are reliably predictive of outcome across the risk spectrum of cutaneous

melanoma. Validation studies on prospectively collected, independent cohort (similar to those performed in breast cancer) are necessary to define the clinical utility of molecular prognostic GEP testing as an adjunct to AJCC staging and other known prognostically significant CP variables or as part of the multidisciplinary decision-making process to guide surveillance imaging, SLNB, and adjuvant therapy.

Existing and emerging GEP tests and other molecular techniques (ie, circulating tumor DNA tests) should be prospectively compared to determine their clinical utility, including with no-cost, contemporary models that incorporate readily available CP variables. Prospective study of the utility of predictive GEP for SLNB risk, in conjunction with well-established CP factors, is ongoing."

In addition, the guidelines state:

"Currently, there is insufficient evidence to support incorporation of current GEP tests into melanoma care. The use of GEP according to specific AJCC-8 melanoma stage (before or after SLBN) requires further prospective investigation in large, contemporary data sets of unselected patients. Prognostic GEP tests to differentiate melanomas at low versus high risk for metastasis should not replace pathologic staging procedures and are not recommended outside of the context of a clinical study or trial. Moreover, since there is a low probability of metastasis in stage I melanoma and a high proportion of false-positive results using these tests, GEP testing should not guide clinical decision-making in this subgroup. In addition, the likelihood of a positive SLNB may be informed by the use of multivariable nomograms/risk calculators. Ongoing prospective investigation will further inform the utility of GEP tests and multivariable nomograms/risk calculators for SLNB risk prediction."

Uveal Melanoma

The National Comprehensive Cancer Network (NCCN) guidelines for uveal melanoma (v.1.2024)[66] state: "Gene expression profiling (GEP) as described by Onken et al is recommended to determine whether the tumor is Class 1A (low risk), Class 1B (medium risk), or Class 2 (high risk) to inform frequency of follow-up."

AMERICAN ACADEMY OF DERMATOLOGY

The American Academy of Dermatology (2019) published guidelines of care for the management of primary cutaneous melanoma.[67] The guidelines state the following regarding GEP tests:

Regarding diagnostic GEP tests:

- "Diagnostic molecular techniques are still largely investigative and may be appropriate as ancillary tests in equivocal melanocytic neoplasms, but they are not recommended for routine diagnostic use in CM. These include comparative genomic hybridization, fluorescence in situ hybridization, gene expression profiling (GEP), and (potentially) next generation sequencing."
- "Ancillary diagnostic molecular techniques (eg, CGH, FISH, GEP) may be used for equivocal melanocytic neoplasms."

Regarding prognostic GEP tests:

- "...there is also insufficient evidence of benefit to recommend routine use of currently available prognostic molecular tests, including GEP, to provide more accurate prognosis beyond currently known clinicopathologic factors" (Strength of evidence: C, Level of evidence II/III)
- "Going forward, GEP assays should be tested against all known histopathologic prognostic factors and contemporary eighth edition of AJCC CM staging to assess their additive value in prognostication."
- "Routine molecular testing, including GEP, for prognostication is discouraged until better use criteria are defined. The application of molecular information for clinical management (eg, sentinel lymph node eligibility, follow-up, and/or therapeutic choice) is not recommended outside of a clinical study or trial."

MELANOMA PREVENTION WORKING GROUP

The Melanoma Prevention Working Group (2020) published consensus recommendations regarding the use of GEP for cutaneous melanoma.[68] After evaluating the available evidence, the working group concluded that the published evidence is “insufficient to establish that routine use for GEP testing provides additional clinical value for melanoma stating and prognostication beyond available clinicopathologic variables,” and that findings are needed from large, representative patient populations with adequate clinical follow-up to allow comparison with these variables.

SUMMARY

There is enough research to show that the DecisionDX-UM™ genetic test can identify certain patients with uveal melanoma that are at higher risk for their cancer to spread. This information can be used to help determine how often patients should be checked for metastatic disease. Therefore, the DecisionDX-UM™ genetic test may be considered medically necessary for patients with primary, localized uveal melanoma.

There is not enough research to show that the DecisionDX-UM™ genetic test can be useful to measure risk in people with other types of disease, including people with uveal cancer that has spread from another site in the body. Therefore, the DecisionDX-UM™ genetic test is considered investigational in people who do not meet the policy criteria.

There is not enough research to show that any other gene expression tests can help to guide patient management and improve health outcomes for people with cutaneous melanoma or pigmented lesions suspected of being melanoma. Therefore, gene expression assays, including but not limited to DecisionDX-Melanoma™, Pigmented Lesion Assay, PLAplus™, and myPath Melanoma™, are considered investigational in patients with cutaneous melanoma or pigmented lesions.

Medical Policy Manual Genetic Testing, Policy No. 41

BRAF Genetic Testing to Select Melanoma or Glioma Patients for Targeted Therapy

Effective: November 1, 2024

Next Review: July 2025
Last Review: September 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

BRAF and MEK inhibitors are drugs that were originally designed to target a variant in the *BRAF* gene found in some advanced melanoma tumors. This BRAF-variant kinase is believed to be actively involved in oncogenic proliferation, and specific inhibition of the kinase has been shown to slow tumor growth and may improve patient survival.

MEDICAL POLICY CRITERIA

I. Testing for *BRAF* variants in tumor tissue to select targeted therapy may be considered **medically necessary** for patients with advanced, metastatic, or unresectable melanoma.

II. Testing for *BRAF* variants for all other patients with melanoma is considered **investigational**.

III. Testing for *BRAF* variants in tumor tissue to select targeted therapy may be considered **medically necessary** for patients with glioma.

IV. Testing for *BRAF* variants for patients with glioma is considered **investigational** for all other purposes.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing?
6. Medical records related to this genetic test
   - History and physical exam
   - Conventional testing and outcomes
   - Conservative treatment provided, if any

BACKGROUND

MELANOMA

Overall incidence rates for melanoma have been increasing for at least 30 years. In advanced (stage IV) melanoma, the disease has spread beyond the original area of skin and nearby lymph nodes. Although only a small proportion of cases are stage IV at diagnosis, prognosis is poor, with a five-year survival of only 15-20%. For several decades since its approval in 1975, cytotoxic chemotherapy with dacarbazine was considered the standard systemic therapy but has low response rates of only 15-25% and median response durations of five to six months. Less than 5% of responses are complete.[1] Temozolomide has similar efficacy with a greater ability to penetrate the central nervous system. Recently immunotherapy with ipilimumab or with checkpoint inhibitors such as pembrolizumab and nivolumab has demonstrated superior efficacy to chemotherapy[2-6] regardless of *BRAF* status and is now recommended as one potential first-line treatment of metastatic or unresectable melanoma by the National Comprehensive Cancer Network (NCCN).[7]

Variants in the *BRAF* kinase gene are common in tumors of patients with advanced melanoma and result in constitutive activation of a key signaling pathway that is associated with oncogenic proliferation. In general, 50 to 70% of melanoma tumors harbor a *BRAF* variant and of these, 80% are positive for *BRAF* V600E and 16% are positive for *BRAF* V600K.[8] Thus,

approximately 45% to 60% of advanced melanoma patients might respond to a BRAF inhibitor targeted to this variant kinase.

BRAF inhibitors (e.g., vemurafenib, dabrafenib) and mitogen-activated extracellular signal-regulated kinase (MEK) inhibitors (e.g., trametinib, cobimetinib) have been developed for use in patients with advanced melanoma. Vemurafenib (trade name Zelboraf®, also known as PLX4032 and RO5185426) was co-developed under an agreement between Roche (Genentech) and Plexxikon. Vemurafenib was developed using a fragment-based, structure-guided approach that allowed the synthesis of a compound with high potency to inhibit the BRAF V600E variant kinase and significantly lower potency to inhibit most of many other kinases tested.[9] Preclinical studies demonstrated that vemurafenib selectively blocked the RAF/MEK/ERK pathway in *BRAF*-variant cells[10-12] and caused regression of *BRAF*-variant human melanoma xenografts in murine models.[9] Paradoxically, preclinical studies also showed that melanoma tumors with the *BRAF* wild-type gene sequence could respond to variant BRAF-specific inhibitors with accelerated growth,[10-12] suggesting that it might be harmful to administer BRAF inhibitors to patients with BRAF wild-type melanoma tumors. Potentiated growth in BRAF wild-type tumors has not yet been confirmed in melanoma patients as the supportive clinical trials were enrichment trials, enrolling only those patients with tumors positive for the *BRAF* V600E variant.

Dabrafenib (trade name Tafinlar®, also known as GSK2118436 or SB-590885) is a BRAF inhibitor developed by GlaxoSmithKline, now Novartis.[13, 14] Dabrafenib inhibits several kinases, including variant forms of BRAF, with greatest activity against the V600E BRAF variant. In vitro and in vivo studies demonstrated dabrafenib's ability to inhibit growth of *BRAF* V600 variant-positive melanoma cells.[15]

Trametinib (trade name Mekinist™) is an inhibitor of MEK1 and MEK2 developed by GlaxoSmithKline. MEK kinases regulate extracellular signal-related kinase (ERK), which promotes cellular proliferation. *BRAF* V600E and V600K variants result in constitutive activation of MEK1 and MEK2.[16] Trametinib inhibits growth of BRAF V600 variant-positive melanoma cells in vitro and in vivo.[17]

Cobimetinib, formally GDC-0973/XL518 (trade name Cotellic®) was developed by Genentech[18] and Exelixis[19]. It is a MEK inhibitor indicated for the treatment of patients with unresectable or metastatic melanoma with a *BRAF* V600E or V600K variant, in combination with vemurafenib. Cobimetinib is not indicated for treatment of patients with wild-type *BRAF* melanoma.

Nivolumab (OPDIVO®), developed by Bristol-Myers Squibb, is not a BRAF or MEK inhibitor, but instead inhibits the PD-1 protein on cells. PD-1 blocks the body's immune system from attacking melanoma tumors. Nivolumab is intended for patients who have been previously treated with ipilimumab and, for melanoma patients whose tumors express a *BRAF* V600 variant, for use after treatment with ipilimumab and a BRAF inhibitor.

GLIOMA

Gliomas encompass a heterogeneous group of tumors and classification of gliomas has changed over time. In 2016, World Health Organization (WHO) published an update of its classification of gliomas based on both histopathologic appearance and molecular parameters.[20] The classification ranges from grade I to IV corresponding to the degree of

malignancy (aggressiveness) with WHO grade I being least aggressive and grade IV being most aggressive.

Low-grade gliomas were historically those classified as WHO grade I or II and include pilocytic astrocytoma, diffuse astrocytoma, and oligodendroglioma. Surgical resection of the tumor is generally performed, along with additional radiation and chemotherapy following surgery except in the case of pilocytic astrocytoma. The optimal timing of additional therapies is unclear. Many patients will recur following initial treatment with a clinical course similar to high-grade glioma. High-grade gliomas (WHO grade III/IV) include anaplastic gliomas and glioblastoma. Maximal surgical resection is the initial treatment followed by combined adjuvant chemoradiotherapy. Temozolomide, an oral alkylating agent, is considered standard systemic chemotherapy for malignant gliomas. The prognosis for patients with high-grade gliomas is poor: the one-year survival in U.S. patients with anaplastic astrocytoma is about 63% and with glioblastoma is about 38%.[21]

There is a high frequency of *BRAF* V600E variants in several types of gliomas. For example, *BRAF* V600E variants have been found in approximately 5% to 10% of pediatric diffusely infiltrating gliomas, 10% to 15% of pilocytic astrocytoma, 20% of ganglioglioma, and more than 50% of pleomorphic xanthoastrocytoma.[22-27] However, it may be rare in adult glioblastoma.[28] There is considerable interest in targeted therapies that inhibit the MAPK pathway, particularly in patients with high-grade glioma and low-grade gliomas whose tumors are in locations that prevent full resection. Evidence from early phase trials in patients with *BRAF* variant-positive melanoma with brain metastases suggest some efficacy for brain tumor response with vemurafenib and dabrafenib,[29, 30] indicating that these agents might be potential therapies for primary brain tumors.

REGULATORY STATUS

The FDA Centers for Devices and Radiological Health (CDRH), for Biologics Evaluation and Research (CBER), and for Drug Evaluation and Research (CDER) developed a draft guidance on in vitro companion diagnostic devices, released on July 14, 2011,[31] to address the "emergence of new technologies that can distinguish subsets of populations that respond differently to treatment." As stated, the FDA encourages the development of treatments that depend on the use of companion diagnostic devices "when an appropriate scientific rationale supports such an approach." In such cases, the FDA intends to review the safety and effectiveness of the companion diagnostic test as used with the therapeutic treatment that depends on its use. The rationale for co-review and approval is the desire to avoid exposing patients to preventable treatment risk.

- **Vemurafenib**

  Vemurafenib and a Class III companion diagnostic test, the cobas® 4800 BRAF V600 Mutation Test, were co-approved by the FDA in August 2011.[32] The test is approved as an aid in selecting melanoma patients whose tumors carry the *BRAF* V600 variant for treatment with vemurafenib.[33] Vemurafenib is indicated for the treatment of patients with unresectable or metastatic melanoma with a *BRAF* V600 variant. The vemurafenib full prescribing information states that confirmation of a *BRAF* V600 variant using an FDA-approved test is required for selection of patients appropriate for therapy.[34]

- **Dabrafenib**

Dabrafenib was originally FDA-approved in May 2013 for the treatment of patients with unresectable or metastatic melanoma with *BRAF* V600E variant, as detected by an FDA-approved test.[15] A 2018 updated approval indicates that it may be used in combination with trametinib for adjuvant treatment of patients with resected stage III melanoma with *BRAF* V600E or V600K variants. Dabrafenib is specifically not indicated for the treatment of patients with wild-type *BRAF* melanoma.

- **Trametinib**

Trametinib was originally FDA-approved in May 2013 for the treatment of patients with unresectable or metastatic melanoma with *BRAF* V600E or V600K variants, as detected by an FDA-approved test.[17] A 2018 update indicates that it may be used in combination with dabrafenib for adjuvant treatment of patients with resected stage III melanoma with *BRAF* V600E or V600K variants. Trametinib is specifically not indicated for the treatment of patients previously treated with BRAF inhibitor therapy.[17]

- **Nivolumab**

Nivolumab was originally FDA-approved December 2014 for the treatment of unresectable or metastatic melanoma.[35] Nivolumab is intended for patients who have been previously treated with ipilimumab and, for melanoma patients whose tumors express an activating BRAF V600 variant, for use after treatment with ipilimumab and a BRAF inhibitor. Nivolumab may also be used in combination with ipilimumab in patients without a *BRAF* V600 variant.

- **Cobimetinib**

Cobimetinib was FDA-approved November 2015 for the treatment of unresectable or metastatic melanoma with a *BRAF* V600E or V600K variant, in combination with vemurafenib, as detected by an FDA-approved test. Cobimetinib is not indicated for treatment of patients with wild-type *BRAF* melanoma.[36]

- **Binimetinib**

Binimetinib was FDA-approved in 2018 for the treatment of unresectable or metastatic melanoma with a *BRAF* V600E or V600K variant, in combination with encorafenib.

- **Encorafenib**

Encorafenib was FDA-approved in 2018 for the treatment of unresectable or metastatic melanoma with a *BRAF* V600E or V600K variant, in combination with binimetinib.

In 2014, the FDA granted accelerated approval of trametinib and dabrafenib as a combination therapy for the treatment of patients with unresectable or metastatic melanoma with BRAF V600E or V600K variants, as detected by an FDA-approved test.[37] Approval of the combination therapy was based on the demonstration of durable objective responses in a multicenter, open-label, randomized (1:1:1), active-controlled, dose-ranging trial enrolling 162 patients with histologically confirmed Stage IIIC or IV melanoma determined to be *BRAF* V600E or V600K. No more than one prior chemotherapy regimen and/or interleukin-2 were permitted. Patients with prior exposure to BRAF inhibitors or MEK inhibitors were ineligible.

In November 2015, cobimetinib was approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with unresectable or metastatic melanoma with *BRAF* V600E or V600K variant, in combination with vemurafenib.[36] Additionally, in 2011, ipilimumab (Yervoy®) was approved by the FDA for the treatment of patients with unresectable or metastatic melanoma. For the first time, a survival advantage was demonstrated in previously treated patients: median survival on ipilimumab of 10 months versus 6.4 months on control medication. However, side effects of ipilimumab can include severe and fatal immune-mediated adverse reactions, especially in patients who are already immune-compromised. Ipilimumab's clinical study did not test metastatic melanoma patients' tumors for *BRAF* status; therefore, it's not known what, if any, clinical relevance *BRAF* status has with respect to ipilimumab.

In 2018, the FDA approved encorafenib and binimetinib together for unresectable or metastatic melanoma with *BRAF* V600 variants.

In 2022, the FDA approved dabrafenib and trametinib together for unresectable or metastatic solid tumors with *BRAF* V600 variants.

EVIDENCE SUMMARY

Validation of the clinical use of any genetic test focuses on three main principles:

1. The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
2. The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. The clinical utility of the test, which refers to how the results of the diagnostic test will be used to change management of the patient, and whether these changes in management lead to clinically important improvements in health outcomes.

This evidence review is focused on the clinical validity and utility of testing.

BRAF TESTING TO SELECT TREATMENT FOR MELANOMA

For individuals with melanoma who receive *BRAF* gene variant testing to select treatment with FDA-approved targeted therapy, the evidence includes FDA-approved therapeutics with NCCN recommendations of 2A or higher and was not extensively evaluated.

GLIOMA

For individuals with glioma who receive *BRAF* gene variant testing to select treatment with FDA-approved targeted therapy, the evidence includes FDA-approved therapeutics with NCCN recommendations of 2A or higher and was not extensively evaluated.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)

NCCN guidelines for cutaneous melanoma (v.2.2024) includes the following recommendations:[7]

- The panel does not recommend *BRAF* or NGS testing for resected stage I–II cutaneous melanoma unless it will inform clinical trial participation.
- *BRAF* mutation testing is recommended for patients with stage III at high risk for recurrence for whom future *BRAF*-directed therapy may be an option.
- For initial presentation with stage IV disease or clinical recurrence, obtain tissue to ascertain alterations in *BRAF*, and in the appropriate clinical setting, *KIT* from either biopsy of the metastasis (preferred) or archival material if the patient is being considered for targeted therapy. Broader genomic profiling (e.g., larger NGS panels, *BRAF* non-V600 mutations) is recommended if feasible, especially if the test results might guide future treatment decisions or eligibility for participation in a clinical trial.
- If *BRAF* single-gene testing was the initial test performed, and is negative, clinicians should strongly consider larger NGS panels to identify other potential genetic targets (e.g., *KIT*, *BRAF* non-V600).

The NCCN guidelines for central nervous system cancers (v.2.2024) state the following:[38]

- The panel encourages molecular testing of glioblastoma because if a driver mutation (such as *BRAF* V600E or *NTRK* fusion) is detected, it may be reasonable to treat with a targeted therapy on a compassionate use basis and/or the patient may have more treatment options in the context of a clinical trial.
- Molecular testing also has a valuable role in improving diagnostic accuracy and prognostic stratification that may inform treatment selection.

The NCCN guidelines for pediatric central nervous system cancers (v.1.2024) include a recommendation to test for *BRAF* V600E and *BRAF* fusion for pediatric gliomas, and further recommend that preferred systemic therapy options for recurrent disease include, but are not limited to, dabrafenib/trametinib or vemurafenib for *BRAF* V600E-positive tumors.[39]

SUMMARY

There is enough research to show that *BRAF* variant testing can improve health outcomes for some melanoma patients by helping them to select an FDA-approved targeted treatment. In addition, clinical practice guidelines recommend treatment with these BRAF inhibitors in certain patients with a V600 *BRAF* variant. Therefore, *BRAF* variant testing may be considered medically necessary to select treatment for patients with advanced, metastatic, or unresectable melanoma. Testing for *BRAF* variants for all other patients with melanoma is considered investigational, as there are no FDA-approved *BRAF*-targeted therapies for early-stage melanoma.

There is enough research to show that *BRAF* variant testing can improve health outcomes for some glioma patients by helping them to select an FDA-approved targeted treatment. In addition, clinical practice guidelines recommend treatment with these BRAF inhibitors in certain patients with a V600 *BRAF* variant. Therefore, *BRAF* variant testing may be considered medically necessary to select treatment for patients with glioma. Testing for *BRAF* variants for other purposes is considered not medically necessary.

Medical Policy Manual Genetic Testing, Policy No. 42

Assays of Genetic Expression in Tumor Tissue as a Technique to Determine Prognosis in Patients with Breast Cancer

Effective: April 1, 2025

Next Review: December 2025
Last Review: February 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

An important part of treatment planning for women with early-stage breast cancer involves evaluating the potential benefit from adjuvant therapies. Tests of genetic expression in tumor tissue have been proposed as techniques to determine prognosis (risk of recurrence) thereby providing additional information to guide treatment decisions for patients with breast cancer.

MEDICAL POLICY CRITERIA

Note: This policy does not address the identification of germ-line DNA alterations in genes (*BRCA1* and *BRCA2*) to provide information on future risk of hereditary breast or ovarian cancer. *BRCA1* and *BRCA2* testing is addressed in a separate medical policy (see Cross References).

I. The use of Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, or EndoPredict® to determine recurrence risk, for deciding whether or not to undergo adjuvant chemotherapy, may be considered **medically necessary** when all of the following criteria are met:

   A. Individual has primary breast cancer, stage I, II, or III (see Policy Guidelines);

   B. Individual has had excision of breast mass and full pathologic evaluation of the

specimen has been completed (i.e., the test should not be ordered on a preliminary core biopsy, however biopsy sample testing after full pathologic evaluation may be indicated in rare circumstances when tumor testing is not possible);

C. Primary tumor size greater than 0.5 cm;

D. Hormone receptor positive (that is ER-positive or PR-positive, see Policy Guidelines);

E. HER2-negative (see Policy Guidelines);

F. Individual has negative lymph nodes or 1 to 3 positive lymph nodes (nodes with micrometastases of 2 mm or smaller are considered node negative); and

G. Individual has not already made the decision to undergo or forego chemotherapy.

II. The use of Breast Cancer Index™ to determine recurrence risk, for deciding whether or not to receive extended endocrine therapy (beyond 5 years), may be considered **medically necessary** when all of the following criteria are met:

A. Individual has primary breast cancer, stage I, II, or III (see Policy Guidelines);

B. Individual has had excision of breast mass and full pathologic evaluation of the specimen has been completed (i.e., the test should not be ordered on a preliminary core biopsy, however biopsy sample testing after full pathologic evaluation may be indicated in rare circumstances when tumor testing is not possible);

C. Primary tumor size greater than 0.5 cm;

D. Hormone receptor positive (that is ER-positive or PR-positive, see Policy Guidelines);

E. HER2-negative (see Policy Guidelines);

F. Individual has negative lymph nodes or 1 to 3 positive lymph nodes (nodes with micrometastases of 2 mm or smaller are considered node negative); and

G. Individual has not already made the decision to undergo or forego extended endocrine therapy.

III. Use of Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, or EndoPredict® on surgical tumor specimens to determine recurrence risk in patients with primary breast cancer is considered **not medically necessary** for patients who do not meet Criterion I. or II. above.

IV. All other uses of gene expression assays for breast cancer are considered **investigational**, including but not limited to:

A. Use of Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, or EndoPredict® for predicting response to specific chemotherapy regimens or determining HER2 status.

B. Use of other assays of genetic expression in breast tumor tissue, including but not limited to BluePrint®, Mammostrat®, TargetPrint®, Oncotype Dx Breast DCIS Score, and Prosigna™/PAM50.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Ductal carcinoma in situ (DCIS) is considered stage 0 breast cancer and is therefore addressed in criterion III.

Hormone receptor and HER2 status may be determined from needle core biopsy or from the full pathological evaluation.

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test
    - History and physical exam
    - Conventional testing and outcomes, including full pathological report of excised breast mass

BACKGROUND

For patients with early-stage breast cancer, adjuvant chemotherapy provides the same proportional benefit regardless of prognosis. However, the absolute benefit of chemotherapy depends on the baseline risk for recurrence. For example, those with the best prognosis have small tumors, are estrogen receptor (ER)-positive, and lymph node-negative. These individuals have an approximately 15% baseline risk of recurrence; approximately 85% of these patients would be disease-free at 10 years with tamoxifen treatment alone and could avoid the toxicity of chemotherapy if they could be accurately identified. Conventional risk classifiers estimate recurrence risk by considering criteria such as tumor size, type, grade and histologic characteristics; hormone receptor status; and lymph node status. However, no single classifier is considered a gold standard, and several common criteria have qualitative or subjective

components that add variability to risk estimates. As a result, more patients are treated with chemotherapy than can benefit. Better predictors of baseline risk could help patients who prefer to avoid chemotherapy if assured that their risk is low, make better treatment decisions in consultation with their physicians.

Several panels of gene expression markers ("signatures") have been identified that appear to predict the baseline risk of breast cancer recurrence after surgery, radiation therapy, and hormonal therapy (for hormone receptor-positive tumors) in those with node-negative disease. The available gene expression tests include:

- Oncotype DX® Breast Recurrence Score (a 21-gene RT-PCR assay; Genomic Health)
- Oncotype DX® Breast DCIS Score
- 70-gene signature MammaPrint® (also referred to as the "Amsterdam signature"; Agendia)
- Mammostrat® (Clarient Diagnostic Services)
- Molecular Grade Index (Aviara MGI℠; AviaraDx, Inc.)
- Breast Cancer Index™, a combination of the Molecular Grade Index (MGI) and the HOXB13:IL17BR Index (bioTheranostics)
- BreastOncPx™ (Breast Cancer Prognosis Gene Expression Assay; LabCorp)
- Prosigna™ (NanoString Technologies)
- NexCourse® Breast IHC4 (Geneoptix)
- BreastPRS™ (Signal Genetics)
- EndoPredict® (Myriad Genetics)
- BluePrint® (Agendia)
- TargetPrint® (Agendia)

If these panels are more accurate than current conventional risk classifiers, they could be used to aid chemotherapy decision-making, where current guidelines do not strongly advocate its use, without negatively affecting disease-free and overall survival outcomes.

Oncotype DX® Breast DCIS Score, which uses a slightly different algorithm than the standard Oncotype DX® to calculate results, is marketed for patients with noninvasive, ductal carcinoma in situ (DCIS) to predict the 10-year risk of local recurrence (DCIS or invasive carcinoma). The stated purpose is to help guide treatment decision making in patients with DCIS treated by local excision, with or without adjuvant tamoxifen therapy.

Of note, gene expression profiling should not be ordered as a substitute for standard ER or progesterone receptor (PR) testing. Gene expression profiles to determine recurrence risk for deciding whether or not to undergo adjuvant chemotherapy should only be ordered after surgery and subsequent pathology examination of the tumor have been completed. The test should be ordered in the context of a physician-patient discussion regarding risk preferences and when the test result will aid the patient in making decisions regarding chemotherapy.

Gene expression patterns have led to the identification of molecular subtypes of breast cancer, which have different prognoses and responses to treatment regimens. These molecular subtypes are largely distinguished by the differential expression of estrogen receptors, progesterone receptors (PR) and human epidermal growth factor receptor 2 (HER2) in the tumor, and are classified as luminal, basal or HER2 type. Luminal-like breast cancers are ER positive, basal-like breast cancers correlate best with ER, PR and HER2 negative ("triple negative"), and HER2 type with high expression of HER2.

At present, the methodology for molecular subtyping is not standardized, and breast cancer subtyping is routinely assessed by immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH).

- BluePrint® is an 80-gene expression assay which classifies breast cancer into basal type, luminal type or ERBB2-type. The test is marketed as an additional stratification into a molecular subtype following risk assessment with MammaPrint®.
- TargetPrint® is a microarray-based gene expression test which offers a quantitative assessment of ER, PR and HER2 overexpression in breast cancer. The test is marketed to be used in conjunction with MammaPrint® and BluePrint®.

EVIDENCE SUMMARY

This evidence review focuses on gene expression profiling (GEP) panels that have prognostic or predictive ability in individuals with early-stage, invasive breast cancer with known ER, PR and HER2 status. The proposed clinical utility of these tests varies depending on the clinical context; specific areas of proposed clinical utility are discussed in this evidence review:

1. Prognosis in patients with node-negative, early-stage, HER2-negative invasive breast cancer who will receive adjuvant hormonal therapy for the purpose of determining whether patients can avoid adjuvant cytotoxic chemotherapy.

2. Prognosis in patients with node-positive (one to three nodes), early stage, HER2-negative invasive breast cancer who will receive adjuvant hormonal therapy for the purpose of determining whether patients can avoid adjuvant cytotoxic chemotherapy.

3. Prognosis in patients with node-negative, early-stage, HER2-negative invasive breast cancer, receiving adjuvant hormonal therapy, who have survived without progression to five years post-diagnosis, for the purpose of determining whether patients should continue adjuvant hormonal therapy.

4. Prognosis in patients with ductal carcinoma in situ (DCIS) for the purpose of selecting patients for radiation therapy.

Randomized controlled trials (RCTs) comparing health outcomes in women with primary breast cancer, who are managed *with* versus *without* gene expression profiling assays, are necessary to reliably establish the clinical utility of these assays.

In 2014, the Blue Cross and Blue Shield Association (BCBSA) Technology Evaluation Center (TEC) addressed gene expression profiling in women with lymph node-negative breast cancer to select adjuvant chemotherapy, specifically the use of Oncotype DX®, MammaPrint®, the Breast Cancer Index™, and Prosigna™/PAM50 gene expression assay.[1] This report did not address the use of gene expression profiling in women with lymph node-positive breast cancer to guide adjuvant chemotherapy. The TEC Assessment concluded that the use of Oncotype DX® to assess the risk of recurrence and to determine if a patient should undergo adjuvant chemotherapy in women with unilateral, hormone receptor-positive, lymph node-negative breast cancer, who will receive hormonal therapy, met the BCBSA TEC criteria. The TEC assessment also concluded that use of MammaPrint®, the Breast Cancer Index™, and Prosigna™ to determine recurrence risk in women with unilateral, hormone receptor-positive, lymph node-negative breast cancer who will receive hormonal therapy does not meet TEC criteria.

Since the TEC Assessment above, many studies have been published that have evaluated GEP testing for a variety of indications. This evidence review focuses on studies presenting a minimum of five-year distant disease recurrence rates, as well as recently published prospective studies specifically designed to evaluate the clinical utility of genetic expression profiles. Studies in which the gene expression algorithm was being developed ("training sets"), studies using convenience samples of patients, and observational studies based on registry data were not included.

ONCOTYPE DX® BREAST RECURRENCE SCORE

Oncotype DX® Breast Recurrence Score is available only from the CLIA-licensed Genomic Health laboratory as a laboratory-developed service, as it has not been cleared or approved by the FDA. Results from the Oncotype DX® gene expression profile are combined into a recurrence score (RS). Tissue sampling, rather than technical performance of the assay, is likely to be the greatest source of variability in results. The Oncotype DX® assay was validated in studies using archived tumor samples from subsets of patients enrolled in published RCTs of early breast cancer treatment. Patients enrolled in the trial arms, from which specimens were obtained, had primary, unilateral breast cancer with no history of prior cancer, and were treated with tamoxifen. Tumors were estrogen receptor positive, most were HER2-negative, and in the case of at least one study, multifocal tumors were excluded.[2]

Oncotype DX® RS for Adjuvant Chemotherapy Decisions in Lymph Node-Negative Patients

As described above, the 2014 BCBSA TEC Assessment concluded that the following circumstance meets the TEC criteria: Use of Oncotype DX® to determine recurrence risk in women with unilateral, hormone receptor-positive, lymph node-negative breast cancer, who will receive hormonal therapy, and are deciding whether to undergo adjuvant chemotherapy.[1] In the AHRQ Technology Assessment described above, the 16 studies included in the assessment uniformly examined cohorts with hormone-receptor positive breast cancer, and most were limited to women with node-negative cancers.[3] Additional studies have evaluated the association between RS and recurrence risk in node-negative patients.[4-7] Results indicate strong, independent associations between Oncotype DX® RS results and distant disease recurrence or death from breast cancer.[6, 8]

Sparano (2018) conducted a RCT, Trial Assigning Individualized Options for Treatment (TAILORx), to evaluate risk of recurrence in women with midrange scores.[9] Women with intermediate-risk scores were randomized to receive either endocrine therapy (n=3,399) or chemoendocrine therapy (n=3,312). Women with low-risk scores (≤10) received endocrine therapy (n=1,619) and women with high-risk scores (≥26) received chemoendocrine therapy (n=1,389). Overall disease-free survival (DFS) estimates showed that adjuvant endocrine therapy was noninferior to chemoendocrine therapy in women with intermediate-risk scores (DFS 83.36% vs. 84.3%, respectively). However, subgroup analyses by age showed women younger than 50 may benefit from chemotherapy.

In secondary analyses of data published by Paik (2004), patient risk levels were individually classified by conventional risk classifiers, and then reclassified by Oncotype DX®.[4] Oncotype DX® added additional risk information to the conventional clinical classification of individual high-risk patients, and identified a subset of patients who would otherwise be recommended for chemotherapy, but are actually at lower risk of recurrence (average 7% to 9% risk at 10 years, upper 95% confidence interval [CI] limits 11% to 15%). Thus, a woman who prefers to

avoid the toxicity and inconvenience of chemotherapy and whose Oncotype DX® RS value shows that she is at very low risk of recurrence, might reasonably decline chemotherapy. The lower the RS value, the greater the confidence that chemotherapy will not provide net benefit; outcomes are improved by avoiding chemotherapy toxicity.

In another RCT, samples were obtained from ER-positive, node-negative breast cancer patients, who were either treated with tamoxifen or tamoxifen plus chemotherapy, and were tested by Oncotype DX®.[2] RS high-risk patients derived clear benefit from chemotherapy, whereas the average benefit for other patients was statistically not significant.

Because clinical care for breast cancer patients has evolved since the original trials that required archived samples for assay validation, differences in evaluation and treatment regimens were considered. It was concluded that Oncotype DX® meets the TEC criteria for the following women with node-negative breast cancer:

- Those receiving aromatase inhibitor (AI)-based hormonal therapy instead of tamoxifen therapy. AI-based therapy would likely reduce recurrence rates for all RS risk groups. Thus, if a patient declined chemotherapy today on the basis of a low-risk RS (risk categories defined by outcomes with tamoxifen treatment), the even lower risk associated with AI treatment would not change that decision.
- Those receiving anthracycline-based chemotherapy instead of CMF. The type of chemotherapy does not change the interpretation of the Oncotype DX® risk estimate. Additionally, a recent meta-analysis indicates that anthracyclines do not improve disease-free or overall survival in women with early HER2-negative breast cancer[10], and therefore may not be prescribed in this population.
- Lymph nodes with micrometastases are not considered positive for purposes of treatment recommendations.[11] Current practice largely involves a detailed histologic examination of sentinel lymph nodes allowing for the detection of micrometastases (< 2 mm in size).
  Those whose tumors are ER-positive or PR-positive. Only ER-positive women were enrolled in Oncotype DX® validation studies, whereas current clinical guidelines include either ER or PR positivity in the treatment pathway for hormone receptor positive women with early-stage breast cancer. Recent studies show that ER-negative, PR-positive patients also tend to benefit from hormonal therapy.[12, 13] Studies documenting the low incidence (1% to 4%) and instability (lack of reproducibility) of the ER-negative/PR-positive subtype[14] and the reduction in reports of this subtype with improved assay techniques[15] suggest that this subtype may represent a false-negative result.

Several nonrandomized studies reporting on the use of the 21-gene assay in lymph-node negative patients have been published[16, 17], including a prosepective study by Sparano (2015) that assigned women with a recurrence score of 0 to 10 to receive endocrine therapy without chemotherapy.[18] At five-years follow-up, 1,626 women with low recurrence scores were included in the analysis. In this patient population, the rate of invasive disease–free survival was 93.8% (95% CI 92.4 to 94.9), the rate of freedom from distant disease was 99.3% (95% CI 98.7 to 99.6), and the rate of freedom from recurrence of breast cancer at a distant or local–regional site was 98.7% (95% CI 97.9 to 99.2). Kizy (2017) evaluated the use of the of Oncotype DX® in women with invasive lobular carcinoma, using data from the Surveillance, Epidemiology and End Results database from 2004 to 2013.[19] There were 7,316 participants included in the study, the majority with grade I or II tumors (93%) and negative lymph nodes (85%). The RS cutpoints used for most of the analyses were 11 and 25, values used in the Trial Assigning Individualized Options for Treatment (TAILORx) to avoid undertreatment. Using

these conservative cutpoints, 8% of the participants were categorized as high-risk, and 72% as intermediate risk. Adjuvant chemotherapy was not associated with any increased five-year BCSS in these high- and intermediate-risk groups.

Several studies have been published regarding the impact of RS results on chemotherapy recommendations by medical oncologists.[20-28] According to these studies, comparing recommendations made prior to and revised after knowledge of RS results show that decisions change in about 25-61% of patients, most often from endocrine therapy plus chemotherapy to endocrine therapy alone.

Oncotype DX® RS for Adjuvant Chemotherapy Decisions in Lymph Node-Positive Patients

In a systematic review partly funded by Genomic Health, Brufsky (2014) [29] assessed articles and abstracts, that evaluated the 21-gene breast cancer profiling assay (using RT-PCR technology) in patients with ER+ and node-positive early-stage breast cancer. Study results suggested that the RS is an independent predictor of disease-free survival, overall survival, and distant recurrence-free survival. Overall, these studies showed that in 26% of 51% of N+ cases, physicians used results of the RS assay to reassess patient status and ultimately change their treatment recommendations. In 60% to 66% of node-negative and node-positive cases, changes in treatment recommendations resulted in the elimination of chemotherapy.

Despite some favorable results of clinical utility, accompanied by author recommendations supporting the use of RS, the overall quality of the review was hampered by several methodological limitations, for example, study authors did not clearly report the systematic methodology used to conduct the literature search, such as details of the literature search criteria or inclusion and exclusion criteria used during the study selection process. In addition, they did not report assessing the quality of the individual clinical studies nor the body of evidence. Authors included abstracts presented at international congresses for detailed evidence review; however, results of these abstracts have yet to be accepted and published by a peer-reviewed journal. Hence, these various limitations substantially weaken the confidence in the findings that support clinical utility of the 21-gene assay in women with node-positive, early-stage breast cancer.

Kalinsky (2021) reported results from the RxPONDER RCT.[30] Participants with hormone-receptor–positive, HER2-negative breast cancer, one to three positive axillary lymph nodes, and a RS of 25 or lower were randomized to endocrine therapy only or to chemotherapy plus endocrine (chemoendocrine) therapy. The primary objective was to determine the effect of chemotherapy on invasive disease–free survival and whether the effect was influenced by the RS. Secondary end points included distant relapse–free survival.

Among postmenopausal women, estimates of invasive disease–free survival at five years were 91.3% in the chemoendocrine group and 91.9% in the endocrine-only group (hazard ratio [HR] 1.02 for invasive disease recurrence, new primary cancer [breast cancer or another type], or death, 95% CI 0.82 to 1.26, p=0.89). In premenopausal women, the rate of invasive disease–free survival at five years among those in the chemoendocrine group was 93.9%, as compared with 89.0% among those in the endocrine-only group (absolute difference, 4.9 percentage points), with a significant chemotherapy benefit (HR 0.60 for invasive disease recurrence, new primary cancer [breast cancer or another type], or death, 95% CI 0.43 to 0.83, p=0.002). The study authors concluded that postmenopausal women with one to three positive axillary lymph nodes and a recurrence score of 0 to 25 could “safely forgo adjuvant chemotherapy without

compromising invasive disease–free survival and distant relapse–free survival." In contrast, premenopausal women with one to three positive lymph nodes "had a significant benefit from chemotherapy, even with a very low recurrence score." A follow-up study by Abdou (2024) found that non-Hispanic Black participants in the study had worse clinical outcomes that non-Hispanic White participants, despite having similar RS scores and similar treatment.[31]

Nitz (2017) conducted a phase 3 Plan B trial with a mixed population of women with node-negative and node-positive breast cancer.[32] The trial was initially designed to compare anthracycline-containing chemotherapy with anthracycline-free therapy. An amendment was made to recommend endocrine therapy alone for patients with an RS of 11 or less that were node-negative or had only one positive node. A total of 2,642 patients were included in the trial. Median age was 56 years, 59% were node-negative, 35% had one positive nodes, and 6% had two or three positive nodes. Details of subgroup analyses of node-positive patients were limited. The authors stated that five-year overall survival in patients with an RS between 12 and 25 was significantly higher than in patients with an RS greater than 25 within all nodal subgroups and that five-year overall survival in low RS patients was higher compared with high RS patients in all nodal subgroups, but rates and CIs were not provided. Five-year DFS in patients with one positive node and a RS ≤11 treated with endocrine therapy alone (n=110) was 94.4% (95% CI 89.5 to 99.3%). The final analysis of the Plan B trial reported similar results regarding RS scores and DFS.[33]

Albain (2010) published retrospective analysis of the OncotypeDX® assay.[34] Study results showed that patients with high RS scores appeared to achieve greater benefit from the addition of chemotherapy than patients with low RS scores, regardless of the total number of affected lymph nodes. In the multivariate analysis of RS interaction with disease-free survival, adjusted for number of positive nodes, was significant for the first five years of follow-up (p=0.029) and remained significant after adjusting for age, race, tumor size, PR status, grade, p53, and HER2. However, the interaction was not significant (p=0.15) after adjusting for ER level (ER gene expression is a component of the 21-gene profile). Interaction results were similar for overall survival.

Additional Applications of Oncotype DX®

In 2008, Genomic Health announced that results of Oncotype DX® tests would include not only the overall test results, but also the results of the quantitative ER and PR tests that are included in the Oncotype DX® panel. This is based on a study that compared the Oncotype DX® ER and PR results with traditional immunohistochemistry (IHC) results.[35] The study reported high concordance between the two assays (90% or better), but that quantitative ER by Oncotype DX® was more strongly associated with disease recurrence than the IHC results. However, ER and PR analyses are traditionally conducted during pathology examination of all breast cancer biopsies, whereas Oncotype DX® is indicated only for known ER-positive tumors, after the pathology examination is complete, when the patient meets specific criteria and chemotherapy is being considered. Thus, Oncotype DX® should not be ordered as a substitute for ER and PR IHC. Additionally, accepted guidelines for ER and PR testing outline standards for high quality IHC testing and do not recommend confirmatory testing, so the 21-gene RS should not be ordered to confirm ER/PR IHC results. A subsequent study by Khoury (2015) reported better correlation between IHC and Oncotype DX® for PR (Spearman correlation, 0.91) than for ER (Spearman correlation, 0.65), but worse concordance (at various cutpoints) for PR than for ER (99% vs 88%, respectively).[36]

Similarly, guidelines for HER2 testing specify IHC and/or FISH methods.[37] Although the HER2 component of the 21-gene assay has been shown to strongly correlate with FISH results,[38] the 21-gene assay should not be ordered to determine or confirm HER2.

MAMMAPRINT®

MammaPrint® has received 510(k) clearance for marketing by the FDA as a prognostic test for women younger than 61 years with ER-positive or ER-negative, lymph node-negative breast cancer. It is approved to assist in categorizing these breast cancer patients into high versus low risk for recurrence, but it is not approved for predicting benefit from adjuvant chemotherapy.

Mammaprint® for Adjuvant Chemotherapy Decisions

The Microarray In Node-Negative and 1 to 3 Positive Lymph Node Disease May Avoid Chemotherapy (MINDACT trial) published by Cardoso (2016), was a prospective trial that enrolled 6,693 women with early-stage breast cancer and assessed their genomic risk using MammaPrint® and their clinical risk using a modified version of Adjuvant! Online for cancer recurrence.[39] Women at low risk according to both methods did not receive chemotherapy. Women with discordant risks were randomized to chemotherapy or to no chemotherapy. Women at high-risk with both methods received chemotherapy. Although there were randomized components of the study, the primary endpoint was a noninferiority outcome of five-year metastasis-free survival rate in one cohort of the study population: those with high clinical risk and low genomic risk who did not receive chemotherapy. Declaring this to be the main end point implies a clinical strategy of using MammaPrint® only in patients at high clinical risk, and deferring chemotherapy in those tested patients who have low genetic risk scores. In this strategy, patients at low clinical risk are not tested with MammaPrint®.

While trial entry criteria included patients with node-positive, estrogen receptor-negative, or *HER2*-positive breast cancer, these patients constituted a minority of those in the study. The main results included these patients. The authors conducted supplemental analyses of various subgroups, including the subset who were node-negative, estrogen receptor-positive, or *HER2*-negative, which were qualitatively similar to the published main results.

In the main article, the principal objective of the study was met. The group at high clinical risk and low genomic risk who did not receive chemotherapy had a distant recurrence rate of 5.3% (95% CI 3.8% to 7.5%). In the node-negative, estrogen receptor-positive, or *HER2*-negative subgroup analysis, this group had a distant recurrence rate of 4.5% (95% CI, 3.8% to 8.4%). Piccart (2021) reported updated results from MINDACT with a median follow-up of 8.7 years.[40] In the updated analysis, five-year distant metastasis-free survival rate for individuals with high clinical risk and low genomic risk receiving no chemotherapy (primary test population, n=644) was 95.1% (95% CI 93.1% to 96.6%), supporting the previous analysis.

In the group with clinical low-risk and high genomic risk, who were not considered in the main outcome, in both the main analysis and in the node-negative, estrogen receptor-positive, or *HER2*-negative subgroup, the results would indicate that the risk of distant recurrence is not low enough to avoid chemotherapy (main analysis distant recurrence 5%, 95% CI 3% to 8.2%, subgroup distant recurrence HR 6.1%, 95% CI 3.9% to 9.4%). In the testing strategy implied in this study, by not testing for genomic risk in the low clinical risk group, these patients would not be identified.

The groups randomized to chemotherapy showed no significant difference in five-year distant recurrence, but the CIs were wide and thus less informative regarding whether chemotherapy is or is not beneficial in these patient groups. In the main study, the HR for chemotherapy in the high clinical risk/low genomic risk was 0.78 (95% CI 0.5 to 1.21). The HR for chemotherapy in the low clinical risk/high genomic risk group was 1.17 (95% CI 0.59 to 2.28).

To assess the impact of MammaPrint® on treatment decision-making, Cusumano (2014) distributed clinical information on 194 patients to multidisciplinary teams initially without and then with MammaPrint® gene signatures.[41] Eighty-six percent of patients were ER-positive, 88% were HER2-negative, and 66% were lymph node-negative. With the addition of MammaPrint® signatures, treatment recommendations changed in 27% of patients: 22% from chemotherapy to no chemotherapy and 35% from no chemotherapy to chemotherapy. In the subset of 453 ER-positive, HER2-negative patients, treatment advice changed in 32% of patients, with similar proportions changing from chemotherapy to no chemotherapy and vice versa.

Mammaprint® for Extended Endocrine Therapy Decisions

Esserman (2017) conducted a secondary analysis on data from women who were node-negative, in the Stockholm tamoxifen trial, which randomized patients with node-negative breast cancer to two years of tamoxifen, followed by an optional randomization for an additional three years to tamoxifen or no treatment.[42] A total of 652 tissue samples from the trial underwent MammaPrint® risk classification, 313 from the tamoxifen arm and 339 from the no therapy arm. The primary outcome was 20-year breast cancer-specific survival (BCSS). Initial classification by MammaPrint® identified 58% of the patients as low risk for distant recurrence and 42% as high risk. Twenty-year BCSS rates were 85% and 74% ($p<0.001$), respectively. Analysis was conducted on a subgroup of the low-risk group, considered ultralow risk. The tamoxifen-treated ultralow-risk group did not experience any deaths at 15 years. Survival rates were high for all patients in the ultralow-risk group, 97% for those treated with tamoxifen and 94% for those untreated.

BREAST CANCER INDEX™ (BCI)

The Breast Cancer Index™ is a simultaneous assessment of the HOXB13:IL17BR (H/I) ratio and the MGI (Molecular Grade Index). The H/I ratio indicates estrogen-mediated signaling; MGI assesses tumor grade by measuring the expression of five cell-cycle genes and provides prognostic information in ER-positive patients regardless of nodal status.

Breast Cancer Index™ for Adjuvant Chemotherapy Decisions

The 2014 TEC Assessment reviewed available studies for the original component assays.[1] There was insufficient evidence to determine whether the H/I ratio is better than conventional risk assessment tools in predicting recurrence. The ten-year recurrence estimates for patients classified as low risk were 17% to 25%, likely too high for most patients and physicians to consider forgoing chemotherapy.

Schroeder (2017)[43] calculated distant recurrence-free survival rates following five years of endocrine therapy among the subset of patients with clinically low-risk (T1N0) breast cancer from the two populations studied by Zhang (2013), described below. The Stockholm trial had 237 patients, and the U.S. medical center cohort contributed 210 patients that were T1N0. BCI classified 68% (160/237) and 64% (135/210) of the Stockholm population and the medical

center population as low risk, respectively. Median follow-up was 17 years for the Stockholm study and 10 years for the medical center cohort. Among the BCI high-risk, HER2-negative participants, the 5- to 15-year distant recurrence-free survival rates in the Stockholm trial and the multi-institutional study were 86.9% (95% CI 78.8% to 95.9%) and 87.5% (95% CI 79.1% to 96.9%), respectively. The rates in the low-risk, HER2-negative groups were 95.2% (95% CI 91.9% to 98.8%) and 98.4% (95% CI 96.1% to 100%), respectively.

A retrospective study by Sgroi (2016) evaluated the use of the BCI in samples from the NCIC MA.14 clinical trial of tamoxifen alone vs. tamoxifen plus octreotide in postmenopausal women with early breast cancer.[44] A total of 292 samples from banked tumor blocks were assayed: 146 from each treatment arm. BCI was categorized as high-risk (BCI ≥ 6.4), intermediate risk (5 ≤ BCI < 6.4), and low risk (BCI < 5). These risk groups were associated with adjusted 10-year relapse-free survival, which was 87.5% in the low-risk group, 83.9% in the intermediate-risk group, and 74.7% in the high-risk group. There was no significant interaction between BCI and treatment group. Because most lymph node-positive patients received chemotherapy, the prognostic utility of BCI could not be assessed for those patients.

Zhang (2013) evaluated a continuous risk model derived from the H/I ratio and MGI in tumor samples from the Stockholm tamoxifen cohort; n=317), along with additional samples from a multi-institutional registry of ER-positive, lymph node-negative patients (n=358), 32% of whom received adjuvant chemotherapy.[45] An optimized continuous recurrence risk model, the Breast Cancer Index™ model, was built using patients from the untreated arm of the Stockholm cohort as a training set. Samples from the endocrine therapy arm of the Stockholm trial and from the multi-center registry were used for the validation studies. The Stockholm validation set included 7% HER2-positive samples and the multicenter registry included 12% HER2-positive samples. The overall 10-year distant recurrence rates for the BCI low, intermediate, and high risk groups in the Stockholm cohort were 4.8% (95% CI 1.7% to 7.8%), 11.7% (95% CI 3.1% to 19.5%), and 21.1% (95% CI 15.3% to 32.0%), respectively, while the 10-year distant recurrent rates for these groups in the multi-center registry were 6.6% (95% CI 2.9% to 10%), 23.3% (95% CI 12.3% to 33%), and 35.8% (95% CI 24.5% to 45.5%), respectively.

Breast Cancer Index™ for Endocrine Therapy Decisions

Sgroi (2013) examined 665 lymph node-negative, ER-positive, postmenopausal women receiving endocrine therapy but no chemotherapy in the ATAC trial.[46] In this group, approximately 10% of samples were HER2+. Two versions of the Breast Cancer Index (BCI) score were generated in the study: the BCI-C, based on cubic combinations of the variables, and the BCI-L, based on linear combinations of the variables. The BCI-L, which is the model used in the development studies by Zhang (2013) described above and represents the commercial version of the BCI, was more effective than the BCI-C at risk discrimination. The overall 10-year distant recurrence rates for the BCI-L low, intermediate, and high-risk groups were 4.8% (95% CI 3.0% to 7.6%), 18.3% (95% CI 12.7% to 25.8%), and 29.0% (95% CI 21.1% to 39.1%), respectively. For patients in the low- and intermediate-risk groups, 10-year distant recurrence risks were similar, regardless of endocrine treatment (tamoxifen, anastrozole, or both).[46] In the high-risk group, recurrence risk was lowest (22%) for patients taking anastrozole only and highest for patients taking tamoxifen only (37%), although these groups were small (54 and 55 patients, respectively).

Sgroi (2013) conducted a prospective-retrospective, nested case-control study within the

MA.17 trial that compared extended endocrine therapy (letrozole) with placebo in postmenopausal women who had hormone receptor-positive cancers.[47] The trial randomized 5,157 women recurrence-free at five years to letrozole or placebo. A case-control design was adopted owing to challenges in obtaining archived tumor samples. An eligible case (319 of which 83 were examined) was one that experienced a local, regional, or distant recurrence and had an available tumor sample. Two controls free of recurrence longer than cases were matched to each case based on age, tumor size, node status, and prior chemotherapy. Any recurrence (locoregional or distant) was used as the endpoint; patients with contralateral or unknown recurrences were excluded. Using the BCI H/I ratio, there was a 42% relative risk reduction in the low-risk group vs. a 77% reduction in the high-risk group. Although statistical significance was lacking in the low-risk group, the CIs were wide and included values consistent with those observed in the high-risk group. The Zhang (2013) study described above,[45] as well as studies by Bartlett (2019)[48] and Noordhoek (2021)[49] also reported a larger potential relative risk reduction with extended endocrine therapy in the H/I high-risk group, with similar uncertainty reflected in the CIs (HR 0.35, 95% CI 0.19 to 0.65; HR 0.35, 95% CI 0.15 to 0.86; and HR 0.34, 95% CI 0.16 to 0.73, respectively).

ONCOTYPE DX® DCIS

Ductal carcinoma in situ (DCIS) is the presence of abnormal cells inside a milk duct in the breast. DCIS is considered the earliest forms of breast cancer and is noninvasive. DCIS requires treatment to prevent the condition from becoming invasive and most women diagnosed with DCIS are effectively treated with breast-conserving surgery and radiation. DCIS diagnosis accounts for about 20% of all newly diagnosed invasive plus noninvasive breast tumors. Recommended treatment is lumpectomy with or without radiation treatment; post-surgical tamoxifen treatment is recommended for ER-positive DCIS, especially if excision alone is used. The overall rate recurrence following DCIS diagnosis is less than 30% and usually occurs within 5 to 10 years after initial diagnosis.

The Oncotype DX® DCIS test uses information from 12 of the 21 genes assayed in the standard Oncotype DX® test for early breast cancer. Scaling and category cut-points are based on an analysis of DCIS Score results from a separate cohort of patients with DCIS; this study has not yet been published and is available only as a meeting abstract.[50]

In a retrospective analysis, Rakovitch (2015) evaluated 571 tumor specimens with negative margins from a convenience cohort of patients with DCIS treated by breast-conserving surgery (lumpectomy) alone.[51] Patients were drawn from a registry of 5752 women in Ontario, Canada, who were diagnosed with DCIS between 1994 and 2003. Median follow-up of the 571 women was 9.6 years. There were 100 local recurrence events (18% prevalence); 43 were DCIS (8% prevalence), and 57 were invasive cancer (10% prevalence). Oncotype DX® DCIS score was significantly associated with local recurrence outcomes (HR 2.15, 95% CI 1.43 to 3.22). Sixty-two percent of patients were classified as low-risk, 17% as intermediate risk, and 21% as high risk. Corresponding 10-year local recurrence estimates were 13% (95% CI 10% to 17%), 33% (95% CI 24% to 45%), and 28% (95% CI 20% to 38%), respectively. Corresponding 10-year estimates for DCIS recurrence (5%, 95% CI 3% to 9%; 14%, 95% CI 8% to 24%; 14%, 95% CI 9% to 22%; respectively) and for invasive breast cancer recurrence (8%, 95% CI 6% to 12%; 21%, 95% CI 13% to 33%; 16%, 95% CI 9% to 25%; respectively) were based on small numbers of events. It is unclear whether estimated recurrence risks for patients classified as low risk are low enough to forgo radiotherapy.

In a retrospective analysis of data and samples from patients in the prospective Eastern Cooperative Oncology Group E5194 study by Solin (2013), the Oncotype DX® Score for DCIS was compared with the 10-year recurrence risk in a subset of DCIS patients treated only with surgery and some with tamoxifen (n=327).[52] Oncotype DX® DCIS Score was significantly associated with recurrence outcomes (HR 2.31, 95% CI 1.15 to 4.49, p=0.02) whether or not patients were treated with tamoxifen. The standard Oncotype DX® Score for early breast cancer was not associated with DCIS recurrence outcomes. The standard Oncotype DX® Score for early breast cancer was not associated with DCIS recurrence outcomes.

Rakovitch (2018) combined the populations from the two studies described above (Solin [2013] and Rakovitch [2015]) and calculated 10-year local recurrence rates by DCIS category (low, intermediate, and high), age, tumor size, and year of diagnosis.[53] Ten-year recurrence rates in the low risk score group ranged from 7.2% (95% CI 5.3% to 10.0%) for those age 50 and above with tumors ≤1 cm to 11.6% (95% CI 7.7% to 15.5%) for those with tumors > 2.5 cm.

DCISIONRT®

The DCISionRT test combines seven monoclonal protein markers (COX-2, FOXA1, HER2, Ki-67, p16/INK4A, PR, and SIAH2) assessed in tumor tissue with four clinicopathologic factors (age at diagnosis, tumor size, palpability, and surgical margin status) to produce a score that stratifies individuals with DCIS into three risk groups: low risk, elevated risk with good response, and elevated risk with poor response. The purpose of the test is to predict radiation benefit in individuals with DCIS following breast conserving surgery.

Warnberg (2021) analyzed the association of DCIS RT score with risk of recurrence in 504 individuals with DCIS enrolled in the SweDCIS randomized trial.[54] This study is Simon Category B. Using a cutoff of DS >3, 52% of participants were categorized as elevated risk and 48% as low risk. In the low-risk group, there was no significant difference in risk of recurrence observed with radiotherapy. In contrast, radiotherapy was associated with reduced risk of total and invasive ipsilateral recurrence in the elevated-risk group.

PROSIGNA™/ PAM50 BREAST CANCER INTRINSIC SUBTYPE CLASSIFIER

PAM50 Breast Cancer Intrinsic Classifier, a qRT-PCR test based on a panel of 50 genes, was developed to identify the breast cancer intrinsic subtypes known as luminal A, luminal B, HER2-enriched, and basal-like, and to generate risk-of-relapse scores in node-negative patients who had not had systemic treatment for their cancer. Prosigna™ evolved from the PAM50 test and uses NanoString's nCounter platform[55] in place of qRT-PCR to assay 46 genes instead of the original 50. The 2014 TEC Assessment reviewed development and validation studies of the PAM50 intrinsic subtype classifier and Prosigna™.[1]

In a study that supported FDA clearance of Prosigna™, Gnant (2014) evaluated tumor samples from 1,047 lymph node-negative patients who participated in the Austrian Breast and Colorectal Cancer Study Group's trial 8 (ABCSG-8); this represented 28% of the original trial sample.[56] ABCSG-8 randomized hormone receptor-positive, postmenopausal women with early-stage breast cancer to five years of endocrine adjuvant therapy, either tamoxifen for five years or tamoxifen for two years followed by anastrozole for three years. Adjuvant or neoadjuvant chemotherapy was not allowed. Both PAM50 subtype and Prosigna™ ROR class were associated with 10-year distant recurrence-free survival, with CIs that overlapped slightly or not at all. Lower confidence limits for women in the luminal A and low-risk groups were

around 94%, and upper confidence limits for luminal B and high-risk groups were approximately 90%. That is, the risk distinction seemed clinically useful.

Dowsett (2013) reported on groups from the ATAC trial stratified by subtype (luminal A or B) and by PAM50 ROR class, both with and without consideration of clinicopathologic factors.[57] Among 739 lymph node-negative patients, 10-year distant recurrence-free survival was 94% in 529 luminal A patients and 75% in 176 luminal B patients, and was comparable with low- and high-risk ROR groups with or without clinical factors: 95%, 85%, and 70% in low-, intermediate-, and high-risk groups, respectively. An ROC analysis in 649 lymph node-negative, HER2-negative patients showed that PAM50 plus clinical factors had greater discriminatory ability than either risk predictor alone. In this study, the commercial assay was performed on 46 of the PAM50 genes (ROR46). Because proliferation-associated genes are given special weighting to produce the Prosigna™ ROR score, it is unclear how closely ROR46 approximated the marketed test; the authors reported a correlation of 0.9989 between ROR50, which incorporated all PAM50 genes, and ROR46 risk classifications.

Two studies published in 2015 presented combined analyses of pretreatment FFPE tumor specimens from ABCSG-8 and ATAC trial monotherapy arms (TransATAC).[58, 59] Median follow-up was 10 years. Sestak (2015) examined the association between ROR score and late distant recurrence (5 to 10 years after diagnosis) in 2,137 postmenopausal women (60% from ABCSG-8).[58] Patients had HR–positive invasive breast cancer treated with only endocrine therapy (anastrozole or tamoxifen; no chemotherapy) for five years without recurrence. The majority of patients (74%) had node-negative disease (87% of patients with node-positive disease had one to three positive lymph nodes), and 92% were HER2-negative. ROR score was determined using a 46-gene subset of the PAM50 genes plus tumor size. Cutpoints differed from cutpoints used in the FDA-approved version of the test, designed to assess recurrence risk in the first 10 years after diagnosis (years 0 to 10). In this study, ROR score less than 26 identified patients with low risk of distant recurrence (<10% risk); ROR score 26 to 68 identified patients with intermediate risk (10% to 20% risk); and ROR score greater than 68 identified patients with high risk (>20% risk) in both node-negative and node-positive patients. Fifty-five percent of women were categorized as low risk, 25% as intermediate risk, and 20% as high risk. Kaplan-Meier estimated risks for late distant recurrence (between five and 10 years) in node-negative patients were 2.3% (95% CI 1.3 to 3.5), 8.5% (95% CI 5.9 to 12.1), and 9.3% (95% CI 5.5 to 15.5), respectively. In node-positive patients, estimated risks were 3.3% (95% CI 1.2 to 8.6), 7.8% (95% CI 4.4 to 13.8), and 20.9% (95% CI 16.1 to 26.9) in low-, intermediate-, and high-risk groups, respectively. It is worth noting that prediction of 10-year survival contingent on five-year survival without recurrence is not informative for treatment decisions at the time of diagnosis.

The other study, by Gnant (2015), evaluated FFPE tissue specimens from 543 patients in the ABCSG-8 and ATAC trials who had one to three positive lymph nodes.[59] The primary endpoint was distant recurrence-free survival, defined as the interval from randomization until distant recurrence or death due to breast cancer. Investigators developed a Clinical Treatment Score (CTS) that integrated nodal status, tumor size, histopathologic grade, patient age, and type of endocrine therapy received (anastrozole or tamoxifen) into a summary score.[60] Risk classification by CTS was compared with and without ROR in subsets of patients with one positive lymph node (n=331) and with two to three positive lymph nodes (n=212). ROR cutpoints for defining risk groups differed from cutpoints used in the FDA-approved version of the test, which were defined by Gnant (2014),[56] discussed below. Among patients with one positive node, 40% were categorized as low risk, 32% as intermediate risk, and 28% as high

risk. Kaplan-Meier estimates for 10-year distant recurrence or death from breast cancer were 6.6% (95% CI 3.3% to 12.8%), 15.5% (95% CI 9.5% to 25.0%), and 25.5% (95% CI 17.5% to 36.0%), respectively. Because the upper bound of the 95% CI for patients categorized as low risk exceeded 10%, usefulness of these risk distinctions is uncertain. For patients with two or three positive nodes, low and intermediate risk groups were combined due to small numbers of patients and events in the low-risk group; 39% of patients were categorized as low/intermediate risk, and 61% were categorized as high risk. The 10-year distant RFS estimates were 12.5% (95% CI 6.6% to 22.8%) and 33.7% (95% CI 25.5% to 43.8%), respectively. When ROR, either as a continuous or a categorical variable, was added to CTS, prognostic information was improved (changes in likelihood ratios were statistically significant) compared with CTS alone for all nodal subgroups, including node-negative patients.

Sestak (2013) reported on the prognostic ability of PAM50 ROR score in 940 (16%) of 5880 patients from the ATAC trial.[61] Thirty percent of patients were lymph node positive. Investigators modified the ROR scoring algorithm to exclude tumor size and defined cutpoints by the median for each outcome; patients were segregated into two rather than three risk classes. These modifications have not been validated and may increase considerably the risk of misclassification bias. Two outcomes were examined, distant recurrence during the first five years after completion of hormone therapy and after five years (up to 10 years). For the latter, the number of patients at risk at the start of the interval was not reported; in the first five years, 71 distant recurrences occurred. Finally, estimated uncertainty (e.g., variance) was not reported for either outcome. Although distant recurrence-free survival was longer in the low-risk than in the high-risk group, given the methodological flaws of the study, the meaning of these results is uncertain.

Hequet (2017)[62] and Martin (2015)[63] evaluated the impact of ROR on treatment decision making in patients with ER-positive, HER2-negative, node-negative breast cancer. Because survival or recurrence outcomes were not reported, these studies are considered uninformative for assessing clinical utility of Prosigna™.

The majority of PAM50/Prosigna™ studies suffered from confounding due to heterogeneous patient samples. It is therefore difficult to estimate outcomes for the patients of interest: ER-positive, HER2-negative, lymph node-negative patients not receiving chemotherapy. In addition, studies reporting 10-year outcomes have not consistently used the commercially available version of the test or used standardized cutpoints for risk category determination. This inconsistency limits the conclusions that can be drawn regarding the potential clinical utility of this test.

BLUEPRINT® AND TARGETPRINT®

Gene expression patterns have led to the identification of molecular subtypes of breast cancer, which have different prognoses and responses to treatment regimens. These molecular subtypes are largely distinguished by differential expression of ER, PR, and HER2 in the tumor, and are classified as luminal, basal, or HER2 type. Luminal type breast cancers are ER-positive; basal type breast cancers correlate best with ER-, PR-, and HER2-negative (“triple negative”) tumors, and HER2 type, with high expression of HER2.

BluePrint® is an 80-gene expression assay that classifies breast cancer into basal type, luminal type or HER2 type. The test is marketed as an additional stratifier into a molecular subtype after risk assessment with MammaPrint®. BluePrint® classifies breast cancer into basal type, luminal type or ERBB2 type. TargetPrint® is a microarray-based gene expression

test that offers a quantitative assessment of ER, PR and HER2 overexpression in breast cancer. Both BluePrint® and TargetPrint® are intended for use with MammaPrint®. Wesseling (2016) compared TargetPrint® to IHC and in situ hybridization (ISH) testing for ER, PR, and HER2 in samples from 806 patients at 22 hospitals. The positive/negative agreement between IHC and TargetPrint® was 96%/87% for ER, 84%/74% for PR, and 74%/98% for HER2.[64] The authors noted substantial discord in IHC/ISH results between different hospitals and indicated that TargetPrint® might improve the reliability of these discordant results by prompting retesting in a reference laboratory.

Gran (2015) compared HER2 testing results by IHC, FISH, and TargetPrint® in 127 tumor specimens from patients with early-stage breast cancer in South Africa.[65] Tumor specimens were fresh frozen (32%) or FFPE (68%). Only specimens with IHC-positive results (n=23) underwent FISH testing, except for one IHC-negative specimen that had a positive TargetPrint® result, subsequently confirmed by reflex FISH. TargetPrint® improved HER2 testing compared with IHC/FISH in four (17%) of 24 cases that underwent both IHC and FISH testing. TargetPrint® performance in this study cannot be fully characterized in the absence of FISH testing of IHC-negative samples.

The BluePrint® molecular subtyping profile was developed using 200 breast cancer specimens that had concordant ER, PR and HER2 protein levels by immunohistochemistry and TargetPrint® mRNA readout.[66] Using a threefold cross validation procedure, the 80 genes thought to best discriminate the three molecular subtypes were identified. BluePrint® was confirmed on four independent validation cohorts (n=784), which included patients from a consecutive series of patients seen at Netherlands Cancer Institute and treated with adjuvant tamoxifen monotherapy (n=274), a group of patients from the RASTER trial (n=100), and two publicly available data sets (n=410). In addition, in 133 patients treated with neoadjuvant chemotherapy, the molecular subtyping profile was tested as a predictor of chemotherapy response. The authors concluded that use of BluePrint® classification showed improved distribution of pCR among molecular subgroups compared with local pathology: 56% of the patients had a pCR in the basal-type subgroup, 3% in the MammaPrint® low-risk, luminal-type subgroup, 11% in the MammaPrint® high-risk, luminal-type subgroup, and 50% in the HER2-type subgroup.

Whitworth (2014) reported reclassification of 94 (22%) of 426 patients with breast cancer who were classified by both IHC/FISH and BluePrint® and treated with neoadjuvant chemotherapy.[67] Six percent of BluePrint® luminal-type patients achieved pCR compared with 10% of IHC/FISH hormone receptor–positive/HER2-negative patients; 53% of BluePrint® HER2-positive patients achieved pCR compared with 38% of IHC/FISH HER2-positive patients (the majority of HER2-positive patients by either method received trastuzumab); and 35% of BluePrint® basal-type patients achieved pCR compared with 37% of IHC/FISH “triple negative” patients.

Wuerstlein (2019) conducted a prospective evaluation of how MammaPrint® and BluePrint® influence clinical therapy decisions in patients with luminal early breast cancer.[68] About 72% (309 out of 430) of patients had node-negative disease. Specifically focusing on the impact of BluePrint® testing, the investigators found that there was a 65% concordance rate between IHC assessment and BluePrint® subtyping for Luminal A or B-like tumors. Notably, BluePrint® reclassified two clinically identified Luminal A-like tumors and four Luminal B-like tumors as Basal type. Additionally, BluePrint® reclassified 46% (80 out of 173) of Luminal B-like tumors to Luminal A, and 24% (62 out of 256) of Luminal A-like tumors to Luminal B. This led to an

overall discordance rate of 34% in subtype classification. The study also highlighted the strong association between chemotherapy recommendations and molecular subtype: 94% (143 out of 152) of patients with molecular Luminal B tumors received a recommendation for chemotherapy, whereas 92% (251 out of 272) of patients with molecular Luminal A tumors were advised to omit chemotherapy.

ENDOPREDICT®

EndoPredict® is a gene expression test that uses reverse transcription polymerase chain reaction (RT-PCR) of 12 genes.

Filipits (2011) reported on the validation of EndoPredict® using tumor samples from women receiving endocrine treatment in the ABCSG-6 and ABCSG-8 trials.[69] The test was successful in 378 out of 395 tumors from ABCSG-6 and 1,324 out of 1,330 tumors from ABCSG-8. All tumors were HER2-negative. Prespecified cutoff points were used to classify the patients into EP and EPclin high- and low-risk groups (5 for EP, 3.3 for EPclin). The EPclin score combines the EP risk score with two clinical parameters, tumor size and nodal status. The 10-year distant recurrence rates for the EP low- and high-risk groups from ABCSG-6 were 8% (95% CI 3% to 13%) and 22% (95% CI 15% to 29%), respectively, and the rates for the EP low- and high-risk groups from ABCSG-8 were 6% (95% CI 2% to 9%) and 15% (95% CI 11% to 20%), respectively. The EPclin score outperformed the EP score in this study, with 10-year distant recurrent rates of 4% (95% CI 1% to 8%) and 28% (95% CI 20% to 36%) in the ABCSG-6 low and high-risk groups, respectively, and 4% (95% CI 2% to 5%) and 22% (95% CI 15% to 29%) in the ABCSG-8 low- and high-risk groups. Filipits (2019) published a follow-up to this study, which reported outcomes for 1,702 patients and reported that patients with low-risk EPclin scores (62.6%) had increased distant recurrence-free rates compared with patients that had high-risk scores (HR 4.77, 95% CI 3.37 to 6.67), and that the EPclin scores were significantly associated with this rate regardless of nodal status.[70]

Sestak (2019) reported results of an analysis of the performance of EndoPredict® to predict chemotherapy benefit.[71] The analysis included 3,746 women; 2,630 patients received five years of endocrine therapy alone (from ABCSG-6/8, TransATAC trials) and 1,116 patients received endocrine therapy plus chemotherapy (from GEICAM 2003-02/9906 trial). There was a significant positive interaction between EPclin as a continuous measure and treatment group for the outcome of the ten-year recurrence rate (interaction p=0.022). Although the comparison is indirect, it may suggest that a high EPclin score can predict chemotherapy benefit in women with ER-positive, HER2-negative disease.

Buus (2016) evaluated EndoPredict® as a prognostic indicator for breast cancer recurrence in women treated endocrine therapy.[72] This study was performed with 928 ER-positive, HER2-negative tumors samples from the TransATAC trial, which randomized post-menopausal women with localized disease to either tamoxifen or anastrozole for five years. High and low risk groups for both EP and EPclin were determined using pre-specified cutpoints. The 10-year recurrence rate for node-negative patients was 3.0% (95% CI 1.5 to 6.0) for the EP low group and 14.5% (95% CI 11.3 to 18.8) for the EP high group. For the node-negative EPclin low and high groups, the 10-year recurrence rates were 5.9% (95% CI 4.0 to 8.6) and 20.0% (95% CI 14.6 to 27.0), respectively. The 10-year recurrence rates were also determined for node-positive patients: 21.3% (95% CI 13.9 to 31.9) for the EP low group, 36.4% (95% CI 29.6 to 40.1) for the EP high group, 5.0% (95% CI 1.2 to 18) for the EPclin low group, and 36.9% (95% CI 30.2 to 44.5) for the EPclin high group.

Martin (2014) assessed tumor samples from 566 ER-positive, HER2-negative patients who participated in the GEICAM 9906 RCT.[73] GEICAM 9906 compared two adjuvant chemotherapy regimens in 1,246 women who had lymph node-positive disease: six 21-day cycles of 5-fluorouracil, epirubicin, and cyclophosphamide (FEC) or four 21-day cycles of FEC followed by eight weekly courses of paclitaxel (FEC-P). EP was successfully assayed in 555 (98%) of 566 tumor samples. There were 25% (n=141) of the samples classified as low-risk by EP score, and 75% (n=414) were high-risk; 10-year metastasis-free survival was 93% in the low-risk group and 70% in the high-risk group (HR for metastasis or death in the high- vs low-risk group, 4.8 (95% CI 2.5 to 9.6, log-rank test p<0.001). Thirteen percent (n=74) of samples were classified as low-risk by EPclin score, and 87% (n=481) were classified as high-risk; 10-year metastasis-free survival was 100% in the low-risk group and 72% in the high-risk group.

EndoPredict® for Endocrine Therapy Decisions

Dubsky (2013) examined predictive ability of EP and EPclin for early (within five years) and late (more than five years post-diagnosis) disease recurrence.[74] Tumor samples from chemotherapy-untreated, ER-positive, HER2-negative patients who participated in one of two RCTs (ABCSG-6 or ABCSG-8) were assayed (total n=1,702). In the trials, patients received either tamoxifen for five years or tamoxifen for two years followed by anastrozole for three years. Forty-nine percent (n=832) of patients were classified as low risk by EP score, and 51% (n=870) were classified as high-risk. Only relative estimates (i.e., HRs) of distant recurrence were reported. In comparison with low-risk patients, high-risk patients had an almost three-fold increase in the risk of recurrence in the first five years after diagnosis (HR 2.80, 95% CI 1.81 to 4.34, log-rank test p<0.001) and a slightly increased risk after five years in those who survived five years (HR 3.28, 95% CI 1.48 to 7.24, log-rank test p=0.002). By EPclin, 1,066 (63%) of 1,702 patients were classified as low-risk, and 636 (37%) were classified as high-risk. In comparison with low-risk patients, high-risk patients had an almost five-fold risk of recurrence within the first five years (HR 4.82, 95% CI 3.12 to 7.44, log-rank test p<0.001) and a more than six-fold increased risk of recurrence after five years (HR 6.26, 95% CI 2.72 to 14.36, log-rank test p<0.001).

EP and EPclin appear to be able to identify a group at low-risk of distant recurrence from years 5 to 10 in this prospective-retrospective study of patients untreated with adjuvant chemotherapy enrolled in the ABCSG-6 and -8 trials. However, in the Filipits (2019) study, the lower-bound of the 95% CI for the distant recurrence rate in the high-risk group falls within a range that may be clinically meaningful for decision-making about avoiding extended ET both at 5-10 years (5.9%, 95% CI 2.2% to 9.5%) and at 5 to 15 years (15.1%, 95% CI 4.0% to 24.9%).[70] These results suggest the possibility that a proportion of high-risk patients may still have been unnecessarily treated with extended ET endocrine therapy based on a gene expression profiling result. ROC statistics (area under the receiver operating characteristic curve) were reported to support incremental improvement with the EP or EPclin over Adjuvant! Online or nodal status, tumor size, or grade. However, they appeared to include EP and EPclin as continuous variables and not threshold cutoffs for those tests that would inform decisions.

TEST COMPARISON STUDIES

Sestak (2018) compared Breast Cancer Index®, Oncotype DX®, Prosigna®, and Endopredict® using samples from the TransATAC RCT.[75] The low-risk categories of all four tests exhibited both low overall 10-year distant recurrence rates and low 5- to 10-year distant recurrence rates (within the threshold of <10%). Comparatively, among those who are

considering adjuvant chemotherapy (n=591), EPclin classified the most women as low risk (n=429) compared with the other three tests which classified 318 to 365 women as low risk. Among those who are considering extended endocrine therapy (n=535), EPclin classified the most women as low risk (n=393) compared with the other three tests, which classified 292 to 351 women as low risk.

Bosl (2017) compared MammaPrint® with EndoPredict® in 48 tumor samples - 29 were node-negative and 19 were node-positive.[76] For the MammaPrint test, RNA quality was low for three samples. Of the 45 tested by MammaPrint, 17 (38%) were classified as low-risk and 28 (62%) were classified as high-risk for recurrence. Four samples were excluded from the EndoPredict® analysis because the tumors were estrogen receptor-positive or HER2-positive, which are not part of the inclusion criteria of this test. Based on the EP molecular score, eight (18%) were classified as low-risk and 36 (82%) were classified as high-risk. Based on the EPclin score, 17 (39%) were considered low-risk and 27 (61%) were considered high-risk. There was no statistically significant agreement between MammaPrint® and molecular EP (overall concordance, 63%) or between MammaPrint® and EPclin (overall concordance, 66%).

Sgroi (2013) compared the Breast Cancer Index™ and Oncotype DX® in 665 lymph node-negative women receiving endocrine therapy but not chemotherapy in the ATAC trial.[46] The distribution of patients across risk groups was similar. For patients receiving tamoxifen alone or in combination with anastrozole, 10-year distant recurrence risk estimates by the two tests were similar within risk groups. In the anastrozole group, the Breast Cancer Index™ was a better predictor of risk: 5% of Breast Cancer Index™ low-risk patients had distant recurrence compared with 9% of Oncotype DX® low-risk patients, and 22% of Breast Cancer Index™ high-risk patients had distant recurrence compared with 13% of Oncotype DX® high-risk patients. Importantly, these values were reported without 95% CIs; it is therefore not possible to assess the degree of overlap between risk groups.

Sestak (2016)[77] examined cross-stratification between the Breast Cancer Index™ and Oncotype DX® RS using the same data as Sgroi (2013). Gene expression analyses for both scores were conducted, and risk categories were determined based on prespecified cutoff points (RS <18: low risk, 18 to 31: intermediate risk, >31: high risk; BCI <5.0825: low risk, 5.0825 to 6.5025: intermediate risk, >6.5025: high risk). Each gene expression score was combined with the CTS an algorithm of nodal status, tumor size, grade, age, and treatment. In a multivariate analysis, when BCI was added to RS plus CTS, there was a significant effect on prognostic information. When RS was added to BCI plus CTS, no additional prognostic information was added.

Dowsett (2013) compared the PAM50 ROR score to the Oncotype DX® RS, four immunohistochemical markers (IHC4) for ER, PR, Ki67 and HER2, and a CTS.[57] Patients had ER-positive, primary breast disease treated with anastrozole or tamoxifen in the ATAC trial, a double-blinded, phase three clinical trial that was designed to compare the ability of anastrozole, tamoxifen, and the two drugs in combination to prevent breast cancer recurrence in postmenopausal women with hormone receptor-positive tumors. Lymph node-negative and positive patients were included. mRNA from 1,017 patients was assessed for ROR, and likelihood ratio tests and concordance indices were used to assess the prognostic information provided beyond that of a CTS, RS, ROR or IHC4. The CTS integrated prognostic information from nodal status, tumor size, histopathologic grade, age and anastrozole or tamoxifen treatment. The authors concluded that the ROR added significant prognostic information beyond CTS in all patients (p<0.001), and in all four subgroups: lymph node negative, lymph

node positive, HER2 negative and HER2 negative/node-negative, and that more information was added by ROR than RS. More patients scored as high risk of recurrence and fewer as intermediate risk by ROR than RS. Prognostic information provided by ROR score and IHC4 was similar.

The study by Buus (2016) described earlier, compared EndoPredict® with Oncotype DX® RS in hormone receptor-positive, HER2-negative tumor samples from the TransATAC study.[72] The EP assay was used to generate an EPclin value that incorporated information about nodal status and tumor size. In this study, EP, EPclin, and RS had similar predictive power for distant recurrence in within five years in node-negative disease, while EP and EPclin had more prognostic value than RS for distant recurrence in 5 to 10 years, regardless of nodal status. Classification as low-risk by EPclin was associated with significantly lower 10-year risk of recurrence than a low-risk classification by RS (EPclin 5.8%, 95% CI 4.0 to 8.3, RS 10.1%, 95% CI 7.7 to 13.1). EPclin classification as high-risk was also more highly associated with cases of recurrence than non-low-risk RS classification. However, for this analysis, both intermediate risk and high-risk RS categories were grouped together to allow comparison between the two risk categories of EPclin and the three risk categories of the RS.

PRACTICE GUIDELINE SUMMARY

National Comprehensive Cancer Network

National Comprehensive Cancer Network (NCCN) guidelines for breast cancer (v.1.2025)[11] recommend that the 21-gene (Oncotype DX® Breast Recurrence Score) assay be strongly considered in node-negative, HR-positive, HER2-negative disease when the tumor is >0.5 cm, and of ductal/NST, lobular, mixed, or micropapillary histology (category 1), if the patient is a candidate for chemotherapy. They note that “other prognostic gene expression assays may be considered to help assess risk of recurrence but have not been validated to predict response to chemotherapy.” This test is also the preferred test for postmenopausal patients with one to three positive nodes (category 1).

MammaPrint® is also considered a category 1 option based on the results of the randomized MINDACT trial, which “demonstrated that the 70-gene assay can identify a subset of patients who have a low likelihood of distal recurrence despite high-risk clinical features (based on tumor size, grade, nodal status).” However, they note that the test is not useful for guiding chemotherapy decisions in those with low clinical risk, as no difference in outcomes with and without chemotherapy were seen in the trial for this group.

Regarding node-positive, HR-positive, HER2-negative disease, the guidelines recommend considering a multigene assay to assess prognosis and determine chemotherapy benefit for patients that are candidates for chemotherapy, The guidelines additionally state:

> “The panel notes in those with N1mi and N1 tumors, while multigene assays have yet to be proven to be predictive for adjuvant chemotherapy benefit, they are prognostic and can be used to identify low-risk patients who are likely to derive little or no absolute benefit from addition of adjuvant chemotherapy to adjuvant endocrine therapy. A secondary analysis of the prospective SWOG 8814 trial using the 21-gene assay demonstrated no benefit for chemotherapy for patients with 1-3 involved axillary lymph nodes and a low RS, and a significant benefit for the addition of adjuvant chemotherapy in those with high-RS (≥ 31). […] Other multigene assays have not proven to be predictive of chemotherapy benefit.”

Oncotype DX® is listed as the preferred multigene assay by the NCCN for node-negative disease, and predictive of chemotherapy response as well as prognostic, while the Breast Cancer Index™, Endopredict®, Prosigna®, and MammaPrint® tests were listed as prognostic only. Oncotype DX®, MammaPrint®, Prosigna®, and Endopredict® are listed as multigene assays that may be considered for individuals with one to three positive nodes, as well as those who are node negative.

The Breast Cancer Index™ is listed as being predictive of benefit of extended endocrine therapy, with evidence indicating that patients that have BCI (H/I) Low test results do not have improved survival with extending endocrine therapy beyond five years.

The guidelines do not recommend the use of multigene or mRNA assays for assignment of HER2 status.

The guidelines do not address the use of assays such as Oncotype DX® DCIS Score or DCISionRT® to guide decisions about radiation therapy in individuals with DCIS.

American Society of Clinical Oncology

In June 2022, the American Society of Clinical Oncology (ASCO) published updated clinical practice guidelines on the use of breast cancer biomarker assay results to guide adjuvant endocrine and chemotherapy decisions in early-stage breast cancer.[78] The recommendations related to the interventions and populations included in this evidence opinion include the following:

Newly Diagnosed ER-Positive, HER2-Negative Breast Cancer

1.1 If a patient has node-negative breast cancer, the clinician may use Oncotype DX test to guide decisions for adjuvant endocrine and chemotherapy (Evidence Quality [EQ]: High, Recommendation Strength [RS]: Strong)

1.2. In the group of patients in Recommendation 1.1 with Oncotype DX score greater than or equal to 26, the clinician should offer chemoendocrine therapy (EQ: High, RS: Strong)

1.3. In the group of patients in Recommendation 1.1 who are 50 years of age or younger with Oncotype DX score 16 to 25, the clinician may offer chemoendocrine therapy. (EQ: Intermediate, RS: Moderate)

1.4. If a patient is postmenopausal and has node-positive breast cancer with 1-3 positive nodes, the clinician may use Oncotype DX test to guide decisions for adjuvant endocrine and chemotherapy (EQ: High, RS: Strong)

1.5. In the group of patients in Recommendation 1.4, the clinician should offer chemoendocrine therapy for those whose Oncotype DX score is greater than or equal to 26 (EQ: High, RS: Strong)

1.6. If a patient is premenopausal and has node-positive breast cancer with 1-3 positive nodes, Oncotype DX test should not be offered to guide decisions for adjuvant systemic chemotherapy (EQ: High, RS: Moderate)

1.7. If a patient has node-positive breast cancer with more than 3 positive nodes, the evidence on the clinical utility of routine Oncotype DX test to guide decisions for

adjuvant endocrine and chemotherapy is insufficient to recommend its use (EQ: Insufficient, RS: Moderate)

1.8. If a patient is older than 50 and has high clinical risk breast cancer, that is node-negative or node-positive with 1-3 positive nodes, the clinician may use MammaPrint test to guide decisions for adjuvant endocrine and chemotherapy (EQ: Intermediate, RS: Strong)

1.9. If a patient is 50 years of age or younger and has high clinical risk, node negative or node-positive with 1-3 positive nodes breast cancer, the clinician should not use the MammaPrint test to guide decisions for adjuvant endocrine and chemotherapy (EQ: High, RS: Strong)

1.10. If a patient has low clinical risk, regardless of age, the evidence on clinical utility of routine MammaPrint test is insufficient to recommend its use (EQ: Intermediate, RS: Moderate)

1.11. If a patient has node-positive breast cancer with more than 3 positive nodes, the evidence on the clinical utility of routine MammaPrint test to guide decisions for adjuvant endocrine and chemotherapy is insufficient to recommend its use (EQ: Insufficient, RS: Strong)

1.12. If a patient is postmenopausal and has breast cancer that is node negative or node-positive with 1-3 positive nodes, the clinician may use EndoPredict test to guide decisions for adjuvant endocrine and chemotherapy (EQ: Intermediate, RS: Moderate)

1.13. If a patient is premenopausal and has breast cancer that is node negative or node-positive with 1-3 positive nodes, the clinician should not use EndoPredict test to guide decisions for adjuvant endocrine and chemotherapy (EQ: Insufficient, RS: Moderate)

1.14. If a patient has breast cancer with more than 3 positive nodes, evidence on the clinical utility of routine use of EndoPredict test to guide decisions for adjuvant endocrine and chemotherapy is insufficient (EQ: Intermediate, RS: Moderate)

1.15. If a patient is postmenopausal and has breast cancer that is node negative, the clinician may use the Prosigna test to guide decisions for adjuvant systemic chemotherapy (EQ: Intermediate, RS: Moderate)

1.16. If a patient is premenopausal, and has node-negative or node-positive breast cancer the clinician should not use the Prosigna test to guide decisions for adjuvant systemic chemotherapy (EQ: Insufficient, RS: Moderate)

1.17. If a patient is postmenopausal and has node-positive breast cancer with 1-3 positive nodes, the evidence is inconclusive to recommend the use of Prosigna test to guide decisions for adjuvant endocrine and chemotherapy (EQ: Intermediate, RS: Moderate)

1.18. If a patient has node-positive breast cancer with more than 3 positive nodes, evidence on the clinical utility of routine use of Prosigna test to guide decisions for adjuvant endocrine and chemotherapy is insufficient to recommend its use (EQ: Insufficient, RS: Strong)

Extended Endocrine Therapy for ER Receptor-Positive HER2-Negative Breast Cancer

1.23. If a patient has node-negative breast cancer and has had 5 years of endocrine therapy without evidence of recurrence, there is insufficient evidence to use Oncotype DX, EndoPredict, Prosigna, Ki67, or IHC4 tests to guide decisions about extended endocrine therapy (EQ: Intermediate, RS: Moderate)

1.24. If a patient has node-negative or node-positive with 1-3 positive nodes breast cancer and has been treated with 5 years of primary endocrine therapy without evidence of recurrence, the clinician may offer BCI test to guide decisions about extended endocrine therapy with either tamoxifen, an AI or a sequence of tamoxifen followed by AI (EQ: Intermediate, RS: Moderate)

1.25. If a patient has node-positive breast cancer with more than 3 positive nodes and has been treated with 5 years of primary endocrine therapy without evidence of recurrence, there is insufficient evidence to use BCI test to guide decisions about extended endocrine therapy with either tamoxifen, an AI or a sequence of tamoxifen followed by AI (EQ: Intermediate, RS: Strong)

HER2-Positive Breast Cancer or Triple-Negative Breast Cancer

1.27. If a patient has HER2-positive breast cancer or TNBC, the clinician should not use multiparameter gene expression or protein assays (Oncotype DX, EndoPredict, MammaPrint, BCI, Prosigna, Ki67, or IHC4) to guide decisions for adjuvant endocrine and chemotherapy (EQ: Intermediate, RS: Strong)

The guidelines do not address the use of assays such as Oncotype DCIS or DCISionRT to guide decisions about radiation therapy in individuals with DCIS.

ASCO 2019 guidelines on the role of patient and disease factors in adjuvant systemic therapy decision-making for early-stage, operable breast cancer state:[79]

- Shared decision making between clinicians and patients is appropriate for adjuvant systemic therapy for breast cancer. For patients older than age 50 years and whose tumors have Oncotype DX recurrence scores less than 26, and for patients age 50 years or younger whose tumors have Oncotype DX recurrence scores less than 16, there is little to no benefit from chemotherapy. Clinicians may offer endocrine therapy alone for these patients. For patients age 50 years or younger with recurrence scores of 16 to 25, clinicians may offer chemoendocrine therapy. Patients with recurrence scores greater than 30 should be considered candidates for chemoendocrine therapy. Based on informal consensus, the Panel recommends that oncologists may offer chemoendocrine therapy to patients with Oncotype DX scores of 26 to 30.
- The MammaPrint assay could be used to guide decisions on withholding adjuvant systemic chemotherapy in patients with hormone receptor–positive lymph node–negative breast cancer and in select patients with lymph node–positive cancers. In both patients with node-positive and node-negative disease, evidence of clinical utility of the MammaPrint assay was only apparent in those determined to be at high clinical risk; the Panel thus did not recommend use of MammaPrint assay in patients determined to be at low clinical risk. Remaining recommendations from the 2016 ASCO guideline endorsement are unchanged.

American Society of Clinical Oncology/College of American Pathologists

In 2010, ASCO and the College of American Pathologists (CAP) issued recommendations on immunohistochemical testing for ER and PR, and issued recommendations in 2007[37, 80] (updated in 2014)[81] for HER2 testing by immunohistochemical and FISH methods. Recommendations do not address the use of gene expression assays to test for ER, PR or HER2 expression.

SUMMARY

ONCOTYPE DX®, BREAST CANCER INDEX™, AND ENDOPREDICT®

Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, and EndoPredict® Assay in Node-Negative Patients and Patients with One to Three Positive Lymph Nodes

There is enough research to show that the Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, and EndoPredict® test can help identify patients with certain types of breast cancer that may be at low risk for disease recurrence and can be useful when making decisions about chemotherapy treatment. In addition, the Breast Cancer Index™ may provide information to help make decisions regarding extended endocrine therapy. Clinical guidelines based on research consider these tests to be an option to help in making treatment decisions for individuals with breast cancer who do not have lymph node involvement, and those with 1-3 positive lymph nodes. Therefore, this testing may be considered medically necessary in patients when policy criteria are met.

Oncotype DX®, Breast Cancer Index™, MammaPrint®, and EndoPredict® Assay in Preliminary Biopsy Samples

There is not enough research to show that the use of the Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, and EndoPredict® test on preliminary biopsy samples (prior to pathological evaluation) may improve health outcomes in breast cancer patients. The large studies that have validated these tests have primarily used surgical specimens. Full pathologic evaluation is important to determine the cellular and molecular features of a cancer, including lymph node status, prior to chemotherapy decision making. In addition, these tests have not been validated for use in making decisions for pre-surgical (neoadjuvant) therapy. Therefore, the use of these tests on preliminary biopsy samples is considered not medically necessary.

Oncotype DX®, Breast Cancer Index™, MammaPrint®, and EndoPredict® Assay in Patients with More than Three Positive Lymph Nodes

There is enough research to show that the use of the Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, MammaPrint®, and EndoPredict® test may not improve health outcomes in breast cancer patients with more than three positive lymph nodes. For these patients, the risk of cancer recurrence without additional recommended therapy may be high. Therefore, testing in node-positive patients with more than three positive lymph nodes is considered not medically necessary.

Gene Expression Testing for DCIS

There is not enough research to show that gene expression tests for ductal carcinoma in situ (DCIS), including but not limited to the Oncotype DX® DCIS or DCISionRT, helps patients make treatment decisions that improve health outcomes. Clinical practice guidelines for breast cancer do not recommend this type of testing. Therefore, gene expression testing for DCIS is considered investigational.

Oncotype DX® Assay to Determine or Confirm HER2 Status

Guidelines based on research recommend using other methods and not Oncotype DX® to confirm HER2 status. Therefore, use of the Oncotype DX® assay to determine or confirm HER2 status is considered investigational.

Other Uses of Oncotype DX®, Breast Cancer Index™, MammaPrint®, or EndoPredict®

There is not enough research to show that using the Oncotype DX® Breast Recurrence Score, Breast Cancer Index™, or Endopredict® tests for purposes other than helping to decide whether to undergo adjuvant chemotherapy can improve survival and other health outcomes for patients with breast cancer. This includes using test results to make decisions about endocrine therapy, to predict response to specific chemotherapy regimens, or to evaluate response to treatments. In addition, there are no clinical guidelines based on research that recommend testing for these purposes. Therefore, the use of these tests for purposes other than helping to decide whether to undergo adjuvant chemotherapy is considered investigational.

BLUEPRINT® AND TARGETPRINT®

There is not enough research to show that BluePrint® and TargetPrint® improve health outcomes in individuals with breast cancer. There are no clinical guidelines based on research that recommend using BluePrint® or TargetPrint® to help determine the risk of cancer recurrence for breast cancer patients. Therefore, the gene expression assays BluePrint® and TargetPrint® are considered investigational for all indications.

OTHER GENE EXPRESSION ASSAYS

There is not enough research to show that other gene expression assays for breast cancer, including the Molecular Grade Index (Aviara MGISM), Prosigna™, or BreastPRS™ tests can help breast cancer patients make treatment decisions that improve health outcomes. Therefore, these tests are considered investigational.

CODES

Codes	Number	Description
CPT	0009U	Oncology (breast cancer), ERBB2 (HER2) copy number by FISH, tumor cells from formalin fixed paraffin embedded tissue isolated using image-based dielectrophoresis (DEP) sorting, reported as ERBB2 gene amplified or non-amplified
	0045U	Oncology (breast ductal carcinoma in situ), mRNA, gene expression profiling by real-time RT-PCR of 12 genes (7 content and 5 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence score
	0153U	Oncology (breast), mRNA, gene expression profiling by next-generation sequencing of 101 genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a triple negative breast cancer clinical subtype(s) with information on immune cell involvement
	0262U	Oncology (solid tumor), gene expression profiling by real-time RT-PCR of 7 gene pathways (ER, AR, PI3K, MAPK, HH, TGFB, Notch), formalin-fixed paraffinembedded (FFPE), algorithm reported as gene pathway activity score

Codes	Number	Description
	0295U	Oncology (breast ductal carcinoma in situ), protein expression profiling by immunohistochemistry of 7 proteins (COX2, FOXA1, HER2, Ki-67, p16, PR, SIAH2), with 4 clinicopathologic factors (size, age, margin status, palpability), utilizing formalin-fixed paraffin- embedded (FFPE) tissue, algorithm reported as a recurrence risk score
	81518	Oncology (breast), mRNA, gene expression profiling by real-time RT-PCR of 11 genes (7 content and 4 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithms reported as percentage risk for metastatic recurrence and likelihood of benefit from extended endocrine therapy
	81519	Oncology (breast), mRNA, gene expression profiling by real-time RT-PCR of 21 genes, utilizing formalin-fixed paraffin embedded tissue, algorithm reported as recurrence score
	81520	Oncology (breast), MRNA gene expression profiling by hybrid capture of 58 genes (50 content and 8 housekeeping), utilizing formalin fixed paraffin-embedded tissue, algorithm reported as a recurrence risk score
	81521	Oncology (breast), MRNA, microarray gene expression profiling of 70 content genes and 465 housekeeping genes, utilizing fresh frozen or formalin-fixed paraffin-embedded tissue, algorithm reported as index related to risk of distant metastasis
	81522	Oncology (breast), mRNA, gene expression profiling by RT-PCR of 12 genes (8 content and 4 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence risk score
	81523	Oncology, mRNA, next-generation sequencing gene expression profiling
HCPCS	S3854	Gene expression profiling panel for use in the management of breast cancer treatment

Medical Policy Manual Genetic Testing, Policy No. 43

Diagnostic Genetic Testing for FMR1 and AFF2 Variants (Including Fragile X and Fragile XE Syndromes)

Effective: April 1, 2024

Next Review: February 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Fragile X syndrome (FXS), caused by expansion of the *FMR1* gene, is characterized by intellectual disability. FXS is also associated with certain physical and behavioral characteristics, including typical facial features, connective tissue anomalies, autism spectrum disorder, and seizures. Fragile XE (FRAXE) syndrome is caused by expansion of the *AFF2* gene (also known as *FMR2*) and is associated with mild intellectual disability without consistent physical features.

MEDICAL POLICY CRITERIA

Note: This policy applies to diagnostic testing only. Reproductive carrier screening is addressed separately (see Cross References).

I. Diagnostic genetic testing for *FMR1* variants may be considered **medically necessary** when one or more of the following criteria are met:

   A. Individuals with intellectual disability, developmental delay, or autism spectrum disorder.

   B. Individuals diagnosed with primary ovarian insufficiency before the age of 40.

C. Prenatal testing of fetuses of known carrier mothers.

D. Individuals with neurologic symptoms consistent with fragile X syndrome, including but not limited to ataxia and intention tremor.

II. Diagnostic genetic testing for *FMR1* variants is considered **not medically necessary** in all other circumstances, including but not limited to children with isolated attention-deficit/hyperactivity.

III. Genetic testing for *AFF2* (*FMR2*) variants is considered **investigational** for fragile XE (FRAXE) syndrome.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
   - History and physical exam including any relevant diagnoses related to the genetic testing
   - Conventional testing and outcomes
   - Conservative treatments, if any

BACKGROUND

Human Genome Variation Society (HGVS) nomenclature[1] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Fragile X Syndrome

Fragile X syndrome (FXS) is the most common cause of heritable intellectual disability, characterized by mild to moderate intellectual disability. In addition to the intellectual impairment, patients present with typical facial characteristics such as an elongated face with a prominent forehead, protruding jaw, and large ears. Connective tissue anomalies include hyperextensible finger and thumb joints, hand calluses, velvet-like skin, flat feet, and mitral valve prolapse. The characteristic appearance of adult males includes macroorchidism. Patients may show behavioral problems including autism spectrum disorders, sleeping problems, social anxiety, poor eye contact, mood disorders and hand-flapping or biting. Another prominent feature of the disorder is neuronal hyperexcitability manifested by hyperactivity, increased sensitivity to sensory stimuli, and a high incidence of epileptic seizures.

Current approaches to therapy are supportive and symptom-based. Psychopharmacologic intervention to modify behavioral problems in a child with fragile X syndrome may represent an important adjunctive therapy when combined with other supportive strategies including speech therapy, occupational therapy, special educational services, and behavioral interventions. Medication management may be indicated to modify attention deficits, problems with impulse control, and hyperactivity. Anxiety-related symptoms, including obsessive compulsive tendencies with perseverative behaviors, also may be present and require medical intervention. Emotional lability and episodes of aggression and self-injury may be a danger to the child and others around him or her; therefore, the use of medication(s) to modify these symptoms also may significantly improve an affected child's ability to participate more successfully in activities in home and school settings.

DNA studies are used to test for fragile X syndrome (FXS). Genotypes of individuals with symptoms of FXS and individuals at risk for carrying the pathogenic variant can be determined by examining the size of the CGG trinucleotide repeat segment and the methylation status of the *FMR1* gene on the X chromosome. There are no known forms of fragile X mental retardation protein (FMRP) deficiency that do not map to the *FMR1* gene. Two main testing approaches are used: polymerase chain reaction (PCR) and Southern blot analysis. In fragile X testing, the high fraction of GC bases in the repeat region makes it extremely difficult for standard PCR techniques to amplify beyond about 100-150 CGG. As a result, Southern blot analysis is commonly used to determine the number of triplet repeats in FXS and methylation status.

CGG-repeat expansion full mutations account for more than 99% of cases of fragile X syndrome (FXS). Therefore, tests that effectively detect and measure the CGG repeat region of the *FMR1* gene are more than 99% sensitive. Positive results are 100% specific. The patient is classified as normal, intermediate (or "gray zone"), premutation, or full mutation based on the number of CGG repeats.

- Full mutation: >200-230 CGG repeats (methylated)

  Patients with a full mutation are associated with FXS, which is caused by expansion of the *FMR1* gene CGG triplet repeat above 200 units in the untranslated region of *FMR1*, leading to a hypermethylation of the promoter region followed by transcriptional inactivation of the gene. The FXS is caused by a loss of the fragile X mental retardation protein (FMRP). Approximately 1% to 3% of children ascertained on the basis of autism diagnosis are shown to have fragile X syndrome.

Full mutations are typically maternally transmitted. The mother of a child with an *FMR1* mutation is almost always a carrier of a premutation or full mutation. Men who are premutation carriers are referred to as transmitting males. All of their daughters will inherit a premutation, but their sons will not inherit the premutation. Males with a full mutation usually have intellectual disability and decreased fertility.

- Premutation: 55-200 CGG repeats (unmethylated)

  Patients with a premutation are carriers and are at small risk for developing a *FMR1*-related disorder, fragile X-associated tremor/ataxia syndrome (FXTAS). This disorder is a late onset, progressive development of intention tremor and ataxia often accompanied by progressive cognitive and behavioral difficulties including memory loss, anxiety, reclusive behavior, deficits of executive function and dementia, or premature ovarian insufficiency (FXPOI).

  Premutation alleles in females are unstable and may expand to full mutations in offspring. Premutations of less than 59 repeats have not been reported to expand to a full mutation in a single generation. Premutation alleles in males may expand or contract by several repeats with transmission; however, expansion to full mutations has not been reported. A considerable number of children being evaluated for autism have been found to have *FMR1* premutations (55-200 CGG repeats).[2]

- Intermediate: 45-54 CGG repeats (unmethylated)
- Normal: 5-44 CGG repeats (unmethylated)

Fragile XE Syndrome

Fragile XE syndrome (FRAXE) is much rarer than FXS, and affects an estimated 1 on 25,000 to 100,000 males.[3] This disorder is characterized by mild intellectual disability, though some affected individuals may have borderline cognitive function that is not severe enough to be classified as a disability.

Similar to FXS, FRAXE is caused by a trinucleotide repeat expansion – nearly all cases are due to the presence of more than 200 repeats of CCG in the *AFF2* gene (sometimes referred to as *FMR2*). Individuals with 50 to 200 CCG repeats are said to have a premutation, which is not associated with impaired cognition.

Regulatory Status

No FDA-cleared genotyping tests were found. Thus, genotyping is offered as a laboratory-developed test. Clinical laboratories may develop and validate tests in-house and market them as a laboratory service. Such tests must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). The laboratory offering the service must be licensed by CLIA for high-complexity testing.

Asuragen offers the Xpansion Interpreter™ test which analyzes AGG sequences that interrupt the CGG repeats which have been suggested to stabilize alleles and protect against expansion in subsequent generations.

Note: An additional test for developmental delays, Lineagen FirstStepDxPLUS, offers sequencing of *FMR1* in combination with a chromosomal microarray genetic test. When *FMR1*

analysis is bundled with CMA analysis or any other genetic test, additional plan medical policies may apply. For the plan's medical policy on CMA analysis, see Cross References in the section above.

EVIDENCE SUMMARY

The focus of this review is on evidence related to the clinical utility of the testing, which is the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and
- Improve health outcomes as a result of those decisions.

FMR1

The conditions caused by abnormal CGG repeats in the *FMR1* gene, FXS, FXTAS, and FXPOI, do not have specific treatments that alter the natural history of the disorders. However, because they represent relatively common causes of conditions that are often difficult to diagnose and involve numerous diagnostic tests, the capability of *FMR1* testing to obtain an accurate definitive diagnosis and avoid additional diagnostic testing supports its clinical utility. Knowledge that the condition is caused by fragile X provides important knowledge to offspring and the risk of disease in subsequent generations.

Since there is no specific treatment for FXS, a definitive diagnosis will not lead to treatment that alters the natural history of the disorder. However, there are several potential ways in which adjunctive management might be changed following genetic testing after confirmation of the diagnosis.[4, 5] Although not related specifically to *FMR1* testing, the American Academy of Pediatrics (AAP) and the American Academy of Neurology (AAN)/Child Neurology Society (CNS) guidelines, described in more detail below, noted the following more immediate and general clinical benefits of achieving a specific genetic diagnosis:

- limit additional diagnostic testing;
- anticipate and manage associated medical and behavioral comorbidities;
- improve understanding of treatment and prognosis;
- allow counseling regarding risk of recurrence in future offspring and help with reproductive planning;
- early diagnosis and intervention in an attempt to ameliorate or improve behavioral and cognitive outcomes over time.

In a 2012 review by Abrams, the importance of early diagnostic and management issues, in conjunction with the identification of family members at risk for or affected by FMR1 variants is discussed.[6] The expanded CGG repeat in the *FMR1* gene, once thought to have clinical significance limited to fragile X syndrome, is now well established as the cause for other fragile X-associated disorders including fragile X-associated primary ovarian insufficiency and fragile X-associated tremor ataxia syndrome in individuals with the premutation (carriers).

Also, FXS is associated with a number of medical and behavioral comorbidities.[7] Behavioral comorbidities may include attention problems, hyperactivity, anxiety, aggression, poor sleep, and self-injury. Individuals with FXS are also prone to seizures, recurrent otitis media, strabismus, gastrointestinal disturbances, and connective tissue problems. A correct diagnosis can lead to the appropriate identification and treatment of these comorbidities.

Hersh (2011) reported on families with an affected male and whether an early diagnosis would have influenced their reproductive decision making.[4] After a diagnosis in the affected male was made, 73% of families reported that the diagnosis of FXS affected their decision to have another child, and 43% of the families surveyed had had a second child with a full mutation.

The feasibility of newborn screening is being investigated.[8] However, there is currently no treatment for FXS that would reduce mortality or morbidity if given in infancy. Also, there are a number of ethical concerns with newborn screening for FXS, including the need for informed consent from both parents, the need for genetic counseling for both full mutation and premutation status, and the detection of carriers in infants.[9]

AFF2

As with FXS, there are no specific treatments available for people diagnosed with FRAXE. In addition, FRAXE is a far less common disorder with a variable presentation ranging from relatively normal cognition to mild intellectual disability. There is limited evidence regarding the clinical utility of testing for *AFF2*. Several studies have screened for FRAXE in populations with intellectual disability[10-13], but only one identified a patient with this disorder.[14]

PRACTICE GUIDELINE SUMMARY

THE AMERICAN COLLEGE OF MEDICAL GENETICS

The purpose of the following American College of Medical Genetics (ACMG) guideline[15] recommendations is to provide aid to clinicians in making referrals for testing the repeat region of the *FMR1* gene:

- Individuals of either sex with intellectual disability, developmental delay, or autism, especially if they have (a) any physical or behavioral characteristics of fragile X syndrome, (b) a family history of fragile X syndrome, or (c) male or female relatives with undiagnosed intellectual disability
- Individuals seeking reproductive counseling who have (a) a family history of fragile X syndrome or (b) a family history of undiagnosed intellectual disability
- Fetuses of known carrier mothers
- Affected individuals or their relatives in the context of a positive cytogenetic fragile X test result who are seeking further counseling related to the risk of carrier status among themselves or their relatives. The cytogenetic test was used prior to the identification of the *FMR1* gene and is significantly less accurate than the current DNA test. DNA testing on such individuals is warranted to accurately identify premutation carriers and to distinguish premutation from full mutation carrier women.

In the clinical genetics evaluation in identifying the etiology of autism spectrum disorders, the ACMG recommends testing for FXS as part of first tier testing.[16]

In 2021, the ACMG released a revised technical standard on laboratory testing for fragile X.[17] The authors noted that the new laboratory standards "are in general agreement" with the 2005 ACMG policy statement summarized above.

THE AMERICAN ACADEMY OF PEDIATRICS

In 2011, the American Academy of Pediatrics (AAP) published consensus guidelines which suggested that, because children with FXS may not have apparent physical features, any child who presents with developmental delay, borderline intellectual abilities or intellectual disability, or has a diagnosis of autism without a specific etiology should undergo molecular testing for FXS to determine the number of CGG repeats.[4]

In 2014, the AAP updated their consensus guidelines which recommend Fragile X testing in patients with global developmental delay (GDD) or intellectual disability (ID).[18] Specifically, the AAP guideline recommended, “fragile X testing should be performed in all boys and girls with GDD/ID of unknown cause. Of boys with GDD/ID of uncertain cause, 2% to 3% will have fragile X syndrome (full mutation of *FMR1*, >200 CGG repeats), as will 1% to 2% of girls (full mutation).”

THE AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS

The 2017 American College of Obstetricians and Gynecologists (ACOG) committee opinion recommended prenatal testing for fragile X syndrome for known carriers of the fragile X premutation or full mutation and for women with a family history of fragile X-related disorders or intellectual disability suggestive of fragile X syndrome.[19] They additionally recommended *FMR1* premutation testing for women younger than 40 with unexplained ovarian insufficiency or failure, or an elevated follicle-stimulating hormone level.

SUMMARY

There is enough research to show that testing the *FMR1* gene can improve the diagnostic process for individuals with fragile X-related symptoms and help in informed reproductive decision making. Also, clinical guidelines based on research from several U.S. professional associations recommend this testing for certain people. Therefore, genetic testing for *FMR1* may be considered medically necessary for patients when criteria are met.

For all other situations, *FRM1* gene testing provides no benefit in directing medical management and is therefore considered not medically necessary.

There is not enough research to show that testing for *AFF2* (*FMR2*) variants can help improve health outcomes for patients or inform reproductive decision making. In addition, there are no clinical guidelines based on research that recommend *AFF2* testing. Therefore, genetic testing for *AFF2* is considered investigational.

Medical Policy Manual Genetic Testing, Policy No. 44

Noninvasive Prenatal Testing to Determine Fetal Aneuploidies, Microdeletions, Single-Gene Disorders, and Twin Zygosity

Effective: October 1, 2024

Next Review: January 2025
Last Review: September 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Fetal cell-free DNA fragments and fetal cells present in the plasma of pregnant women can be used for fetal screening, including testing for fetal sex chromosome aneuploidies (e.g., Turners, Klinefelter syndrome), fetal sex determination, twin zygosity, and microdeletion syndromes (e.g., Prader-Willi/Angelman syndrome).

MEDICAL POLICY CRITERIA

Note: This policy does not address reproductive carrier screening (see Cross References).

I. Genetic testing of maternal plasma for fetal trisomies 13, 18, and 21 may be considered **medically necessary**.

II. For *member contracts subject to Washington's State Board of Health Rule* (WAC 246-680), genetic testing of maternal plasma for fetal sex chromosome aneuploidies (e.g., sex chromosome aneuploidy (SCAs) or sex chromosome aneuploidy panel (SCAP) testing) may be considered **medically necessary**.

III. For *all other member contracts*, genetic testing of maternal plasma for fetal sex chromosome aneuploidies (e.g., sex chromosome aneuploidy (SCAs) or sex chromosome aneuploidy panel (SCAP) testing) is considered **investigational.**

IV. Genetic testing of maternal plasma for fetal sex determination is considered **not medically necessary**.

V. Genetic testing of maternal plasma for fetal microdeletion syndromes is considered **investigational**.

VI. Genetic testing of maternal plasma for twin zygosity is considered **investigational.**

VII. Genetic testing of maternal plasma for diagnosing fetal single-gene disorders, including but not limited to the Vistara™ test, is considered **investigational**.

VIII. Combination tests that include microdeletion, twin zygosity, and/or single-gene disorder testing are considered **investigational** (see Policy Guidelines).

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

COMBINATION TESTS

Combination tests that include investigational test components (such as microdeletion or single-gene testing) in addition to the standard trisomy testing include, but are not limited to the following tests:

- MaterniT® 21 PLUS (Labcorp)
- Panorama™ (Natera)
- Unity™ (BillionToOne)

TESTING RESULTS

Karyotyping would be necessary to exclude the possibility of a false-positive, nucleic acid sequencing– based test. Before testing, women should be counseled about the risk of a false-positive test. In a 2015 committee opinion, the American College of Obstetricians and Gynecologists recommended that all patients receive information on the risks and benefits of various methods of prenatal screening and diagnostic testing for fetal aneuploidies, including the option of no testing.

Studies published to date on noninvasive prenatal screening for fetal aneuploidies have reported rare but occasional false positives. False-positive findings have been found to be associated with factors including placental mosaicism, vanishing twins, and maternal malignancies. Diagnostic testing is necessary to confirm positive cell-free fetal DNA tests, and management decisions should not be based solely on the results of cell-free fetal DNA testing. The American College of Obstetricians and Gynecologists further recommended that patients with indeterminate or uninterpretable (i.e., “no call”) cell-free fetal DNA test results be referred for genetic counseling and offered ultrasound evaluation and diagnostic testing because “no call” findings have been associated with an increased risk of aneuploidy.

Cell-free fetal DNA screening does not assess risk of neural tube defects. Patients should continue to be offered ultrasound or maternal serum α-fetoprotein screening.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy

criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- Name of the genetic test(s) or panel test
- Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
- The analyses included in the test (e.g., trisomies, sex chromosome aneuploidies, etc.)
- Relevant billing codes
- Blood draw date
- Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
- Medical records related to this genetic test

BACKGROUND

Historically, karyotype testing was an optional test used to examine chromosomes in a sample of fetal cells to help identify genetic disorders. Karyotype testing is an invasive and requires either an amniocentesis or a chorionic villi sampling test (CVS). Newer non-invasive prenatal screening tests have been developed that analyzes fetal cell-free DNA (cfDNA) or fetal cells circulating in maternal blood. Most DNA is contained within cells, but a small amount circulates freely in the bloodstream, called cfDNA. This non-invasive prenatal screening test (NIPT) analyzes the maternal serum for fetal trisomy aneuploidies and can also include testing for fetal sex chromosomes aneuploidies, microdeletions, twin zygosity, and fetal sex determination.

FETAL TRISOMY ANEUPLOIDY TESTING

National guidelines recommend that all pregnant women be offered screening for fetal chromosomal abnormalities, the majority of which are aneuploidies (an abnormal number of chromosomes). Fetal chromosomal abnormalities occur in approximately 1 in 160 live births. The trisomy syndromes are aneuploidies involving three copies of one chromosome. Trisomies 21 (Down syndrome, T21), 18 (Edwards syndrome, T18) and 13 (Patau syndrome, T13) are the most common forms of fetal aneuploidy that survive to birth. The most important risk factor for Down syndrome is maternal age, with an approximate risk of 1/1500 in young women that increases to nearly 1/10 by age 48.[1]

Standard aneuploidy screening involves combinations of maternal serum markers and fetal ultrasound done at various stages of pregnancy. The detection rate for various combinations of noninvasive testing ranges from 60% to 96% when the false-positive rate is set at 5%. When tests indicate a high risk of a trisomy syndrome, direct karyotyping of fetal tissue obtained by amniocentesis or CVS is required to confirm that T21 or another trisomy is present. Both

amniocentesis and CVS are invasive procedures and have procedure-associated risks of fetal injury, fetal loss and infection. A new screening strategy that reduces unnecessary amniocentesis and CVS procedures or increases detection of T21, T18, and T13 could improve outcomes. Confirmation of positive noninvasive screening tests with amniocentesis or CVS is recommended; with more accurate tests, fewer women would receive positive screening results.

SEX CHROMOSOME ANEUPLOIDY

Some of the NIPT prenatal tests also include testing for sex chromosome aneuploidies (SCAs) or sex chromosome aneuploidy panel (SCAP) testing. Abnormalities in the number of X or Y chromosomes result in the following syndromes:

- Turner syndrome (Monosomy X or 45, X)
- Klinefelter syndrome (47, XXY)
- Triple X syndrome (47, XXX)
- Jacob syndrome (47, XYY)
- XXYY syndrome (48, XXYY)

Sex chromosome aneuploidies occur in approximately 1 in 400 live births. These aneuploidies are typically diagnosed postnatally, sometimes not until adulthood, such as during an evaluation of diminished fertility. Alternatively, sex chromosome aneuploidies may be diagnosed incidentally during invasive karyotype testing of pregnant women at high risk for Down syndrome. Potential benefits of early identification (e.g., the opportunity for early management of the manifestations of the condition), must be balanced against potential harms that can include stigmatization.

MICRODELETION SYNDROMES

Microdeletion syndromes are defined as a group of clinically recognizable disorders characterized by a small (< 5Mb) deletion of a chromosomal segment spanning multiple disease genes, each potentially contributing to the phenotype independently. The phenotype is defined as the set of observable characteristics of an individual resulting from the interaction of its genotype with the environment. Microdeletion testing can include, but is not limited to the following conditions or syndromes:

- 22q deletion syndrome (DiGeorge)
- 22q11 deletion syndrome (Shprintzen syndrome)
- 15q11.2 (Prader-Willi/Angelman syndromes)
- 5p deletion (Cri du chat syndrome)
- 1p36 deletion syndrome
- 4p deletion (Wolf-Hirschhorn syndrome)

Clinical implications of prenatal testing for microdeletions are not well defined. It is unclear whether prenatal diagnosis is appropriate given the inherent difficulty in accurately predicting the phenotype for the myriad of microdeletion syndromes. Though laboratories may offer screening for microdeletion syndromes, screening for these microdeletion syndromes is not currently the main intent of NIPT screening tests.

SINGLE-GENE DISORDERS

Single-gene disorders (also known as monogenic disorders) are caused by a variation in a single gene. Individually, single-gene disorders are rare, but collectively are present in approximately 1% of births. The Vistara Single-Gene Disorder Test panel screens for 25 conditions that result from variants across 30 genes, which have a combined incidence of 1 in 600 (0.17%).[2] These include Noonan syndrome and other Noonan spectrum disorders, skeletal disorders (e.g., osteogenesis imperfecta, achondroplasia), craniosynostosis syndromes, Cornelia de Lange syndrome, Alagille syndrome, tuberous sclerosis, epileptic encephalopathy, *SYNGAP1*-related intellectual disability, CHARGE syndrome, Sotos syndrome, and Rett syndrome. The clinical presentation and severity of these disorders can vary widely. Some, but not all, can be detected by prenatal ultrasound examination.

FETAL SEX DETERMINATION

Sequencing-based testing of maternal serum for determination of fetal sex in the first trimester of pregnancy is possible. However, the current standard of care for fetal sex is ultrasound. Fetal sex includes:

- Male (XX)
- Female (XY)

TWIN ZYGOSITY TESTING

Twin gestations occur in approximately 1 in 30 live births in the United States and have a 4- to 10-fold increased risk of perinatal complications.[3] Dizygotic or "fraternal" twins occur from ovulation and fertilization of two oocytes, which results in dichorionic placentation and two separate placentas. In contrast to dichorionic twins, monochorionic twin pregnancies share their blood supply. Monochorionic twins account for about 20% of twin gestations and are at higher risk of structural defects, miscarriage, preterm delivery, and selective fetal growth restriction compared to dichorionic twins.[3] Up to 15% of monochorionic twin pregnancies are affected by twin-to-twin transfusion syndrome (TTTS), a condition characterized by relative hypovolemia of one twin and hypervolemia of the other.[4] According to estimates from live births, TTTS occurs in up to 15% of monochorionic twin pregnancies. In these twin pregnancies, serial fetal ultrasound examinations are necessary to monitor for development of TTTS as well as selective intrauterine growth restriction because these disorders have high morbidity and mortality and are amenable to interventions that can improve outcomes.[4] NIPT using cell-free fetal DNA to determine zygosity in twin pregnancies could potentially inform decisions about early surveillance for TTTS and other monochorionic twin-related abnormalities. In particular, determining zygosity with NIPT could potentially assist in the assessment of chorionicity when ultrasound findings are not clear.

REGULATORY STATUS

None of the commercially available sequencing assays listed above have been submitted to or reviewed by the U.S. Food and Drug Administration (FDA). Clinical laboratories may develop and validate tests in-house and market them as a laboratory service. Laboratory-developed tests (LDTs) must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). Laboratories offering LDTs must be licensed by CLIA for high-complexity testing. The NIPT panels vary significantly in the base components and additional options a provider may choose on the requisition form. Commercial tests include, but are not limited to, the following:

- **Harmony**™ Prenatal Test (Ariosa Diagnostics, now Roche).

  Tests for fetal trisomies.

  Additional options for testing fetal sex chromosome aneuploidies, fetal sex, monosomy X, and 22q11.2 microdeletion.

- **InformaSeq**SM **Prenatal Test** (Integrated Genetics, a division of LabCorp)

  Tests for fetal trisomies.

  Optional testing includes fetal sex chromosome and fetal sex.

- **MaterniT Genome** (Sequenom Laboratories, now LabCorp)

  Tests for genome wide aneuploidies

- **MaterniT21™ Plus** (Sequenom Laboratories, now LabCorp).

  Tests for fetal trisomies and fetal sex.

  Additional items to include microdeletions, other chromosomes (T16, T22), and sex chromosomes aneuploidies.

- **Panorama**™ (Natera).

  Tests for fetal trisomies, fetal sex chromosome aneuploidies, triploidy, microdeletions, and fetal sex.

- **Prequel™ Prenatal Screen** (Myriad)

  Tests for fetal trisomies, with options for sex chromosome and microdeletion testing.

- **Progenity Innatal® Prenatal Screen** (Progenity)

  Tests for fetal trisomies, may include fetal sex chromosome aneuploidies and fetal sex.

- **Verifi**® Prenatal Test (Illumina, formerly Verinata Health).

  There are two options for these tests which may include fetal trisomies, fetal sex chromosomes aneuploidies, microdeletions, and fetal sex.

- **Vistara™** Single Gene NIPT (Natera)

  Tests for 25 autosomal dominant and X-linked conditions across 30 genes.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[5] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Assessment of a diagnostic technology such as maternal plasma DNA sequencing tests typically focuses on three parameters:

1. Analytic validity;
2. Clinical validity (includes calculations of sensitivity and specificity in appropriate populations of patients); and
3. Clinical utility (demonstration that the diagnostic information can be used to improve patient health outcomes).

The focus of this evidence summary below is on the clinical validity and utility of these tests.

The evidence regarding these three questions was addressed in the 2012 and 2014 BlueCross BlueShield Association Technology Evaluation Center (TEC) Assessments.[6, 7] The initial Assessment, published in 2012, focused on detection of T21/Down syndrome because the majority of published data at the time was concentrated on this trisomy. Additionally, large numbers of cases were included in several publications, and all companies had published data regarding the detection of T21. The subsequent Assessment, published in 2014, reviewed the available data for detection of T18, T13, and sex chromosome aneuploidies (SCAs). The scope of both TEC Assessments was limited to the evaluation of tests that are available in the United States. Additional literature published after publication the TEC Assessments is also addressed in the analysis below.

CLINICAL VALIDITY

Multiple Conditions

Gil (2017) published a systematic review with meta-analysis which evaluated the performance of screening for fetal trisomies 21, 18 and 13 and sex chromosome aneuploidies.[8] This summary will only focus on the results for sex chromosome aneuploidies. There were 36 total cases of monosomy X and 7,677 unaffected singleton pregnancies. The pooled weighted detection rate and false positive rate were 95.8% (95% confidence interval [CI] 70.3 to 99.5%) and 0.14% (95% CI 0.05 to 0.38%), respectively. Also, there were 17 cases of sex chromosome abnormalities that were not monosomy X and 5,383 unaffected singleton pregnancies. The pooled weighted detection rate and false positive rate were 100% (95% CI 83.6 to 100%) and 0.003% (95% CI 0 to 0.07%), respectively. The authors concluded that the number of cases for sex chromosome aneuploidy was too small to calculate overall screening performance.

Norton (2016) conducted a high-quality systematic review and meta-analysis which evaluated cohort studies comparing sequential screening to cell free DNA detection rates for fetal chromosomal abnormalities.[9] A total of 452,901 women underwent sequential screening and out of those women, 2575 (0.57%) had a fetal chromosomal abnormality. Of those abnormalities, the detection rate was 81.6% (total of 2,101). Additionally, 19,929 euploid fetuses had positive sequential screening resulting in a detection rate of 4.5%. The authors concluded that cfDNA testing has good performance for fetal sex and the detection rate of sequential screening for all aneuploidies was significantly greater than cfDNA ($p<0.0001$).

Mackie (2016) conducted a systematic review with meta-analysis evaluating the performance of cell free fetal DNA testing for all conditions (singleton pregnancies only).[10] A total of 117 studies addressing 18 conditions were included. The meta-analysis showed that for fetal sex (60 studies with 11,179 tests), the sensitivity and specificity were 0.989 (95% CI 0.980 to 0.994) and 0.996 (95% CI 0.989 to 0.998), respectively. For monosomy X (80 studies and 6,712 tests), the sensitivity was 0.929 (95% CI 0.741 to 0.984) and specificity 0.999 (95% CI

0.995 to 0.999). The authors concluded that fetal sex can be considered diagnostic but that testing for aneuploidies should only be considered as screening.

Fetal Sex Chromosome Aneuploidies

A Cochrane review by Badeau (2017) evaluated diagnostic accuracy of NIPT for sex chromosome anomalies.[11] Twelve studies were identified on the 45,X chromosome with sensitivities of 91.7% to 92.4% and specificities of 99.6% to 99.8%. Reviewers calculated that of 100,000 pregnancies, 1,039 would be affected by 45,X. Of these, 953 tested with massively parallel shotgun sequencing and 960 tested with targeted massively parallel sequencing would be detected and 86 and 79 cases, respectively, would be missed. Of the 98,961 unaffected women, 396 and 198 pregnant women would undergo an unnecessary invasive test. The authors were unable to perform meta-analyses of NIPT for chromosomes 47,XXX, 47,XXY, and 47,XYY due to insufficient evidence.

A systematic review published after the Cochrane review had similar results, showing high sensitivity (94.1%, 95% CI 90.8% to 96.3%) and specificity (94.1%, 95% CI 90.8% to 96.3%), but more false positives (235 per 100,000) than tests for the common trisomies.[12] Subgroup analyses showed variation in positive predictive value (PPV) by type of sex chromosome aneuploidy, from 32% (95% CI 27.0% to 37.4%) for monosomy X to 70% (95% CI 63.9% to 77.1%) for XYY syndrome, explained by higher sensitivity and specificity for the Y chromosome and high risk of false-positive results for aneuploidies involving the X chromosome only.

Gil (2015) published results from a systematic review and meta-analysis that examined the analysis of cfDNA in maternal blood in screening for fetal aneuploidies between January 2011 and January 2015.[13] Thirty-seven articles were included in the review; however, just 28 of these studies reported on sex chromosome aneuploidy testing. Sixteen of the 28 studies addressed the detection of monosomy X (Turner syndrome). The authors found, that of the 177 singleton pregnancies with fetal monosomy X, the detection rate varied between 66.7% and 100% and the false-positive rate varied between 0% and 0.52%. The pooled weighted detection rate was 90.3% (95% CI 85.7 to 94.2%), and the false-positive rate was 0.23% (95% CI 0.14 to 0.34%). The remaining 12 studies reported on the performance of sex chromosome abnormalities other than monosomy X (i.e., 47XXX, 47XXY, 47XYY), in a combined total of 56 affected and 6,699 non-sex chromosome aneuploidy singleton pregnancies. The pooled detection rate was 93.0% (95% CI 85.8 to 97.8% and the false-positive rate was 0.14% (95% CI 0.06 to 0.24%). This study has significant methodological limitations, which include but are not limited to, very small sample sizes, high risk of bias in relation to flow and timing (i.e., consecutive cases), testing performed in selected populations, and a lack of clarity about karyotyping, and the studies did not clearly define the patient's risk category.

The 2014 BCBSA TEC Assessment included a meta-analysis of sequencing-based studies published through April 15, 2014 that included a report on sex chromosome anomalies.[7] The largest number of studies (14 studies, total of 152 cases) published on sex chromosome aneuploidies addressed detection of monosomy X. Pooled sensitivity for detecting monosomy X was 83% (95% CI 74% to 90%) and pooled specificity was 100% (95% CI 100% to 100%). In addition, 11 studies with a total of 51 cases were identified on the performance of sequencing-based tests in identifying other sex chromosome anomalies. Pooled sensitivity was 89% (95% CI 50% to 98%) and pooled specificity was 100% (100% to 100%). The meta-

analysis of studies on sex chromosome aneuploidies did not differentiate between high and low-risk populations.

A study published by Wang (2015), which was not included in the above systematic reviews, examined the concordance of NIPT results among 109 consecutive cases with positive or negative NIPT results and compared those findings with the cytogenetic prenatal and/or postnatal karyotype results.[14] Sixteen of these cases were tested for fetal sex chromosome aneuploidies. The authors found that of these, the true positive rate was 38% (6/16 cases), and the false positive rate to be 62% (10/16 cases). This study has methodological limitations, including small sample size and the design, which was limited to testing at just one of the four main laboratories performing NIPT in the U.S., all of which use different methodologies or algorithms.

A larger study by Guy (2019) reported results for NIPT testing from a large laboratory testing company.[15] Of the 75,658 samples received (from 72,176 women), 69,794 had successful testing. Approximately 87% represented “high risk” pregnancies. The reported PPV was 69% for SCAs and 75% for microdeletions.

A study by Yang (2021) evaluated the performance of NIPT for SCA detection in a cohort of 47,800 patients in Southern China.[16] Of the 238 high-risk cases that were detected by NIPT, 170 patients had available information on subsequent prenatal diagnostic testing, such as karyotyping and CMA. These included 137 cases of 45X, 27 cases of 47XXX, and 74 cases of 47XYY/47XXY. The PPV of the NIPT testing was reported to be 30.00% for 45X, 70.58% for 47XXX, and 81.13% for 47XYY/47XXY.

Reiss (2017) compared NIPT to nuchal translucency screening for SCA among patients at a single prenatal diagnosis center. Of the 2,851 patients, 18 were positive for an SCA by NIPT. There were no false positives among the five cases that screened positive for 47XXX or the two cases that screened positive for 47XXY. Among the 11 positive screens for monosomy X, only one was a true positive. Four additional cases of monosomy X were identified due to cystic hygromas, one of which had a negative NIPT result.

Microdeletion syndromes

In a systematic review of NIPT using cfDNA in general risk pregnancies conducted for ACMG, Rose (2022) included 17 studies of screening for copy number variants (microdeletions and microduplications).[17] Meta-analyses were not conducted due to study heterogeneity. Although screening identified a small number of copy number variants (CNVs), confirmatory testing was frequently unavailable and complete ascertainment of cases was lacking. Sample sizes in each study were relatively small and sensitivities varied greatly. Additionally, it was often difficult to distinguish between low- and high-risk cohort in individual studies. The study authors concluded that the performance of NIPT was significantly poorer when targeting CNVs than the common trisomies and additional outcome studies are needed to understand the unique clinical value of NIPT for CNVs when compared with other approaches.

Zaninović (2022) conducted a systematic review of NIPT for CNVs and microdeletions.[18] A total of 32 studies were identified with literature searches conducted through February 2022. Of these, 21 studies concerned screening for microdeletion syndromes. Meta-analyses were not conducted due to study heterogeneity. Although a comprehensive quality assessment of studies was not conducted, the study authors described notable limitations of the included studies. Most studies did not define indications for screening, and some included only high-risk

pregnancies. Negative predictive values could not be determined because none of the studies performed systematic confirmatory analysis by chromosomal microarray analysis for negative/low-risk cases, mostly relying on clinical follow-up. The study authors concluded that given the limited follow-up and validation data available, NIPT for microdeletions and CNVs should be used with caution.

Familiari (2021) conducted a systematic review of the literature on screening for fetal microdeletions and microduplications using cfDNA.[19] A total of seven studies met inclusion criteria, representing 210 cases of microdeletions or microduplications. The overall pooled PPV was 44.1% (95% CI 31.49 to 63.07, range 28.9% to 90.6%). Limitations in the individual studies included retrospective design, low number of cases for each condition, lack of a standardized confirmation of the disease, low detail regarding the presence of absence of ultrasound anomalies and sonographic protocol used, different gestational ages at the time of the test, and variation in background risk. The authors noted that confirmatory testing was seldom reported in studies, under the assumption that all anomalies would have been identified in the newborn by physical exam. However, because many newborns with microdeletion and microduplication syndromes will not demonstrate phenotypical anomalies, standard neonatal examination cannot be considered a reliable ascertainment method and the detection rate and negative predictive value could not be determined from this body of evidence.

Additional non-randomized studies from companies offering microdeletion testing have been published evaluating data from clinical samples submitted for screening. Dar (2022) conducted a prospective analysis of 20,887 women who underwent NIPT testing at 21 centers in six countries.[20] A genetic outcome result was available for 18,289 women (87.6%), and 12 cases of 22q11.2 deletion syndrome were confirmed in the cohort. Limitations of the study include the low number of overall confirmed cases, wide confidence intervals for sensitivity, positive and false positive values, and varied indications for testing.

Soster (2021) conducted a retrospective analysis of 55,517 samples submitted for genome-wide cfDNA screening at a commercial laboratory between 2015 and 2018.[21] Diagnostic testing results were available in 42.5% (n=1,142) of screen-positive samples, and 0.82% of screen-negative samples, with overall 2.98% of samples with diagnostic outcomes. Microdeletion syndromes included 1p36 deletion, Wolf–Hirschhorn, Cri-du-chat, Langer–Giedion, Jacobsen, Prader–Willi, Angelman, and DiGeorge syndrome. Test performance characteristics were based on the 1,569 patients who had diagnostic testing performed, and an overall PPV of 72.6% was reported.

Wang (2021) conducted a prospective analysis of 39,002 pregnant women who received NIPT in a single center between 2018 and 2020.[22] There were 473 (1.21%) pregnancies that tested positive for fetal chromosome abnormalities, of which 95 were microdeletion/microduplication syndrome cases. Limitations of this study include variable types of diagnostic testing and specimen types, a large number of patients who refused to receive a prenatal diagnosis (n=135) and then were lost to follow-up (n=128), and low percentage of overall specimens that had diagnostic testing results available.

Fetal Sex Determination

The current standard of care for fetal sex determination is ultrasound.

Three reviews report on the use of cfDNA for fetal sex determination. Davaney (2011) published results from a systematic review and meta-analysis to determine if noninvasive prenatal determination of fetal sex using cfDNA provides an alternative to invasive techniques for some heritable disorders.[23] From 57 selected studies, 80 data sets (representing 3524 male-bearing pregnancies and 3,017 female-bearing pregnancies) were analyzed. Authors reported that despite inter-study variability, performance was high using maternal blood. Sensitivity and specificity for detection of Y chromosome sequences was greatest using RT-qPCR after 20 weeks' gestation. Tests using urine and tests performed before seven weeks' gestation were unreliable.

Wright (2012) published results from a review and meta-analysis of the published literature to evaluate the use of cfDNA for prenatal determination of fetal sex.[24] The authors reviewed 90 studies, incorporating 9,965 pregnancies and 10,587 fetal sex results. Overall mean sensitivity was 96.6% (95% CI 95.2% to 97.7%) and mean specificity was 98.9% (95% CI 98.1% to 99.4%). The authors identified one limitation of their study as the inability to properly evaluate the proportion of inconclusive or uncertain results, which is known to be problematic with this technique and may vary with gestational age. Further, literature-based reviews are at risk of publication bias due to the suppression of unwanted findings. The authors concluded that fetal sex can be determined with a high level of accuracy by analyzing cfDNA.

Colmant (2013) published a review of the published literature evaluating the use of cfDNA and ultrasound for prenatal determination of fetal sex during the first trimester of pregnancy.[25] The authors identified 16 reports of the determination of fetal sex in maternal blood and 13 reports of the determination by ultrasound. Authors determined a sensitivity and specificity of nearly 100% from eight weeks of gestation for cfDNA and from 13 weeks of gestation for ultrasound respectively. Authors concluded that fetal sex can be determined with a high level of accuracy by analyzing cfDNA and at an earlier gestation than ultrasound.

Twin Zygosity

Norwitz (2019) conducted a validation study of a single-nucleotide polymorphism-based NIPT in twin pregnancies.[3] The study included 95 samples with confirmed zygosity: 30 monozygotic and 65 dizygotic. Two of the 95 samples did not receive results due to low fetal fraction. Among the 93 pregnancies that yielded results, monozygotic sensitivity was 100% (29/29) and monozygotic specificity was 100% (64/64). A major limitation of this study was a lack of information on timing of the index test and the use of different methods to confirm zygosity.

Single-Gene Disorders

The performance characteristics of the Vistara NIPT were evaluated in a retrospective validation study conducted by Zhang (2019).[26] Most of the study participants were high risk due to prenatal ultrasound findings or a family history of genetic disease. The validation cohort included 76 cases (3 positive and 73 negative) and the clinical study included 422 samples (32 positive and 390 negative). Pathogenic or likely pathogenic variants were confirmed using a secondary NGS assay. Sanger sequencing was used to confirm positive findings if an invasive specimen (e.g., amniotic fluid) or a postnatal sample was available. Of the 35 positive results, 20 had a confirmed diagnosis. Pregnancy outcome data were obtained for 26 of 35 (74.2%) positive tests and 198 of 463 (42.7%) negative tests from both the validation and clinical studies.

Mohan (2022) reported on the clinical experience of Vistara NIPT in a series of 2,208 pregnancies.[2] Of 2,416 initial tests, 132 (5.5%) tests were ineligible and 76 (3.1%) did not pass quality control. Indications for NIPT included family history (6.0%), abnormal ultrasound finding (23.3%), advanced paternal age (41.3%), and unspecified/other/advanced maternal age (29.4%). In cases without abnormal ultrasound findings or family history, the test positive rate was 6 of 52 (0.4% (6/52). Positive variants were confirmed by a secondary NGS assay using deeper sequencing, and variants of unknown significance were not reported. Confirmatory prenatal or postnatal diagnostic testing was recommended for all screen-positive patients. Overall, the test positive rate was 125 of 2,208 (5.7%), and of these, follow-up information was available for 67 (53.6%), with none classified as false positive. Positive tests in cases without abnormal ultrasound findings or family history were found for 6/52 (0.4%).

Major limitations of these studies include a lack of confirmatory testing and selection bias. Because of missing data, it is not possible to determine accurate estimates of true positive and true negative tests. In addition, a large proportion of participants in both studies had a previous screening with findings suggestive of a potential disorder. It is unclear if single-gene NIPT is intended to be an adjunct to or replacement for other screening tests such as ultrasound. More clarity on the proposed use of the testing would be needed to adequately evaluate performance characteristics.

CLINICAL UTILITY

Fetal Sex Chromosome Aneuploidies

The impact of screening for sex chromosome aneuploidies has not been modeled in published studies. Fetal sex chromosome aneuploidies were not included in the decision analysis of the 2014 BCBSA TEC Assessment because the implications of a screen-positive finding and diagnostic confirmation were considered to differ significantly when compared to T13 and T18.[7] Finally, fetal sex aneuploidies are generally diagnosed postnatally in association with specific health problems, such as delayed puberty, or diminished fertility or infertility. Therefore, the balance of benefits and harms of cfDNA prenatal screen and subsequent diagnosis of sex chromosome fetal aneuploidies, each of which has variable and uncertain prognosis, is unclear.

Microdeletion syndromes

The clinical utility of testing for any specific microdeletion or any panel of microdeletions is uncertain.

There is a potential that prenatal identification of individuals with microdeletion syndromes could improve health outcomes due to the ability to allow for informed reproductive decision making, and/or to initiate earlier treatment; however, data demonstrating improvement are unavailable. Given the variability of expressivity of microdeletion syndromes and the lack of experience with routine genetic screening for microdeletions, clinical decision making based on genetic test results is not well defined. It is not clear what follow-up testing or treatments might be indicated for screen-detected individuals. Routine prenatal screening may identify a small percentage of fetuses with microdeletion variants earlier in pregnancy than would otherwise have occurred (e.g., by ultrasound evaluation and diagnostic testing). At the same time, routine prenatal screening for microdeletions would also result in false-positive tests and a larger number of invasive confirmatory tests. The large number of confirmatory tests could lead to a net harm because of pregnancy loss.

Most treatment decisions would be made after birth, and it is unclear whether testing in utero will lead to earlier detection and treatment of clinical disease after birth. Moreover, clinical decision making when a maternal microdeletion is detected in a pregnant woman without previous knowledge of a genetic variant is unclear.

Single-Gene Disorders

No studies were identified that evaluated whether cfDNA testing for single-gene disorders improves outcomes compared with standard care. There is a potential that prenatal identification of pregnancies with single-gene disorders could improve health outcomes due to the ability to allow for informed reproductive decision making and/or initiate earlier treatment; however, data demonstrating improvement are unavailable. Given the variability of single-gene disorders identified by this testing and the lack of experience with routine genetic screening for single-gene disorders, clinical decision-making based on this testing is not well defined.

Twin Zygosity

No studies were identified that evaluated whether cfDNA testing for twin zygosity improves outcomes compared with standard care.

PRACTICE GUIDELINE SUMMARY

AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS AND SOCIETY FOR MATERNAL-FETAL MEDICINE (ACOG/SMFM)

Noninvasive Prenatal Screening for Fetal Aneuploidies

In 2020, ACOG and SMFM released a practice bulletin summary (No. 226) on screening for fetal aneuploidy.[27] The following recommendations are based on “good and consistent” scientific evidence:

- “Cell-free DNA is the most sensitive and specific screening test for the common fetal aneuploidies. Nevertheless, it has the potential for false-positive and false-negative results. Furthermore, cell-free DNA testing is not equivalent to diagnostic testing.”
- “Patients with a positive screening test result for fetal aneuploidy should undergo genetic counseling and a comprehensive ultrasound evaluation with an opportunity for diagnostic testing to confirm results.”
- “Patients with a negative screening test result should be made aware that this substantially decreases their risk of the targeted aneuploidy but does not ensure that the fetus is unaffected. The potential for a fetus to be affected by genetic disorders that are not evaluated by the screening or diagnostic test should also be reviewed. Even if patients have a negative screening test result, they may choose diagnostic testing later in pregnancy, particularly if additional findings become evident such as fetal anomalies identified on ultrasound examination.”
- “Patients whose cell-free DNA screening test results are not reported by the laboratory or are uninterpretable (a no-call test result) should be informed that test failure is associated with an increased risk of aneuploidy, receive further genetic counseling and be offered comprehensive ultrasound evaluation and diagnostic testing.”

The following recommendations are based on “limited or inconsistent” scientific evidence:

- “The use of cell-free DNA screening as follow-up for patients with a screen positive serum analyte screening test result is an option for patients who want to avoid a diagnostic test. However, patients should be informed that this approach may delay definitive diagnosis and will fail to identify some fetuses with chromosomal abnormalities.” “No method of aneuploidy screening is as accurate in twin gestations as it is in singleton pregnancies; this information should be incorporated into pretest counseling for patients with multiple gestations.”
- “Cell-free DNA screening can be performed in twin pregnancies. Overall, performance of screening for trisomy 21 by cell-free DNA in twin pregnancies is encouraging, but the total number of reported affected cases is small. Given the small number of affected cases it is difficult to determine an accurate detection rate for trisomy 18 and 13.”

The following recommendations are based primarily on based “primarily on consensus and expert opinion:

- “In multifetal gestations, if a fetal demise, vanishing twin, or anomaly is identified in one fetus, there is a significant risk of an inaccurate test result if serum-based aneuploidy screening or cell-free DNA is used. This information should be reviewed with the patient and diagnostic testing should be offered.
- “Patients with unusual or multiple aneuploidies detected by cell-free DNA should be referred for genetic counseling and maternal–fetal medicine consultation.”

Cell-free DNA Screening for Single-Gene Disorders

In a practice advisory on cell-free DNA screening for single-gene disorders published in 2019 and reaffirmed in 2021,[28] ACOG stated, "Although this technology is available clinically and marketed as a single-gene disorder prenatal screening option for obstetric care providers to consider in their practice, often in presence of advanced paternal age, there has not been sufficient data to provide information regarding accuracy and positive and negative predictive value in the general population. For this reason, single-gene cell-free DNA screening is not currently recommended in pregnancy.”

AMERICAN COLLEGE OF MEDICAL GENETICS AND GENOMICS

In 2023, the American College of Medical Genetics and Genomics (ACMG) published a position statement on noninvasive prenatal screening (NIPS) for fetal aneuploidy for fetal chromosome abnormalities in a general-risk population.[29] Relevant recommendations are as follows:

- ACMG recommends NPS over traditional screening methods for all pregnant patients with singleton gestation for fetal trisomies 21, 18, and 13 (strong recommendation based on high certainty of evidence)
- ACMG recommends NIPS over traditional methods for trisomy screening in twin gestations (strong recommendation, based on high certainty of evidence)

- ACMG recommends that NIPS be offered to patients with a singleton gestation to screen for fetal SCA (strong recommendation, based on high certainty of evidence)
- ACMG suggests that NIPS for 22q11.2 deletion syndrome be offered to all patients (conditional recommendation, based on moderate certainty of the evidence)
- At this time, there is insufficient evidence to recommend routine screening for CNVs other than 22q11.2 deletions (no recommendation, owing to lack of clinically relevant evidence and validation)
- At this time, there is insufficient evidence to recommend or not recommend NIPS for the identification of RATS [rare autosomal trisomies] (no recommendation, owing to lack of clinically relevant evidence)

SUMMARY

FOR MEMBER CONTRACTS SUBJECT TO WASHINGTON'S STATE BOARD OF HEALTH RULE (WAC 246-680)

For member contracts subject to Washington's State Board of Health Rule, criteria for sex chromosome aneuploidy testing are based on the Rule. Therefore, for member contracts subject to Washington's State Board of Health Rule (WAC 246-680), sex chromosome aneuploidy testing using cell-free DNA may be considered medically necessary.

FOR MEMBER CONTRACTS *NOT* SUBJECT TO WASHINGTON'S STATE BOARD OF HEALTH RULE (WAC 246-680)

There is not enough research to show an improvement in health outcomes for non-invasive screening using fetal DNA to detect fetal sex chromosome aneuploidies. The current research shows mixed results for detection of abnormalities, including high false-positive rates. Therefore, non-invasive prenatal testing (NIPT) for fetal sex chromosome aneuploidies is considered investigational.

FOR ALL MEMBER CONTRACTS

Testing for Fetal Trisomies 13, 18, and 21

There is enough research to show that non-invasive prenatal testing (NIPT) for fetal trisomies 13, 18, and 21 are important for informing patient management and reproductive decision making. This testing is recommended by evidence-based clinical practice guidelines. Therefore, NIPT testing for trisomies 13, 18, and 21 may be considered medically necessary.

Fetal Sex Determination Testing

Research does not show that the use of nucleic acid sequencing-based testing for fetal sex determination is more beneficial than fetal ultrasound, which is the current clinical standard for determining fetal sex. Therefore, non-invasive prenatal testing (NIPT) for fetal sex determination is considered not medically necessary.

Microdeletion Testing

There is not enough research to show an improvement in health outcomes for non-invasive screening using fetal DNA to detect fetal microdeletion syndromes. The current research shows mixed results for detection of abnormalities. In addition, there are no evidence-based practice guidelines that recommend testing for fetal microdeletions. Therefore, non-invasive prenatal testing (NIPT) for fetal microdeletion syndromes is considered investigational.

Twin Zygosity Testing

There is not enough research to show that non-invasive screening using fetal DNA to detect twin zygosity leads to improvements in health outcomes. The current research for this type of testing is very limited. In addition, there are no evidence-based practice guidelines that recommend this testing. Therefore, non-invasive prenatal testing (NIPT) for twin zygosity is considered investigational.

Single-gene Disorder Testing

There is not enough research to show that non-invasive screening using fetal DNA to detect single-gene disorders leads to improvements in health outcomes. The current research for this type of testing is very limited. In addition, there are no evidence-based practice guidelines that recommend this testing. Therefore, non-invasive prenatal testing (NIPT) for single gene disorders (e.g., Vistara™) is considered investigational.

Combination Testing

There is not enough research to show that certain components of combination tests, including microdeletion testing, twin zygosity testing, and/or single-gene disorder testing, leads to improvements in health outcomes. In addition, there are no evidence-based practice guidelines that recommend this testing. Combination tests that include investigational components (microdeletion, twin zygosity, and/or single-gene disorders) are considered investigational.

CODES

NOTE: There are specific CPT codes for trisomy testing and for microdeletion testing. It is inappropriate to use nonspecific molecular pathology CPT codes (i.e., 81400-81408) for trisomy or microdeletion testing.

Codes	Number	Description
CPT	0060U	Twin zygosity, genomic targeted sequence analysis of chromosome 2, using circulating cell-free fetal DNA in maternal blood
	0341U	Fetal aneuploidy DNA sequencing comparative analysis, fetal DNA from products of conception, reported as normal (euploidy), monosomy, trisomy, or partial deletion/duplication, mosaicism, and segmental aneuploid
		Carrier screening for severe inherited conditions (eg, cystic fibrosis, spinal muscular atrophy, beta hemoglobinopathies [including sickle cell disease], alpha thalassemia), regardless of race or self-identified ancestry, genomic sequence analysis panel, must include analysis of 5 genes (*CFTR*, *SMN1*, *HBB*, *HBA1*, *HBA2*)

Codes	Number	Description
	0489U	Obstetrics (single-gene noninvasive prenatal test), cell free DNA sequence analysis of 1 or more targets (eg, CFTR, SMN1, HBB, HBA1, HBA2) to identify paternally inherited pathogenic variants, and relative mutation-dosage analysis based on molecular counts to determine fetal inheritance of maternal mutation, algorithm reported as a fetal risk score for the condition (eg, cystic fibrosis, spinal muscular atrophy, beta hemoglobinopathies [including sickle cell disease], alpha thalassemia)
	81220	CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; common variants (eg, ACMG/ACOG guidelines)
	81243	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
	81329	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gene analysis; dosage/deletion analysis (eg, carrier testing), includes SMN2 (survival of motor neuron 2, centromeric) analysis, if performed
	81363	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); duplication/deletion variant(s)
	81364	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); full gene sequence
	81408	Molecular pathology procedure, Level 9
	81422	Fetal chromosomal microdeletion(s) genomic sequence analysis (eg, DiGeorge syndrome, Cri-du-chat syndrome), circulating cell-free fetal DNA in maternal blood
	81479	Unlisted molecular pathology procedure
	81599	Unlisted multianalyte assay with algorithmic analysis
HCPCS	None

Medical Policy Manual Genetic Testing, Policy No. 51

Genetic Testing for CADASIL Syndrome

Effective: June 1, 2024

Next Review: April 2025
Last Review: April 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Variants in the *NOTCH3* gene have been causally associated with CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). Genetic testing is available to determine if pathogenic variants exist in the *NOTCH3* gene for patients with suspected CADASIL and their family members.

MEDICAL POLICY CRITERIA

I. Genetic testing of *NOTCH3* for the diagnosis of CADASIL may be considered **medically necessary** when one or more of the following criteria are met:
   A. Clinical signs and symptoms are consistent with CADASIL (subcortical ischemic events, cognitive impairment, migraine with aura, mood disturbances, and/or apathy); or
   B. In adults when there is a first- or second-degree family member with a diagnosis of CADASIL syndrome**.**

II. Genetic testing for CADASIL syndrome for all other situations, including but not limited to testing in children, is considered **investigational.**

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

CLINICAL SIGNS AND SYMPTOMS

The clinical presentation of CADASIL varies among and within families. The disease is characterized by five main symptoms: subcortical ischemic events, cognitive impairment, migraine with aura, mood disturbances, and apathy.

FAMILY MEMBERS

- First-degree relatives are parents, siblings, and children of an individual; and
- Second-degree relatives are grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings (siblings with one shared biological parent) of an individual.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or mutations being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence of testing. Medical records related to this genetic test, if available:
   - History and physical exam
   - Conventional testing and outcomes
   - Conservative treatment provided

1. Genetic and Molecular Diagnostic Testing, Genetic Testing, Policy No. 20

BACKGROUND

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an uncommon, autosomal dominant disease, although it is the most common cause of hereditary stroke and hereditary vascular dementia in adults. The CADASIL syndrome is an adult-onset, disabling systemic condition, characterized by migraine with aura, recurrent lacunar strokes, progressive cognitive impairment, and psychiatric disorders. The overall prevalence of the disease is unknown in the general population.

The clinical presentation of CADASIL is variable and may be confused with multiple sclerosis, Alzheimer dementia, and Binswanger disease. The specific clinical signs and symptoms, along with family history and brain magnetic resonance imaging (MRI) findings, are important in determining the diagnosis of CADASIL. The clinical features and mode of inheritance (autosomal dominant versus autosomal recessive) help to distinguish other inherited disorders in the differential diagnosis from CADASIL.

When the differential diagnosis includes CADASIL, various other tests are available for diagnosis:

- Genetic testing by direct sequencing of selected exons or of exons 2-24 of the *NOTCH3* gene (see Scientific Evidence section below). Identification of a *NOTCH3* pathogenic variant definitively establishes a diagnosis of CADASIL without the need for additional testing (eg, skin biopsy).
- Immunohistochemistry assay of a skin biopsy sample, using a monoclonal antibody with reactivity against the extracellular domain of the NOTCH3 receptor. Positive immunostaining reveals the accumulation of NOTCH3 protein in the walls of small blood vessels.[1] Lesnick Oberstein (2003) estimated sensitivity and specificity at 85-90% and 95-100%, respectively, for two observers of the test results in a population of patients and controls correlated with clinical, genetic and MRI parameters.[2]
- Detection of granular osmiophilic material (GOM) in the same skin biopsy sample by electron microscopy. The major component of GOM is the ectodomain of the *NOTCH3* gene product.[3] GOM accumulates directly in vascular smooth muscle cells and, when present, is considered a hallmark of the disease. [4] However, GOM may not be present in all biopsy samples. Sensitivity has been reported as low as 45% and 57%, but specificity is generally near or at 100%.[5-7]
- Examination of brain tissue for the presence of GOM. GOM was originally described as limited to brain vessels.[8] Examination of brain biopsy or autopsy after death was an early gold standard for diagnosis. In some cases, peripheral staining for GOM has been absent even though positive results were seen in brain vessels.

NOTCH3 VARIANTS

Variants in *NOTCH3* have been identified as the underlying cause of CADASIL. In almost all cases, the variants lead to loss or gain of a cysteine residue that could lead to increased reactivity of the NOTCH3 protein, resulting in ligand-binding and toxic effects.[9]

The *NOTCH3* gene is found on chromosome 19p13.2-p13.1 and encodes the third discovered human homologue of the Drosophila melanogaster type I membrane protein NOTCH. The NOTCH3 protein consists of 2,321 amino acids primarily expressed in vascular smooth muscle cells and plays an important role in the control of vascular transduction. It has an extracellular ligand-binding domain of 34 epidermal growth factor-like repeats, traverses the membrane once, and has an intracellular domain required for signal transduction.[10]

Variants in the *NOTCH3* gene have been differentiated into those that are causative of the CADASIL syndrome (pathogenic variants) and those that are of uncertain significance. Pathogenic variants affect conserved cysteine residues within 34 epidermal growth factor (EGF)-like repeat domains in the extracellular portion of the NOTCH3 protein.[10, 11] More than 150 pathogenic variants have been reported in at least 500 pedigrees. *NOTCH3* has 33 exons, but all CADASIL variants reported to date have been found in exons 2–24, which encode the 34 EGF-like repeats, with strong clustering in exons 3 and 4, which encode EGFR 2–5 (>40% of variants in >70% of families occur in these exons).[12]

REGULATORY STATUS

Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; laboratory-developed tests (LDTs) must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). *NOTCH3* genetic testing is available under the auspices of CLIA. Laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, the U.S. Food and Drug Administration has not chosen to require any regulatory review of this test.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[13] is used to describe variants found in DNA and serves as an international standard. It was implemented for genetic testing medical evidence review updates in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

1. The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
2. The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. The clinical utility of the test, which refers to how the results of the diagnostic test will be used to change management of the patient, and whether these changes in management lead to clinically important improvements in health outcomes.

ANALYTICAL VALIDITY

Limited data on analytic validity of *NOTCH3* testing were identified. The test is generally done by gene sequencing analysis, which is expected to have high analytic validity when performed under optimal conditions.

Fernandez (2015) described the development of a next-generation sequencing (NGS) protocol for *NOTCH3* and *HTRA1* genes in 70 patients referred for clinical suspicion of CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), all of whom had previously undergone Sanger sequencing of exons 3 and 4 of the *NOTCH3* gene.[14] *NOTCH3* variants were detected in six patients on NGS, including two variants previously detected with Sanger sequencing and four variants in exons 6, 11, and 19.

CLINICAL VALIDITY

Several retrospective and prospective studies have examined the association between *NOTCH3* genes and cerebral autosomal dominant arteriopathy with CADASIL, as shown in Table 1. These studies have been divided into two categories:

- Part 1, diagnostic studies, in which the patients enrolled were suspected, but not confirmed to have CADASIL; and
- Part 2, clinical validity studies, in which the patients had already been diagnosed with the disease by some method other than genetic testing. The diagnostic studies are more likely to represent the target population in which the test would be used.

Table 1. Studies of the association of NOTCH3 with CADASIL

Study	Patients Evaluated	*NOTCH3* Exons Evaluated	Results	
Part 1 Diagnostic Studies			**Diagnostic Yield**	**Specificity**
Maksemous 2016[15]	Patients: 44 patients with suspected CADASIL previously screened for standard sequencing exons (3 and 4, and/or 2, 11, 18, 19) by Sanger sequencing and classified as negative for known pathogenic variants	Custom NGS panel	Patients: six typical CADASIL variants were identified in 7/44 patients.	NR
Yin 2015[16]	Patients: 47 subjects from 34 families (Chinese) diagnosed with suspected CADASIL Patient diagnosis/selection: MRI abnormalities and the presence of more than one typical symptom (eg, migraine, stroke, cognitive deficits, psychiatric symptoms) or the presence of atypical symptoms with a positive family history	Testing method: exons 3 and 4 screened first; if no variants detected, remaining exons analyzed	Patients: six known variants were identified in eight families and two novel variants were identified in two families (exons 3 and 4), and one VUS was identified in one family (exon 2). Overall NOTCH3 variant prevalence: 29.4%	NR
Choi 2011[8]	Patients: 151 consecutive Korean patients with acute ischemic stroke. Patient Selection: History of acute ischemic stroke, neurologic exam, cranial computed tomography or MRI.	Bidirectional sequencing of exons 3, 4, 6, 11 and 18.	Patients: six patients (4%) were found with the identical *NOTCH3* variant (R544C; exon 11). Of these, all had pre-existing lacunar infarction, five (83.3%) had grade 2-3 white-matter hyperintensity lesions, and a history of hypertension; a history of stroke and dementia was higher in patients with variants. Family Members: No data for additional family members	NR
Mosca 2011[9]	Patients: 140 patients with clinical suspicion of CADASIL (Italian and Chinese). Patient Selection: History of premature strokes; migraine with aura; vascular dementia; suggestive MRI findings; a consistent family history; or a combination of the above criteria.	Direct sequencing of exons 2-8, 10, 14, 19, 20, and 22.	Patients: 14 patients with causative variants located in 10 different exons. 126 patients free of pathogenic variants. Family Members: Analysis of 15 additional family members identified 11 of the same causative variants.	NR
Lee 2009[17]	Patients: 39 patients with suspected CADASIL (China).	Direct sequencing of exons 2-23.	Patients: nine different single nucleotide variants identified in 21/39 patients.	100% No variants found in 100 healthy

Study	Patients Evaluated	*NOTCH3* Exons Evaluated	Results	
	100 healthy elderly controls 80 years or older. Patient Selection: Suggestive MRI findings and at least one of the following: young age at onset, cognitive decline, psychiatric disorders, or consistent family history.		Family members: No data for additional family members	elderly controls.
Markus 2002[7]	Patients: 83 patients with suspected CADASIL (UK). Patient Selection: Patients were younger than 60 years of age with recurrent lacunar stroke with leukoaraiosis on neuroimaging. Migraine, psychiatric disorders, or dementia could occur but were not essential.	Direct sequencing of exons 3-4; SSCP of exons 2, 5-23.	Patients: 15 different single nucleotide variants identified in 48 families with a total of 116 symptomatic patients, 73% in exon 4, 8% in exon 3, and 6% in exons 5 and 6. Family Members: No data for additional family members	NR
Part 2 Clinical Validity Studies			**Sensitivity**	**Specificity**
Choi 2013[18]	Patients: 73 unrelated patients diagnosed with CADASIL between 2004-2009. Patient Diagnosis/Selection: Patients were diagnosed via clinical and MRI, and stroke history.	Bidirectional sequencing of R544C (exon 11).	Patients: 65 of 73 Patients (90.3%) had the same R544C genotype.	NR
Tikka 2009[19]	Patients: 131 patients from 28 families diagnosed with CADASIL (Finnish, Swedish, and French). Patient Diagnosis/Selection: EM examination of skin biopsy was performed; 26 asymptomatic controls from CADASIL families.	Direct sequencing of exons 2-24.	Sensitivity: 100% Patients: 131 CADASIL patients were variant positive. Family Members: No data for additional family patients. No variant reporting per family or per unrelated individual.	100% No variants were found in the 26 negative controls.
Dotti et al. 2005[20]	Patients: 28 unrelated, consecutively diagnosed patients with CADASIL (Italian). Patient Diagnosis/Selection: Patients were diagnosed via clinical and MRI.	DHPLC, followed by confirmatory sequencing of identified variants.	Sensitivity: 100%. Patients: All 28 patients had variants.	NR

Study	Patients Evaluated	*NOTCH3* Exons Evaluated	Results	
Peters 2005[21]	Patients: 125 unrelated patients diagnosed with CADASIL. Patient Diagnosis/Selection: Skin biopsy-proven CADASIL pts referred between 1994 and 2003 (German).	Bidirectional sequencing of all exons.	Sensitivity: 96% Patients: 54 distinct variants in 120 (96.0%) of the 125 patients. In five patients (4.0%), no variant was identified. Family Members: No data for additional family patients	NR
Joutel 1997[22]	Patients: 50 unrelated patients with a clinical suspicion of CADASIL and 100 healthy controls. Patient Diagnosis/Selection: History of recurrent strokes, migraine with aura, vascular dementia, or a combination; brain MRI with suggestive findings; and a consistent familial history.	SSCP or heteroduplex analysis of all exons, followed by confirmatory sequencing of identified variants.	Sensitivity: 90% Patients: 45 of 50 CADASIL patients had variants.	100% No variants were found in 100 healthy controls.

Key: MRI, magnetic resonance imaging; SSCP, single-stranded conformational polymorphism; EM, electron microscope; DHPLC, denaturing high-performance liquid chromatography

The results of the clinical validity studies demonstrate that a *NOTCH3* variant is found in a high percentage of patients with a clinical diagnosis of CADASIL, with studies reporting a clinical sensitivity of 90-100%. Limited data on specificity is from testing small numbers of healthy controls, and no false positive *NOTCH3* variants have been reported in these populations. The diagnostic yield studies report a variable diagnostic yield, ranging from 10-54%. These lower numbers likely reflect testing in heterogeneous populations that include patients with other disorders.

CLINICAL UTILITY

Genetic testing may have clinical utility in several situations. The clinical situations addressed in herein are:

- Confirmation of a clinical diagnosis of CADASIL in an individual with signs and symptoms of the disease; and
- Informing the reproductive decision-making process in preimplantation testing, prenatal (in utero) testing or altering reproductive planning decisions when a *NOTCH3* pathogenic variant is present in a parent.

Confirmation of a CADASIL Diagnosis

The clinical specificity of genetic testing for CADASIL is high, and false-positive results have not been reported in studies of clinical validity. Therefore, a positive genetic test in a patient with clinical signs and symptoms of CADASIL is sufficient to confirm the diagnosis with a high degree of certainty. The clinical sensitivity is also relatively high, in the range of 90% to 100%

for patients with a clinical diagnosis of CADASIL. This indicates that a negative test reduces the likelihood that CADASIL is present. However, because false-negative tests do occur, a negative test is less definitive in ruling out CADASIL. Whether a negative test is sufficient to rule out CADASIL depends on the pretest likelihood that CADASIL is present.

Hack (2023) published a three-tiered risk stratification system for individualized *NOTCH3*-small vessel disease prediction based on *NOTCH3* genotype.[23] The frequency of cysteine-altering missense variants in each EGF repeat domain was assessed in the CADASIL literature, cohorts, and population databases among 2,574 CADASIL patients and 1,657 individuals from population databases. EGF repeat domains were classified as either low, medium, or high risk. The three risk categories were validated with comparisons to small vessel disease imaging markers and clinical outcomes using a genotype-phenotype dataset of 434 CADASIL patients and 1,003 individuals with *NOTCH3* cysteine-altering variants. CADASIL patients and individuals with *NOTCH3* cysteine-altering variants had 379 unique *NOTCH3* cysteine-altering variants. Nine EGF repeat domains were classified as high risk, 10 were classified as medium risk, and 11 were classified as low risk. In the population genotype-phenotype dataset, individuals with high risk EGF repeat variants had the highest risk of stroke (odds ratio [OR]=10.81, 95% confidence interval [CI]: 5.46 to 21.37) followed by medium risk individuals (OR=1.81, 95% CI: 0.84 to 3.88), and low risk individuals (OR=1). In the CADASIL genotype-phenotype group, patients with high risk EGF repeat domain variants had a significantly higher risk of stroke (p=0.002) and disability (p=0.041).

Chen (2021) published a study in 45 patients with young-onset cognitive impairment with leukodystrophy in which a custom panel of 200 neurodegeneration-associated genes was performed.[24] The frequency of gene variants was evaluated along with study participants' brain magnetic resonance imaging (MRI) findings to inform the diagnostic utility of combining the two approaches. In more than half (19/37, 51.4%) of patients with MRI changes consistent with vascular cognitive impairment secondary to small vessel disease (VCI-SVD), a pathogenic variant was identified, including all patients with pathogenic NOTCH3 (17/19, 89.5%) and HTRA1 variants (2/19, 11.5%). Anterior temporal white matter involvement was specific to patients with pathogenic NOTCH3 variants (6/17, 35.3%) in this cohort. No pathogenic variant was identified in 26/45 (57.8%) patients evaluated. The impact of genetic testing on health care decision making or on clinical outcomes was not evaluated in this study.

Pescini (2012) published a study that attempted to identify clinical factors that increase the likelihood of a pathogenic variant being present and therefore might be helpful in selecting patients for testing.[25] The authors first performed a systematic review to determine the frequency with which clinical and radiologic factors are associated with a positive genetic test. Evidence was identified from 15 clinical series of patients with CADASIL. Table 2 summarizes the pooled frequency of clinical and radiologic features.

Table 2. Clinical and Radiological Features in Patients with NOTCH3 Variants

Features	No. With NOTCH3 Variant	Percent With NOTCH3 Variant, %
Clinical features		
Migraine	239/463	52%
Migraine with aura	65/85	76%
Transient ischemic attack/stroke	380/526	72%
Psychiatric disturbance	106/380	28%
Cognitive decline	188/434	43%
Radiologic features		

Features	No. With NOTCH3 Variant	Percent With NOTCH3 Variant, %
LE (leukoencephalopathy)	277/277	100%
LE extended to temporal pole	174/235	74%
LE extended to external capsule	228/303	75%
Subcortical infarcts	210/254	83%

Using these frequencies, a preliminary scoring system was developed and tested in 61 patients with *NOTCH3* variants, and in 54 patients with phenotypic features of CADASIL who were *NOTCH3*-negative. With the addition of family history and age at onset of transient ischemic attack (TIA)/stroke, a scoring system was developed with the following point values: migraine (1); migraine with aura (3); TIA/stroke (1); TIA/stroke 50 years old or younger (2); psychiatric disturbance (1); cognitive decline (3); leukoencephalopathy (3); leukoencephalopathy extended to temporal pole (1); leukoencephalopathy extended to external capsule (5); subcortical infarcts (2); family history, one generation (1); and family history, two generations or more (2). The authors recommended that a total score of 14 be used to select patients for testing, because this score resulted in a high sensitivity (96.7%) and a moderately high specificity (74.2%).

A 2017 study reported by Mizuta analyzed clinical features of Japanese patients suspected for CADASIL to determine new diagnostic criteria for CADASIL.[26] Criteria were developed and validated with two separate groups of genetically diagnosed CADASIL patients, with 37 patients in the first group and 65 in the second. Controls groups were young stroke patients (n = 67) and CADASIL-like patients without *NOTCH3* variants (n = 53). Clinical criteria were as follows:

1. Age at onset less than or equal to 55 years
2. At least two of the following clinical findings:
    a. Either subcortical dementia, long tract signs, or pseudobulbar palsy.
    b. Stroke-like episode with a focal neurological deficit.
    c. Mood disorder.
    d. Migraine.
3. Autosomal dominant inheritance.
4. White matter lesions involving the anterior temporal pole by MRI or CT.
5. Exclusion of leukodystrophy

Genetic and pathological criteria were:

- *NOTCH3* variants localized in exons 2–24 and result in the gain or loss of cysteine residues in the epidermal growth factor-like repeat domain. Cysteine-sparing variants should be carefully evaluated by skin biopsy and segregation studies.
- The pathological hallmark of CADASIL is granular osmiophilic material (GOM) detected by electron microscopy. Immunostaining of NOTCH3 extracellular domain is also useful.

CADASIL diagnosis was considered definite when white matter lesions were detected by MRI or CT, clinical criteria #5 was met, and genetic or pathological criteria were met. Diagnosis was considered probable when the subject met all five clinical criteria and possible when the subject had abnormal white matter lesions and either was less than or equal to 55 years old or had at least one of the symptoms in clinical criteria number two. The sensitivity and specificity of the new criteria were 97.1% and 7.5%, respectively, when calculated using both control

groups. Sensitivity and specificity of the scale proposed by Pescini (above) using this cohort was also calculated. Sensitivity and specificity were 52.1% and 64.1%, respectively.

Currently, no specific clinical treatment for CADASIL has established efficacy. Supportive care in the form of practical help, emotional support, and counseling are appropriate for affected individuals and their families.[3] Studies that addressed the efficacy of potential treatments for CADASIL are summarized below.

De Maria (2014) reported the results of a randomized, double-blinded trial comparing sapropterin with placebo for adults with CADASIL.[27] Sapropterin is a synthetic analog of tetrahydrobiopterin, which is an essential cofactor in nitric oxide synthesis in endothelial cells. Given nitric oxide's role in cerebrovascular function, the authors hypothesized that sapropterin supplementation would improve cerebral endothelium-dependent vasodilation in CADASIL patients. Endothelial dysfunction was assessed using the reactive hyperemia peripheral arterial tonometry (RH-PAT) response, which has been shown to be impaired in patients with CADASIL syndrome. Peripheral arterial tonometry (PAT) is a noninvasive, quantitative test that measures changes in digital pulse volume during reactive hyperemia (RH) and evaluates the endothelial function of resistance arteries and nitric oxide–mediated changes in microvascular response. The study randomized 61 subjects from 38 families, 32 to sapropterin and 29 to placebo. In intention-to-treat analysis, there was no significant difference in change in RH-PAT response (mean difference in RH-PAT change, 0.19: 95% confidence interval, -0.18 to 0.56). Both groups demonstrated improvements in RH-PAT values over the course of the study, but, after results were adjusted for age, sex, and clinical characteristics, the improvement was not associated with treatment.

Another study published by Huang (2010) evaluated the efficacy and tolerance of a 24-week treatment with acetazolamide 250 mg/d to improve cerebral hemodynamics in CADASIL patients (n=16)..[28] Treatment with acetazolamide resulted in a significant increase of mean blood flow velocity (MFV) in the middle cerebral artery (MCA) compared with MFV in the MCA at rest before treatment (57.68±12.7 cm/s vs 67.12±9.4 cm/s; p=0.001). During the treatment period, none of the subjects developed new neurologic symptoms, and the original symptoms in these patients (e.g., headaches, dizziness) were relieved. A double-blind, placebo-controlled trial evaluating the efficacy and safety of donepezil hydrochloride (HCl) in individuals with CADASIL was published in 2008 by Dichgans.[29] The study showed donepezil HCl had no effect on the primary cognitive endpoint, the Cognitive subscale of the Vascular AD Assessment Scale score in patients with CADASIL and cognitive impairment.

Peters (2007) evaluated the use of 3-hydroxy-3-methylglutaryl-coenzyme A-reductase inhibitors (statins) in 24 CADASIL subjects treated with atorvastatin for eight weeks.[30] Treatment was started at 40 mg, followed by a dosage increase to 80 mg after four weeks. Transcranial Doppler sonography measuring MFV in the MCA was performed at baseline and at the end of treatment. There was no significant treatment effect on MFV (p=0.5) or cerebral vasoreactivity, as assessed by hypercapnia (p=0.5) or intravenous L-arginine (p=0.4) in the overall cohort. However, an inverse correlation was found between vasoreactivity at baseline and changes of both CO2- and L-arginine–induced vasomotor response (both p<0.05). Short-term treatment with atorvastatin resulted in no significant improvement of hemodynamic parameters in the overall cohort of CADASIL subjects.

Genetic Testing of *NOTCH3* in Relatives of Patients with CADASIL

For individuals that have family members with CADASIL syndrome who receive genetic testing, the evidence is limited. Relevant outcomes are overall survival, test accuracy and validity, changes in reproductive decision making, change in disease status, and morbid events. For family members of an individual with known CADASIL, knowledge of the presence of a familial variant may lead to changes in lifestyle decisions for the affected individual (eg, reproduction, employment). However, the impact of these lifestyle decisions on health outcomes is uncertain, and there are no interventions for asymptomatic individuals that are known to delay or prevent the onset of disease. A chain of evidence can be constructed to demonstrate that identification of a NOTCH3 familial variant predicts future development of CADASIL in asymptomatic individuals, eliminates the need for additional diagnostic testing, allows for earlier monitoring for development of systems, aids in reproductive planning and helps determine the likelihood of an affected offspring.

It has been suggested that asymptomatic family members follow the guidelines for presymptomatic testing for Huntington disease. Genetic counseling is recommended to discuss the impact of positive or negative test results, followed by molecular testing if desired.[4] For an asymptomatic individual, knowledge of variant status will generally not lead to any management changes that can prevent or delay the onset of the disorder. Avoiding tobacco use may be one factor that delays onset of disease, but this is a general recommendation that is not altered by genetic testing.

PRACTICE GUIDELINE SUMMARY

In a 2023 scientific statement, the American Heart Association reviewed the current clinical, genetic, and imaging aspects of CADASIL to provide prevention, management, and therapeutic considerations to support future treatment recommendations.[31] In consideration of when to test for *NOTCH3* mutations, the statement recommends to "consider gene testing in patients with small vessel stroke before 55 years of age with a paucity of vascular risk factors (eg, normotensive, nondiabetic, nonsmoker) or positive family history of CADASIL."

SUMMARY

There is enough research to show that testing for *NOTCH3* variants can help diagnose CADASIL in patients with signs and symptoms consistent with CADASIL. Therefore, genetic testing to confirm the diagnosis of CADASIL syndrome may be considered medically necessary when the policy criteria are met.

There is enough evidence to show that testing for *NOTCH3* variants associated with CADASIL in individuals who have a family member with the disease can help patients make reproductive planning decisions and avoid unnecessary diagnostic testing. Therefore, genetic testing for *NOTCH3* variants in adults that have a first- or second-degree family member with a diagnosis of CADASIL syndrome may be considered medically necessary.

There is not enough research to show that genetic testing for CADASIL improves health outcomes or decision-making in patients that do not meet the policy criteria. Therefore, genetic testing for CADASIL syndrome in all other situations, including but not limited to testing in children, is considered investigational.

Diagnostic Genetic Testing for α-Thalassemia

Effective: April 1, 2024

Next Review: January 2025
Last Review: February 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Alpha-thalassemia represents a group of clinical syndromes of varying severity characterized by hemolytic anemia and ineffective hematopoiesis. Genetic defects in any or all of four α-globin genes are causative of these syndromes.

MEDICAL POLICY CRITERIA

Note: This policy applies to diagnostic testing only. Reproductive carrier screening is addressed separately (see Cross References).

I. Diagnostic prenatal (fetal) genetic testing for α-thalassemia may be considered **medically necessary**.

II. Diagnostic genetic testing to confirm a diagnosis of α-thalassemia is considered **not medically necessary**.

III. Diagnostic genetic testing for α-thalassemia in other clinical situations is considered **investigational**, including in patients with hemoglobin H disease (alpha-thalassemia intermedia) to determine prognosis.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

Strategies for testing may include testing for individual genes or in combination, such as in a panel.

Alpha-thalassemias include:

- Thalassemia trait (α-thalassemia minor)
- Hemoglobin H Disease (α-thalassemia intermedia)
- Hemoglobin Bart's (α-thalassemia major, hydrops fetalis)

BIOCHEMICAL TESTING

Biochemical testing to determine whether α-thalassemia is present should be the first step in evaluating the presence of the condition. Biochemical testing consists of complete blood count (CBC), microscopic examination of the peripheral blood smear, and hemoglobin electrophoresis. In silent carriers and in α-thalassemia trait, the hemoglobin electrophoresis will most likely be normal. However, there should be evidence of possible α-thalassemia minor on the CBC and peripheral smear.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF DOCUMENTATION:

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
    - History and physical exam including any relevant diagnoses related to the genetic testing
    - Conventional testing and outcomes
    - Conservative treatments, if any

BACKGROUND

ALPHA-THALASSEMIA

Alpha-thalassemia is a common genetic disorder, affecting approximately 5% of the world's

population.[1] The frequency of variants is highly dependent on ethnicity, with the highest rates seen in Asians, and much lower rates in Northern Europeans. The carrier rate is estimated to be 1 in 20 in Southeast Asians, 1 in 30 for Africans, and between 1 in 30 and 1 in 50 for individuals of Mediterranean ancestry. By contrast, for individuals of northern European ancestry, the carrier rate is less than 1 in 1000.

Physiology

Hemoglobin, which is the major oxygen-carrying protein molecule of red blood cells (RBCs), consists of two α-globin chains and two β-globin chains. Alpha-thalassemia refers to a group of syndromes that arise from deficient production of α-globin chains. Deficient α-globin production leads to an excess of β-globin chains, which results in anemia by a number of mechanisms[2]:

- Ineffective erythropoiesis in the bone marrow.
- Production of nonfunctional hemoglobin molecules.
- Shortened survival of RBCs due to intravascular hemolysis and increased uptake of the abnormal RBCs by the liver and spleen.

The physiologic basis of α-thalassemia is a genetic defect in the genes coding for α-globin production. Each individual carries four genes that code for α-globin (two copies each of *HBA1* and *HBA2*, located on chromosome 16), with the wild genotype (normal) being aa/aa. Genetic variants may occur in any or all of these four α-globin genes. The number of genetic variants determines the phenotype and severity of the α-thalassemia syndromes. There are four different syndromes, which are classified below.

Silent Carrier

Silent carrier (α-thalassemia minima) arises from one of four abnormal α genes (αα/α-), and is a silent carrier state. A small amount of abnormal hemoglobin can be detected in the peripheral blood, and there may be mild hypochromia and microcytosis present, but there is no anemia or other clinical manifestations.

Thalassemia Trait

Thalassemia trait (α-thalassemia minor), also called α-thalassemia trait, arises from the loss of two α-globin genes, resulting in one of two genotypes (αα/--, or α-/α-). Mild anemia is present, and RBCs are hypochromic and microcytic. Clinical symptoms are usually absent and, in most cases, the hemoglobin electrophoresis is normal.

Hemoglobin H Disease

Hemoglobin H (HbH) disease (α-thalassemia intermedia) results from three abnormal α-globin genes (α-/--), resulting in moderate-to-severe anemia. In HbH disease, there is an imbalance in α- and β-globin gene chain synthesis, resulting in the precipitation of excess β chains into the characteristic hemoglobin H, or β-tetramer.[2]

HbH has marked phenotypic variability, but most individuals have mild disease.[3] Splenomegaly is common and can lead to the need for splenectomy, for which transfusion support may be required.[1] Iron chelation therapy may be indicated for increased iron deposition. Inappropriate iron therapy and oxidant drugs that can exacerbate hemolysis should

be avoided in patients with HbH disease. A minority of people with HbH develop jaundice, hepatomegaly, and mild to moderate skeletal changes associated with thalassemia (e.g., hypertrophy of the maxilla, bossing of the skull).[3]

There is an association between genotype and phenotype among patients with HbH disease. Individuals with a nondeletion variant typically have an earlier presentation, more severe anemia, jaundice, and bone changes, and more frequently require transfusions.

Hemoglobin Bart's

Hemoglobin Bart's (α-thalassemia major) results from variants in all four α-globin genes (--/--), which prevents production of α-globin chains. This condition causes hydrops fetalis, which often leads to intrauterine death or death shortly after birth. There are also increased complications during pregnancy for a woman carrying a fetus with hydrops fetalis. They include hypertension, preeclampsia, antepartum hemorrhage, renal failure, premature labor, and abruption placenta.[1]

Genetic Testing

A number of different types of genetic abnormalities on the *HBA1* and *HBA2* genes are associated with α-thalassemia. Deletion of one or more of the α-globin chains is the most common genetic defect. This type of genetic defect is found in approximately 90% of cases.[3] Large genetic rearrangements can also occur from defects in crossover and/or recombination of genetic material during reproduction. Point mutations in one or more of the α genes that impair transcription and/or translation of the α-globin chains.

Testing is commercially available through several genetic labs. Targeted variant analysis for known α-globin gene variants can be performed using Gap polymerase chain reaction (Gap-PCR) or sequence analysis. Newer testing methods used to detect α-thalassemia variants include multiplex amplification methods and next generation sequencing (NGS).[3]

REGULATORY STATUS

Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; laboratory-developed tests (LDTs) must meet the general regulatory standards of the Clinical Laboratory Improvement Amendments (CLIA). Genetic testing for α-thalassemia is available under the auspices of CLIA. Laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, the U.S. Food and Drug Administration has chosen not to require any regulatory review of this test.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[4] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

GENETIC TESTING FOR ALPHA-THALASSEMIA

Validation of the clinical use of any genetic test focuses on three main principles:

1. The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
2. The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. The clinical utility of the test, i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

The published literature on genetic testing for α-thalassemia consists primarily of reports describing the molecular genetics of testing, the types of variants encountered, and genotype-phenotype correlations.[5-11]

Analytic Validity

A variety of testing methods can be used to evaluate the two genes related to α-globin production, *HBA1* and *HBA2*, including sequence analysis of the entire coding region, targeted variant analysis via polymerase chain reaction (PCR), and deletion/duplication analysis. Therefore, the analytic validity depends on the method used, but would generally be expected to be high.

One 2016 study identified evaluated the reproducibility and accuracy of a PCR-based multicolor melting curve analysis method for detecting common nondeletional variants in the *HBA2* gene from 700 whole blood samples.[12] Reproducibility of the assay was high. In the clinical samples, there was 100% concordance between the 20 genotypes identified and the genotyping method. Petropoulou (2015) evaluated a PCR-based high-resolution melting curve analysis of duplicated areas of the *HBA1 and HBA2* genes with novel nondeletion variants.[13] The study included 62 samples with previously identified novel variants and 18 normal controls; the melting curve analysis was able to distinguish at least 80% of novel homozygote samples detected by earlier generation tests.

Clinical Validity

Clinical validity is expected to be high when the causative variant is a large deletion of one or more α-globin gene, as PCR testing is generally considered highly accurate for this purpose. When a point variant is present, the clinical validity is less certain.

Henderson (2016) reported on a retrospective study of genotype and phenotype correlations of the novel thalassemia and abnormal hemoglobin variants identified after adoption of routine DNA sequencing of α- and β-globin genes for all U.K. samples referred for evaluation of hemoglobinopathy for the preceding 10 years.[14] Of a total of approximately 12,000 samples, 15 novel α-thalassemia variants, 19 novel β-thalassemia variants, and 11 novel β-globin variants were detected.

Clinical Utility

There are several potential areas for clinical utility. Genetic testing can be used to determine the genetic abnormalities underlying a clinical diagnosis of α-thalassemia. It can also be used to define the genetics of α-globin genes in relatives of patients with a clinical diagnosis of α-

thalassemia. Prenatal (in utero) testing can also be performed to determine the presence and type of α-thalassemia of a fetus. Prenatal testing is not addressed in this evidence review.

Confirming a Diagnosis

The diagnosis of α-thalassemia can be made without genetic testing. This is first done by analyzing the complete blood count (CBC) and peripheral blood smear, in conjunction with testing for other forms of anemia. Patients with a CBC demonstrating microcytic, hypochromic red blood cell (RBC) indices who are not found to have iron deficiency, have a high likelihood of thalassemia. On peripheral blood smear, the presence of inclusion bodies and target cells is consistent with the diagnosis of α-thalassemia.

Hemoglobin electrophoresis can distinguish between the asymptomatic carrier states and α-thalassemia intermedia (HbH disease) by identifying the types and amounts of abnormal hemoglobin present. In the carrier states, greater than 95% of the hemoglobin molecules are normal (hemoglobin A), with a small minority of hemoglobin A_2 present (1%-3%).[15] Alpha-thalassemia intermedia is diagnosed by finding a substantial portion of hemoglobin H (1%-30%) on electrophoresis.[15] In α-thalassemia major, the majority of the hemoglobin is abnormal, in the form of hemoglobin Bart's (85%-90%).[15]

However, biochemical testing, including CBC and hemoglobin electrophoresis, cannot always reliably distinguish between the asymptomatic carrier state and α-thalassemia trait, because the hemoglobin electrophoresis is typically normal in both conditions. Genetic testing can differentiate between the asymptomatic carrier state (α-thalassemia minima) and α-thalassemia trait (α-thalassemia minor) by measuring the number of abnormal genes present. This distinction is not important clinically because both the carrier state and α-thalassemia trait are asymptomatic conditions that do not require specific medical care treatment. Alpha-thalassemia trait may overlap in RBC indices values with iron deficiency states, so it is important that iron supplementation not be continued unnecessarily in patients with α-thalassemia trait. However, it would be reasonable to make a diagnosis of α-thalassemia trait in a patient with microcytic, hypochromic RBC indices without evidence of iron deficiency, either before or after a trial of iron supplementation. Because the diagnosis of clinically relevant α-thalassemia conditions can usually be made without genetic testing, there is little utility to genetic testing of a patient with a clinical diagnosis of thalassemia to determine the underlying genetic abnormalities.

Prognostic Testing in Patients with HbH Disease

Among patients with HbH disease, there is heterogeneity in the nature of the variant (i.e., deletional vs. nondeletional), with differences across geographic areas and ethnic groups.[16] Patients with deletional variants may have a less severe course of illness than those with nondeletional variants.[16] In a cohort of 147 Thai pediatric patients with HbH disease, those with nondeletional variants were more likely to have pallor after fever, hepatomegaly, splenomegaly, jaundice, short stature, need for transfusions, and gallstones.[17]

The evidence suggests that different genetic variants leading to α-thalassemia are associated with different prognoses.[18] However, clinical diagnosis can be made based on red cell indices to guide therapy, and no evidence was identified to indicate that patient management or outcomes would be changed by prognostic testing.[19]

Section Summary: Clinical Utility

The clinical utility of genetic testing for α-thalassemia may occur in several settings. For confirming a diagnosis of α-thalassemia, because the diagnosis of clinically actionable types can generally be made on the basis of nongenetic testing, there is little utility to genetic testing. For patients with HbH disease, there may be a genotype-phenotype correlation for disease severity; however, no studies were identified that suggested patient management or outcomes would be altered by genetic testing. Therefore, genetic testing for determining the prognosis of HbH disease is not associated with improved clinical utility.

SUMMARY OF EVIDENCE

For individuals who have suspected α-thalassemia who receive genetic testing for α-thalassemia, the evidence includes case reports and case series documenting the association between pathogenic variants and clinical syndromes. Relevant outcomes are overall survival, disease-specific survival, test accuracy and validity, symptoms, and quality of life. For the α-thalassemia syndromes that have clinical implications, diagnosis can be made based on biochemical testing without genetic testing. The evidence is sufficient to determine that the technology is unlikely to improve the net health outcome.

For individuals who have hemoglobin H disease (α-thalassemia intermedia) who receive genetic testing for α-thalassemia, the evidence includes case series that correlate specific variants with prognosis of disease. Relevant outcomes are overall survival, disease-specific survival, symptoms, and quality of life. There is some evidence for a genotype-phenotype correlation with disease severity, but no current evidence indicates that patient management or outcomes would be altered by genetic testing. The evidence is insufficient to determine the effects of the technology on health outcomes.

SUMMARY

There is enough research to show that prenatal testing for α-thalassemia can improve health outcomes. Prenatal fetal testing informs reproductive decision making, including decisions regarding continuation of the pregnancy, birthing decisions, and enabling for timely treatment of a condition that could be treated either in utero or immediately after birth. Therefore, prenatal testing for α-thalassemia may be considered medically necessary.

There is enough research to show that diagnosis of α-thalassemia syndromes can be made based on biochemical testing without genetic testing. Therefore, genetic testing to confirm a diagnosis of α-thalassemia is considered not medically necessary.

There is not enough research to show that genetic testing for α-thalassemia can improve health outcomes for patients with any other conditions, including people who have hemoglobin H disease (α-thalassemia intermedia). In addition, there are no clinical guidelines based on research that recommend this testing. Therefore, genetic testing is considered investigational for patients with hemoglobin H disease or for other clinical situations.

Genetic Testing for Primary Mitochondrial Disorders

Effective: January 1, 2024

Next Review: January 2024
Last Review: December 2023

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Primary mitochondrial disorders are caused by variants in mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) that directly affect the function of the oxidative phosphorylation complex in mitochondria. They often manifest as progressive, multisystem disorders. There are currently no effective treatments for mitochondrial disorders, but genetic testing may allow patients to avoid more invasive laboratory testing and provide information for reproductive decision-making.

MEDICAL POLICY CRITERIA

Notes: This policy applies only to diagnostic testing for primary mitochondrial disorders (see Policy Guidelines). It does not apply to reproductive carrier screening of asymptomatic individuals or testing for other disorders that affect mitochondria, such as fatty acid oxidation disorders (see Cross References).

I. Genetic testing for the diagnosis of primary mitochondrial disorders (see Policy Guidelines), including single-gene testing, panel testing and/or whole mitochondrial genome sequencing, may be considered **medically necessary** when all of the following Criteria are met:

A. Signs and symptoms of a primary mitochondrial disorder are present (see Policy Guidelines); and

B. One of the following is met:

1. A clinical diagnosis cannot be made without additional testing, and a muscle or liver biopsy has not been performed; or

2. A genetic diagnosis may be informative for reproductive planning purposes.

II. Genetic testing for diagnosis of primary mitochondrial disorders is considered **investigational** when Criterion I. is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

EXAMPLES OF PRIMARY MITOCHONDRIAL DISORDERS

(Not all-inclusive)

- Alpers (aka Alpers-Huttenlocher) syndrome
- Barth syndrome
- Chronic progressive external ophthalmoplegia (CPEO)
- Coenzyme Q_{10} deficiency
- Growth retardation, amino aciduria, cholestasis, iron overload, lactic acidosis, and early death (GRACILE) syndrome
- Infantile-onset spinocerebellar ataxia (IOSCA)
- Kearns-Sayre syndrome
- Leber hereditary optic neuropathy (LHON)
- Leigh syndrome
- Maternally inherited deafness and diabetes (MIDD)
- Mitochondrial DNA depletion syndrome; mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)
- Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)
- Mitochondrial recessive ataxia syndrome (MIRAS)
- Myoclonus epilepsy with ragged red fibers (MERFF)
- Neuropathy, ataxia, and retinitis pigmentosa (NARP)
- Pearson syndrome
- Sensory ataxia neuropathy, dysarthria, ophthalmoplegia (SANDO)

SIGNS AND SYMPTOMS

Primary mitochondrial disorders can have a variety of presentations, depending on the molecular cause. They are often multisystem disorders, and may include (not all-inclusive):

- skeletal muscle myopathy
- cardiomyopathy
- encephalopathy
- ophthalmoplegia
- neuropathy

- hypotonia/muscle weakness
- seizures
- developmental delay
- ataxia
- deafness
- short stature

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review. If any of these items are not submitted, it could impact our review and decision outcome.

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
   - History and physical exam including any specific signs and symptoms and/or relevant diagnoses related to the genetic testing

BACKGROUND

MITOCHONDRIAL DNA

Mitochondria are organelles within each cell that contain their own set of DNA, distinct from the nuclear DNA that makes up most of the human genome. Human mitochondrial DNA (mtDNA) consists of 37 genes. Thirteen genes code for protein subunits of the mitochondrial oxidative phosphorylation complex and the remaining 24 genes are responsible for proteins involved in the translation and/or assembly of the mitochondrial complex.[1] Additionally, there are over 1000 nuclear genes coding for proteins that support mitochondrial function.[2] The protein products from these genes are produced in the nucleus and later migrate to the mitochondria.

Mitochondrial DNA differs from nuclear DNA (nDNA) in several important ways. Inheritance of mtDNA does not follow traditional Mendelian patterns. Rather, mtDNA is inherited only from maternal DNA so disorders that result from variants in mtDNA can only be passed on by the mother. Also, there are thousands of copies of each mtDNA gene in each cell, as opposed to nDNA, which contains only one copy per cell. Because there are many copies of each gene, variants may be present in some copies of the gene but not others. This phenomenon is called heteroplasmy. Heteroplasmy can be expressed as a percentage of genes that have the variant ranging from 0% to 100%. Clinical expression of the variant will generally depend on a

threshold effect (i.e., clinical symptoms will begin to appear when the percentage of mutated genes exceeds a threshold amount).[3]

PRIMARY MITOCHONDRIAL DISORDERS

Primary mitochondrial disorders arise from dysfunction of the mitochondrial electron transport chain (ETC). The ETC is responsible for aerobic metabolism, and dysfunction, therefore, affects a wide variety of physiologic pathways dependent on aerobic metabolism. Organs with a high-energy requirement, such as the central nervous system, cardiovascular system, and skeletal muscle, are preferentially affected by mitochondrial dysfunction.

Table 1 (below) lists some of the more common primary mitochondrial disorders. Most of these disorders are characterized by multisystem dysfunction, which generally includes myopathies and neurologic dysfunction, and may involve multiple other organs. Each defined mitochondrial disease has a characteristic set of signs or symptoms. The severity of illness is heterogeneous and can vary markedly. Some patients will have only mild symptoms for which they never require medical care, while other patients have severe symptoms, a large burden of morbidity, and a shortened life expectancy.

The prevalence of these disorders has risen over the last two decades as the pathophysiology and clinical manifestations have been better characterized. It is currently estimated that the minimum prevalence of primary mitochondrial diseases is at least 1 in 5000.[1 4]

Diagnosis

The diagnosis of primary mitochondrial diseases can be difficult. The individual symptoms are nonspecific, and symptom patterns can overlap considerably. As a result, a patient often cannot be easily classified into any particular syndrome.[5] Biochemical testing is indicated for patients who do not have a clear clinical diagnosis of a specific disorder. Measurement of serum lactic acid is often used as a screening test but the test is neither sensitive nor specific for mitochondrial diseases.[2]

A muscle biopsy can be performed if the diagnosis is uncertain after biochemical workup. However, this invasive test is not definitive in all cases. The presence of "ragged red fibers" on histologic analysis is consistent with a mitochondrial disease. Ragged red fibers represent a proliferation of defective mitochondria.[1] This characteristic finding may not be present in all types of mitochondrial diseases and also may be absent early in the course of disease.[2]

Treatment

Treatment of primary mitochondrial disease is largely supportive because there are no specific therapies that impact the natural history of the disorder.[5] Identification of complications such as diabetes and cardiac dysfunction is important for early treatment of these conditions. A number of vitamins and cofactors (e.g., coenzyme Q, riboflavin) have been used but empirical evidence of benefit is lacking.[6] Exercise therapy for myopathy is often prescribed but the effect on clinical outcomes is uncertain.[5] The possibility of gene transfer therapy is under consideration but is at an early stage of development and untested in clinical trials.

Genetic Testing

Primary mitochondrial diseases can be caused by pathogenic variants in the maternally inherited mtDNA or one of many nDNA genes. Genetic testing for mitochondrial diseases may

involve testing for single nucleotide variants, deletion and duplication analysis, and/or whole exome sequencing of nuclear or mtDNA. The type of testing done depends on the specific disorder being considered. For some primary mitochondrial diseases such as mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS) and myoclonic epilepsy with ragged red fibers (MERFF), most variants are single nucleotide variants, and there is a finite number of variants associated with the disorder. When testing for one of these disorders, known pathogenic variants can be tested for with polymerase chain reaction, or sequence analysis can be performed on the particular gene. For other mitochondrial diseases, such as chronic progressive external ophthalmoplegia and Kearns-Sayre syndrome, the most common variants are deletions, and therefore duplication and deletion analysis would be the first test when these disorders are suspected. Table 1 provides examples of clinical symptoms and particular genetic variants in mtDNA or nDNA associated with particular mitochondrial syndromes.[5 7] A repository of published and unpublished data on variants in human mtDNA is available in the MITOMAP database.[8] Lists of mtDNA and nDNA genes that may lead to mitochondrial diseases and testing laboratories in the U.S. are provided at Genetic Testing Registry of the National Center for Biotechnology Information website.[9]

Table 1. Examples of Mitochondrial Diseases, Clinical Manifestations, and Associated Pathogenic Genes (not all inclusive)

Syndrome	Main Clinical Manifestations	Major Genes Involved
MELAS	• Stroke-like episodes at age <40 y • Seizures and/or dementia • Pigmentary retinopathy • Lactic acidosis	• *MT-TL1*, *MT-ND5* (>95%) • *MT-TF, MT-TH, MT-TK, MT-TQ, MT-TS1, MT-TS2, MT-ND1, MT-ND6* (rare)
MERFF	• Myoclonus • Seizures • Cerebellar ataxia • Myopathy	• *MT-TK* (>80%) • *MT-TF, MT-TP* (rare)
CPEO	• External ophthalmoplegia • Bilateral ptosis	• Various deletions of mitochondrial DNA
Kearns-Sayre syndrome	• External ophthalmoplegia at age <20 y • Pigmentary retinopathy • Cerebellar ataxia • Heart block	• Various deletions of mitochondrial DNA
Leigh syndrome	• Subacute relapsing encephalopathy • Infantile-onset • Cerebellar/brainstem dysfunction	• *MT-ATP6, MT-TL1, MT-TK, MT-TW, MT-TV, MT-ND1, MT-ND2, MT-ND3, MT-ND4, MT-ND5, MT-ND6, MT-CO3* • *Mitochondrial DNA deletions (rare)* • *SUCLA2, NDUSFx, NDFVx, SDHA, BCS1L, SURF1, SCO2, COX15*
LHON	• Painless bilateral visual failure • Male predominance • Dystonia • Cardiac pre-excitation syndromes	• *MT-ND1, MT-ND4, MT-ND6*

Syndrome	Main Clinical Manifestations	Major Genes Involved
NARP	• Peripheral neuropathy • Ataxia • Pigmentary retinopathy	• *MT-ATP6*
MNGIE	• Intestinal malabsorption • Cachexia • External ophthalmoplegia • Neuropathy	• *TP*
IOSCA	• Ataxia • Hypotonia • Athetosis • Ophthalmoplegia • Seizures	• *TWINKLE*
SANDO	• Ataxic neuropathy • Dysarthria • Ophthalmoparesis	• *POLG*
Alpers syndrome	• Intractable epilepsy • Psychomotor regression • Liver disease	• *POLG, DGUOK, MPV17*
GRACILE	• Growth retardation • Aminoaciduria • Cholestasis • Iron overload • Lactic acidosis	• *NDUSFx*
Coenzyme Q_{10} deficiency	• Encephalopathy • Steroid-resistant nephrotic syndrome • Hypertrophic cardiomyopathy • Retinopathy • Hearing loss	• *COQ2* • *COQ9* • *CABC1* • *ETFDH*

Adapted from Chinnery (2014)5, and Angelini (2009).[7]
CPEO: chronic progressive external ophthalmoplegia; GRACILE: growth retardation, aminoaciduria, cholestasis, iron overload, early death; IOSCA: infantile onset spinal cerebellar atrophy; LHON: Leber hereditary optic neuropathy; MELAS: mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes; MERFF: myoclonic epilepsy with ragged-red fibers; MNGIE: mitochondrial neurogastrointestinal encephalopathy; NARP: neuropathy, ataxia, and retinitis pigmentosa; SANDO: sensory ataxia, neuropathy, dysarthria and ophthalmoplegia.

EVIDENCE SUMMARY

The purpose of genetic testing in patients who have signs and symptoms of mitochondrial diseases is to confirm the diagnosis. Diagnosis of a specific mitochondrial disease is complex due to the phenotypic heterogeneity and general lack of genotype-phenotype associations, particularly in infants and children. Identifying a disease-causing variant can end the diagnostic odyssey for families and help to avoid muscle (or in some cases, liver) biopsy for patients. While the current treatment for most patients with mitochondrial disease is primarily supportive, potential treatments exist for patients with coenzyme Q_{10} deficiency and mitochondrial neurogastrointestinal encephalopathy, although evidence for their effectiveness is not conclusive.

CLINICAL VALIDITY

A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

The evidence on the clinical sensitivity and specificity of genetic testing for mitochondrial diseases is limited. There are some small case series of patients with a well-defined syndrome such as MELAS syndrome, and some studies include larger numbers of patients with less specific clinical diagnoses. There are wide variations in reported testing yields, probably reflecting the selection process used to evaluate patients for testing.

Several series of patients with mixed diagnoses or suspected mitochondrial diseases have been published. In these studies, the variant detection rate (or yield) may or may not be an accurate estimate of clinical sensitivity, because the proportion of patients with a mitochondrial disease is uncertain (see Table 2).

Table 2. Studies Reporting Diagnostic Yield for Suspected Mitochondrial Diseases

Study	Population	N	Genetic Test	Design	Yield, n (5)
Riley (2020)[10]	Australian cohort of children with suspected mitochondrial disease	40	Trio GS	• Prospective enrollment • Selection method not reported	• 22 (67.5%) with "causal" variants • 22 (50%) with a "definitive molecular diagnosis" per modified Nijmegen mitochondrial disease severity scale
Nogueira (2019)[11]	Children and adults suspected of having mitochondrial disease	146	Panel of 209 genes	• Prospective /retrospective not reported • Selection method not reported	• 16 (11%) with "causative" variants • 20 (14%) with VUS • 54/107 (50%) with defects identified on muscle biopsy
Fang (2017)[12]	Children and young adults suspected of having mitochondrial disease	141	Targeted panel	• Prospective enrollment • Selection method not reported	• 40 (28%) with "causative" variants
Legati (2016)[13]	Patients clinically diagnosed with mitochondrial disease	NGS: 125 WES: 10	Custom panel of 132 genes, WES for those negative	• Prospective/ retrospective not reported • Selection method not reported	*NGS:* • 19 (15%) with "causative" variants • 27 (22%) with possible pathogenic variants *WES:* • 6 (60%) with "causative" variants
Pronicka (2016)[14]	Patients referred for possible or probable	113	WES followed by SS	• Prospective /retrospective samples included;	• 67 (59%) with likely pathogenic variants

Study	Population	N	Genetic Test	Design	Yield, n (5)
	mitochondrial disease			consecutive patients included in prospective sample • Selection method for retrospective samples not reported	• 30 (64%) of neonates with likely pathogenic variants
Kohda (2016)[15]	Children with early-onset respiratory chain disease	142	mtWGS plus WES of the nDNA	• Prospective enrollment • Selection method not reported	• 29 (20%) with known pathogenic variants • 53 (37%) inconclusive but possibly pathogenic variants
Wortmann (2015)[16]	Children and young adults with a suspected mitochondrial disease	109	Panel of 238 genes followed by WES	• Prospective enrollment • Selection method not reported	• 42 (39%) with pathogenic variants
Ohtake (2014)[17]	Patients with mitochondrial respiratory chain diseases	104	WES of the nDNA	• Prospective/ retrospective not reported • Selection method not reported	• 18 (17%) with known pathogenic variants • 27 (26%) with likely pathogenic variants
Taylor (2014)[18]	Patients with suspected mitochondrial disease and multiple respiratory chain complex defects	53	WES validated with SS	• Prospective/ retrospective not reported; selection method not reported but only included patients with multiple respiratory chain complex defects	• 28 (53%) with known pathogenic variants • 4 (8%) with likely pathogenic variants
Lieber (2013)[19]	Patients with suspected mitochondrial diseases and heterogeneous clinical symptoms	102	mtWGS and 1,598 nuclear genes	• Prospective/ retrospective not reported • Patients in a repository having highest clinical suspicion of disease selected	• 22 (22%) with likely pathogenic variants • 26 (25%) VUS
DaRe (2013)[20]	Patients with diagnosed or	148	Panel of 447 genes	• Prospective /retrospective	• 13 (9%) possible pathogenic variants

Study	Population	N	Genetic Test	Design	Yield, n (5)
	suspected mitochondrial diseases			not reported; consecutive patients	• 67 (45%) with VUS
McCormick (2013)[21]	Patients with suspected mitochondrial disease	152	mtWGS, array, SS	• Retrospective chart review; consecutive patients included	• 25 (16%) with "definite" mitochondrial disease • 46 (30%) with "probable" or "possible" mitochondrial disease
Calvo (2012)[22]	Infants with clinical and biochemical evidence of oxidative phosphorylation disease	42	mtWGS and 1034 nuclear genes	• Prospective/ retrospective not reported • Selection method not reported	• 10 (24%) with known pathogenic variants • 13 (31%) possible pathogenic variants
Qi (2007)[23]	Patients with mitochondrial encephalopathies (MELAS, MERRF, Leigh syndrome, LHON, or an overlap syndrome)	552	PCR-RFLP analysis, PCR	• Prospective/ retrospective not reported • Selection method not reported	• 64 (12%) with pathogenic variants

GS: genome sequencing; LHON: Leber hereditary optic neuropathy; MELAS: mitochondrial encephalopathy with lactic acidosis and stroke-like episodes; MERRF: myoclonic epilepsy with ragged red fibers; mtDNA: mitochondrial DNA; nDNA: nuclear DNA: NGS: next-generation sequencing; PCR: polymerase chain reaction; RFLP: restriction fragment length polymorphism; VUS: variant of uncertain significance; WES: whole-exome sequencing; mtWGS: whole mitochondrial genome sequencing; SS: Sanger sequencing.

The clinical specificity of genetic testing for mitochondrial diseases is largely unknown, but false-positive results have been reported.[24] Some epidemiologic evidence is available on the population prevalence of pathogenic variants, which provides some indirect evidence on the potential for false-positive results.

Elliott (2008) published a study of population-based testing reported that the prevalence of pathogenic variants is higher than the prevalence of clinical disease.[25] In this study, 3,168 consecutive newborns were tested for the presence of one or more of the 10 most common mtDNA variants thought to be associated with clinical disease. At least one pathogenic variant was identified in 15 (0.54%) of 3,168 people (95% confidence interval 0.30% to 0.89%). This finding implies that there are many more people with a variant who are asymptomatic than there are people with clinical disease, and this raises the possibility of false-positive results on genetic testing.

An earlier population-based study by Majamaa (1998) evaluated the prevalence of the nucleotide 3,243 variant associated with MELAS syndrome.[26] This study included 245,201 subjects from Finland. Participants were screened for common symptoms associated with MELAS, and screen-positive patients were tested for the variant. The population prevalence was estimated at 16.3 (0.16%) in 100,000. This study might have underestimated the prevalence because patients who screened negative were not tested for the variant.

In addition to false-positive results, there are variants of uncertain significance detected in substantial numbers of patients. The number of variants increases when NGS methods are used to examine a larger portion of the genome. In a study by DaRe (2013), which used targeted exome sequencing, variants of uncertain significance (VUS) were far more common than definite pathogenic variants.[20] In that study, 148 patients with suspected or confirmed mitochondrial diseases were tested using a genetic panel that included 447 genes. Thirteen patients were found to have pathogenic variants. In contrast, VUS were very common, occurring at a rate of 6.5 per patient.

A further consideration is the clinical heterogeneity of variants known to be pathogenic. Some variants associated with mitochondrial diseases can result in heterogeneous clinical phenotypes, and this may cause uncertainty about the pathogenicity of the variant detected. For example, the nucleotide 3,243 variant in the *MT-TL1* gene is found in most patients with clinically defined MELAS syndrome.[27] This same variant has also been associated with chronic progressive external ophthalmoplegia and Leigh syndrome.[28] Therefore, the more closely the clinical syndrome matches MELAS, the more likely a positive genetic test will represent a pathogenic variant.

CLINICAL UTILITY

A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing.

Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from randomized controlled trials. No direct evidence on clinical utility was identified.

There are two ways that clinical utility might be demonstrated from a chain of evidence. First, confirmation of the diagnosis may have benefits in ending the need for further clinical workup and eliminating the need for a muscle biopsy. Second, knowledge of pathogenic variant status may have benefits for individuals in determining their risk of passing on the disorder to offspring.

Confirmation of Diagnosis in Individuals with Signs and/or Symptoms of a Mitochondrial Disease

For patients with signs and symptoms consistent with a defined mitochondrial syndrome, testing can be targeted to those pathogenic variants associated with that particular syndrome. In the presence of a clinical picture consistent with the syndrome, the presence of a known pathogenic variant will confirm the diagnosis with a high degree of certainty. Confirmation of the diagnosis by genetic testing can result in a reduced need for further testing, especially a muscle biopsy. However, a negative genetic test in the blood does not rule out a mitochondrial disease and should be reflexed to testing in the affected tissue to avoid the possibility of missing tissue-specific variants or low levels of heteroplasmy in blood.

There is no specific therapy for mitochondrial diseases. Treatment is largely supportive management for complications of the disease. It is possible that confirmation of the diagnosis by genetic testing would lead to management changes, such as increased surveillance for

complications of the disease and/or the prescription of exercise therapy or antioxidants. However, the impact of these management changes on health outcomes is not known. A Cochrane review updated by Pfeffer (2012) did not find any clear evidence supporting the use of any intervention for the treatment of mitochondrial disorders.[29]

Reproductive Testing

When there is a disease of moderate severity or higher, it is reasonable to assume that many patients will consider the results of testing in reproductive decision-making. For purposes of informing family planning, when a pathogenic variant is detected in the nDNA of a prospective parent or in the mtDNA of a prospective mother, the prospective parent can choose to refrain from having children. If the variant is in the nDNA, the prospective parent could also choose medically-assisted reproduction during which pre-implantation testing would permit a choice to avoid an affected offspring. The use of pre-implantation testing when a pathogenic variant is identified in the mtDNA of an affected mother is complicated by issues of heteroplasmy of the mtDNA variant, threshold levels, and phenotypic expression leading.

PRACTICE GUIDELINE SUMMARY

MITOCHONDRIAL MEDICINE SOCIETY

The Mitochondrial Medicine Society (2015) published a consensus statement on the diagnosis and management of mitochondrial disease.[30] Most evidence was grade III or less (case-control, low-quality cohort studies, or expert opinion without an explicit critical appraisal) using the Oxford Centre for Evidence-Based Medicine criteria. Consensus recommendations were reported using the Delphi method. A subset of the consensus recommendations for DNA testing are as follows:

1. "Massively parallel sequencing/NGS [next-generation sequencing] of the mtDNA [mitochondrial DNA] genome is the preferred methodology when testing mtDNA and should be performed in cases of suspected mitochondrial disease instead of testing for a limited number of pathogenic point mutations.
2. mtDNA deletion and duplication testing should be performed in cases of suspected mitochondrial disease via NGS of the mtDNA genome, especially in all patients undergoing a diagnostic tissue biopsy.
    a. If a single small deletion is identified using polymerase chain reaction-based analysis, then one should be cautious in associating these findings with a primary mitochondrial disorder.
    b. When multiple mtDNA deletions are noted, sequencing of nuclear genes involved in mtDNA biosynthesis is recommended.
3. When considering nuclear gene testing in patients with likely primary mitochondrial disease, NGS methodologies providing complete coverage of known mitochondrial disease genes is preferred. Single-gene testing should usually be avoided because mutations in different genes can produce the same phenotype. If no known mutation is identified via known NGS gene panels, then whole exome sequencing should be considered."

SUMMARY

There is enough research to show that diagnostic genetic testing for primary mitochondrial

diseases can improve health outcomes for certain patients. Primary mitochondrial diseases are multisystem diseases that arise from dysfunction in the mitochondrial protein complexes involved in oxidative metabolism. Although there are no specific treatments for these disorders, they can be difficult to diagnose, and genetic testing may allow patients to avoid more invasive muscle or liver biopsies. Genetic testing also has the potential to inform reproductive testing and decision-making. Therefore, diagnostic genetic testing may be considered medically necessary when policy criteria are met.

There is not enough research to show that genetic testing to diagnose primary mitochondrial disorders can improve health outcomes for patients that do not meet the policy criteria. There is no specific therapy for mitochondrial diseases. Treatment is largely supportive management for complications of the disease. It is possible that confirmation of the diagnosis by genetic testing would lead to management changes, such as increased surveillance for complications of the disease and/or the prescription of exercise therapy or antioxidants. However, the impact of these management changes on health outcomes is not known. Therefore, this testing is considered investigational when policy criteria are not met.

CODES

Codes	Number	Description
CPT	0417U	Rare diseases (constitutional/heritable disorders), whole mitochondrial genome sequence with heteroplasmy detection and deletion analysis, nuclear encoded mitochondrial gene analysis of 335 nuclear genes, including sequence changes, deletions, insertions, and copy number variants analysis, blood or saliva, identification and categorization of mitochondrial disorder–associated genetic variants
	81401	Molecular Path Level 2: includes the following genes: MT-TS1, MT-RNR1, MT-ATP6, MT-ND4, MT-ND6, MT-ND5, MT-TL1, MT-TS1, MT-RNR1
	81403	Molecular Path Level 4: includes the following genes: MT-RNR1, MT-TS1
	81404	Molecular Path Level 5: includes the following genes: C10orf2, MPV17, NDUFA1, NDUFAF2, NDUFS4, SCO2, SLC25A4 , TACO1
	81405	Molecular Path Level 6: includes the following genes: BCS1L, COX10, COX15, DGUOK, MPV17, NDUFV1, RRM2B, SCO1, SURF1, TK2 , TYMP
	81406	Molecular Path Level 7: includes the following genes: FASTKD2, NDUFS1, SDHA
	81440	Nuclear encoded mitochondrial genes (eg, neurologic or myopathic phenotypes), genomic sequence panel, must include analysis of at least 100 genes, including BCS1L, C10orf2, COQ2, COX10, DGUOK, MPV17, OPA1, PDSS2, POLG, POLG2, RRM2B, SCO1, SCO2, SLC25A4, SUCLA2, SUCLG1, TAZ, TK2, and TYMP
	81460	Whole mitochondrial genome (eg, Leigh syndrome, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes [MELAS], myoclonic epilepsy with ragged-red fibers [MERFF], neuropathy, ataxia, and retinitis pigmentosa [NARP], Leber hereditary optic neuropathy [LHON]), genomic sequence, must include sequence analysis of entire mitochondrial genome with heteroplasmy detection
	81465	Whole mitochondrial genome large deletion analysis panel (eg, Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia), including heteroplasmy detection, if performed
HCPCS	None

Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Targeted testing for specific gene variants, including *EGFR* and *BRAF* analysis, can be used to predict treatment response to targeted therapy in patients with advanced NSCLC.

MEDICAL POLICY CRITERIA

I. Testing for *NTRK, NRG1,* and *RET* gene fusions and *BRAF*, *EGFR*, *ALK*, *ERBB2* (HER2), *KRAS*, *MET, PD-L1*, and *ROS1* variants may be considered **medically necessary** for patients with non-small cell lung cancer (NSCLC) for selection of therapy.

II. The Oncomine™ Dx Target test may be considered **medically necessary** for patients with NSCLC for selection of therapy.

III. Testing for purposes other than treatment selection in NSCLC is considered **investigational**.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

The Oncomine™ Dx Target test was approved by the FDA as a companion diagnostic to aid is selecting NSCLC patients for treatment with gefitinib (Iressa®), crizotinib (Xalcori®), or a combination of dabrafenib (Tafinlar®) and trametinib (Mekinist®). The test identifies tumors that have *EGFR* variants, *ROS1* fusions, and/or the *BRAF* V600E variant.

The FDA approved cobas® EGFR Mutation Test v2 is only intended to be used to aid in identifying patients with NSCLC whose tumors have defined *EGFR* mutations and for whom safety and efficacy of a drug have been established. This test may be run on either tumor or plasma samples.

LIST OF INFORMATION NEEDED FOR REVIEW

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variants being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test
   - o History and physical exam
   - o Conventional testing and outcomes
   - o Conservative treatment provided, if any

BACKGROUND

TARGETED THERAPY FOR NON-SMALL CELL LUNG CANCER (NSCLC)

Treatment options for NSCLC depend on disease stage and include various combinations of surgery, radiation therapy, chemotherapy, and best supportive care. In up to 85% of cases, the cancer has spread locally beyond the lungs at diagnosis, precluding surgical eradication. In addition, up to 40% of patients with NSCLC present with metastatic disease.[1] Treatment of

advanced NSCLC has generally been with platinum-based chemotherapy, with a median survival of 8 to 11 months and a one-year survival of 30% to 45%.[2, 3] More recently, the identification of specific, targetable oncogenic “driver” variants in a subset of NSCLCs has resulted in a reclassification of lung tumors to include molecular subtypes, which are predominantly of adenocarcinoma histology.

EPIDERMAL GROWTH FACTOR RECEPTOR (*EGFR*)

EGFR is a receptor tyrosine kinase (TK) frequently overexpressed and activated in NSCLC. Laboratory and animal experiments have shown that therapeutic interdiction of the EGFR pathway could be used to halt tumor growth in solid tumors that express EGFR.[4] These observations led to the development of two main classes of anti-EGFR agents for use in various types of cancer: small molecule TKIs and monoclonal antibodies (MAbs) that block EGFR-ligand interaction.[5] The prevalence of *EGFR* variants in NSCLC varies by population, with the highest prevalence in non-smoking, Asian women, with adenocarcinoma, in whom *EGFR* variants have been reported to be up to 30-50%. The reported prevalence in the Caucasian population is approximately 10%.[6]

Variants in two regions of the *EGFR* gene (exons 18-24)—small deletions in exon 19 and a point mutation in exon 21 (L858R)—appear to predict tumor response to first and second generation tyrosine kinase inhibitors (TKIs) such as erlotinib, gefitinib and afatinib.[7, 8] In addition, a single point mutation in exon 20 (T790M) appears to predict tumor response to third generation TKIs such as osimertinib. These can be detected by direct sequencing or polymerase chain reaction (PCR) technologies.

Testing is intended for use in patients with advanced NSCLC. Patients with either small deletions in exon 19 or a point mutation in exon 21 (L858R) of the tyrosine kinase domain of the EGFR gene are considered good candidates for treatment with first and second generation TKIs. Patients with the point mutation in exon 20 (T790M), which is indicative of acquired resistance to first and second generation TKIs, are considered good candidates for third generation TKIs. Patients found to be wild-type are unlikely to respond to TKIs, so other treatment options should be considered.

ALK

ALK is a TK that is aberrantly activated in NSCLC due to a chromosomal rearrangement that leads to a fusion gene and expression of a protein with constitutive activity that has been demonstrated to play a role in controlling cell proliferation. The *EML4-ALK* fusion gene results from an inversion within the short arm of chromosome 2. The *EML4-ALK* rearrangement (“*ALK*-positive”) is detected in 3% to 6% of NSCLC patients, with the highest prevalence in never-smokers or light ex-smokers who have adenocarcinoma.

BRAF

RAF proteins are serine/threonine kinases that are downstream of RAS in the RAS-RAF-ERK-MAPK pathway. In this pathway, the *BRAF* gene is the most frequently altered in NSCLC, in approximately 1-3% of adenocarcinomas. Unlike melanoma, about 50% of the variants in NSCLC are non-V600E variants.[9] Most *BRAF* variants occur more frequently in smokers.

ERBB2

ERBB2 is the gene that codes for the human epidermal growth factor receptor 2 (HER2) protein. HER2 is a member of the HER (EGFR) family of TK receptors and has no specific ligand. When activated, it forms dimers with other EGFR family members. HER2 is expressed in approximately 25% of NSCLC. *ERBB2* variants are detected mainly in exon 20 in 1% to 2% of NSCLC, predominantly in adenocarcinomas in nonsmoking women.[9]

KRAS

KRAS is a G-protein involved in the EGFR-related signal transmission. The *KRAS* gene, which encodes RAS proteins, can harbor oncogenic variants that result in a constitutively activated protein, independent of signaling from the EGF receptor, possibly rendering a tumor resistant to therapies that target the EFG receptor. Variants in the *KRAS* gene, mainly codons 12 and 13, have been reported in 20-30% of NSCLC, and occur most often in adenocarcinomas in heavy smokers.

MET

MET amplification is one of the critical events for acquired resistance in *EGFR*-mutated adenocarcinomas refractory to EGFR TKIs.

NRG1

NRG1 gene fusions are relatively rare but can act as oncogenic drivers for NSCLC and other cancer types. They are mainly seen in lung invasive mucinous adenocarcinomas.

NTRK

NTRK gene fusions encode tropomyosin receptor kinase fusion proteins that act as oncogenic drivers for solid tumors including lung, salivary gland, thyroid, and sarcoma. It is estimated that NTRK gene fusions occur in 0.2% of patients with NSCLC and do not typically overlap with other oncogenic drivers.

PD-L1

Programmed cell ligand-1 (PD-L1) is a transmembrane protein expressed on the surface of multiple tissue types, including many tumor cells. Blocking the PD-L1 protein may prevent cancer cells from inactivating T cells.

RET

RET (rearranged during transfection) is a proto-oncogene that encodes a receptor TK growth factor. Translocations that result in fusion genes with several partners have been reported. RET fusions occur in 0.6% to 2% of NSCLCs and 1.2% to 2% of adenocarcinomas.

ROS1

ROS1 codes for a receptor TK of the insulin receptor family, and chromosomal rearrangements result in fusion genes. The prevalence of *ROS1* fusions in NSCLC varies from 0.9% to 3.7%. Patients with *ROS1* fusions are typically never-smokers with adenocarcinoma.

REGULATORY STATUS

The FDA Centers for Devices and Radiological Health (CDRH), for Biologics Evaluation and

Research (CBER), and for Drug Evaluation and Research (CDER) developed a draft guidance on in vitro companion diagnostic devices, which was released on July 14, 2011,[8] to address the "emergence of new technologies that can distinguish subsets of populations that respond differently to treatment." As stated, the FDA encourages the development of treatments that depend on the use of companion diagnostic devices "when an appropriate scientific rationale supports such an approach." In such cases, the FDA intends to review the safety and effectiveness of the companion diagnostic test as used with the therapeutic treatment that depends on its use. The rationale for co-review and approval is the desire to avoid exposing patients to preventable treatment risk.

The Oncomine™ Dx Target test is an FDA approved companion diagnostic test for *EGFR* variants, *ROS1* gene fusions, *RET* variants, *ERBB2* variants, and the *BRAF* V600E variant, to aid in selection of the following targeted therapies for NSCLC:

- gefitinib (Iressa®)
- crizotinib (Xalcori®)
- dabrafenib (Tafinlar®) plus trametinib (Mekinist®)
- pralsetinib (Gavreto®)
- amivantamab (Rybrevant®)
- fam-trastuzumab deruxtecan-nxki (Enhertu®)
- selpercatinib (Retevmo®)

There are two other U.S. Food and Drug Administration (FDA)-approved companion diagnostic tests that specifically test for *EGFR* variants in NSCLC, intended to be used with select FDA approved *EGFR* tyrosine kinase inhibitors (TKIs):

- The cobas® *EGFR* Mutation Test v2 is a companion diagnostic test for the detection of exon 19 deletions and exon 20 and 21 (T790M and L858R, respectively) substitution variants in the *EGFR* gene in NSCLC tumor tissue. The FDA states:

  > "The test is intended to be used as an aid in selecting patients with NSCLC for whose tumors have defined *EGFR* variants and for whom safety and efficacy of a drug have been established as follows:
  >
  > - Tarceva® (erlotinib) - Exon 19 deletions and L858R
  > - Tagrisso® (osimertinib) - T790M"

  This test (v2) was approved 11/13/2015 as a result of an expansion of the original cobas® *EGFR* Mutation Test to cover testing for the T790M point mutation for use of osimertinib.

- The therascreen® *EGFR* Rotor Gene Q polymerase chain reaction (PCR) Kit is an automated molecular assay designed to detect the presence of *EGFR* exon 19 deletions and the exon 21 (L858R) substitution variant in NSCLC tumor tissue. The test is intended to be used to select patients with NSCLC for whom GILOTRIF® (afatinib) or IRESSA® (gefitinib) is indicated.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[10] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing

medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

The focus of the following review is on evidence related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and
- Improve health outcomes as a result of those decisions.

The clinical utility of testing for variants in the *EGFR* gene and others to guide TKI treatment in patients with advanced NSCLC has been unequivocally demonstrated. Testing for variants in the other genes is also well-supported by published evidence. Therefore, this review will focus on literature that has been published on the investigational indications described in this policy.

No studies were identified that evaluated targeted genetic testing for patients with NSCLC for purposes other than treatment selection.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)[11]

NCCN guidelines for the treatment of metastatic NSCLC (v.1.2025) recommend testing for genetic variants in *EGFR*, *ALK*, *KRAS*, *ROS1*, *BRAF*, *NTRK1/2/3*, *MET*, *RET*, *ERBB2*, and *NRG1*, and testing for HER2 and PD-L1 expression for patients with non-squamous NSCLC (i.e., adenocarcinoma, large cell carcinoma, or NSCLC not otherwise specified). For patients with squamous cell carcinoma, the guidelines recommend PD-L1 testing, and considering *EGFR*, *ALK*, *KRAS*, *NTRK*, *MET*, *RET*, *ROS1, NRG1,* and *BRAF* molecular testing and HER2 expression testing.

According to these recommendations, molecular testing for all advanced or metastatic NSCLC should be conducted as a part of broad molecular profiling.

COLLEGE OF AMERICAN PATHOLOGISTS, INTERNATIONAL ASSOCIATION FOR THE STUDY OF LUNG CANCER, AND ASSOCIATION FOR MOLECULAR PATHOLOGY (CAP/IASLC/AMP)

The 2018 updated guidelines issued jointly by the CAP/IASLC/AMP recommend:[12]

- *ROS1* testing must be performed on all lung adenocarcinoma patients, irrespective of clinical characteristics. (Strong Recommendation)
- ROS1 IHC may be used as a screening test in lung adenocarcinoma patients; however, positive ROS1 IHC results should be confirmed by a molecular or cytogenetic method. (Expert Consensus Opinion)
- *BRAF* molecular testing is currently not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include *BRAF* as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative. (Expert Consensus Opinion)
- *RET* molecular testing is not recommended as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include *RET* as part of larger testing panels

performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative. (Expert Consensus Opinion)
- *ERBB2* (HER2) molecular testing is not indicated as a routine stand-alone assay. outside the context of a clinical trial. It is appropriate to include *ERBB2* (HER2) mutation analysis as part of a larger testing panel performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative. (Expert Consensus Opinion)
- *KRAS* molecular testing is not indicated as a routine stand-alone assay as a sole determinant of targeted therapy. It is appropriate to include *KRAS* as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative. (Expert Consensus Opinion)
- *MET* molecular testing is not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include *MET* as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative. (Expert Consensus Opinion)

Regarding cell-free DNA (cfDNA) testing, the guidelines state:

- There is currently insufficient evidence to support the use of circulating cfDNA molecular methods for the diagnosis of primary lung adenocarcinoma. (No Recommendation)
- In some clinical settings in which tissue is limited and/or insufficient for molecular testing, physicians may use a cfDNA assay to identify EGFR mutations. (Recommendation)
- Physicians may use cfDNA methods to identify EGFR T790M mutations in lung adenocarcinoma patients with progression or secondary clinical resistance to EGFR-targeted TKI; testing of the tumor sample is recommended if the plasma result is negative. (Expert Consensus Opinion)
- There is currently insufficient evidence to support the use of circulating tumor cell molecular analysis for the diagnosis of primary lung adenocarcinoma, the identification of EGFR or other mutations, or the identification of EGFR T790M mutations at the time of EGFR TKI resistance. (No Recommendation)

AMERICAN SOCIETY OF CLINICAL ONCOLOGY

In 2021, the American Society of Clinical Oncology (ASCO) and Ontario Health published updated guidelines on therapy for stage IV NSCLC with driver alterations.[13] The updated recommendations were based on a systematic review of RCTs from December 2015 to January 2020 and meeting abstracts from ASCO 2020. The recommendations include the following:

- All patients with nonsquamous NSCLC should have the results of testing for potentially targetable mutations (alterations) before implementing therapy for advanced lung cancer, regardless of smoking status, when possible.
- Targeted therapies against *ROS-1* fusions, *BRAF* V600e mutations, *RET* fusions, *MET* exon 14 skipping mutations, and *NTRK* fusions should be offered to patients, either as initial or second-line therapy when not given in the first-line setting.
- Chemotherapy is still an option at most stages.

The above guidelines were updated in 2023 to add amivantamab monotherapy and mobocertinib monotherapy for second-line treatment in advanced NSCLC with an *EGFR* exon

20 insertion, and sotorasib monotherapy for second-line treatment in advanced NSCLC with a *KRAS*-G12C mutation.[14]

In 2022, ASCO published a guideline on the management of stage III NSCLC.[15] The recommendations were based on a literature search of systematic reviews, meta-analyses, and randomized controlled trials published from 1990 through 2021. Relevant recommendations include the following:

- Presence of oncogenic driver alterations, available therapies, and patient characteristics should be taken into account.
- Patients with resected stage III NSCLC with *EGFR* exon 19 deletion or exon 21 L858R mutation may be offered adjuvant osimertinib after platinum-based chemotherapy.

SUMMARY

NTRK, NRG1, AND *RET* GENE FUSIONS AND *BRAF*, *EGFR*, *ALK*, *KRAS*, *MET, PD-L1*, *ERBB2,* AND *ROS1*

There is enough research to show that testing for *NTRK, NRG1,* and *RET* gene fusions and *BRAF*, *EGFR*, *ALK*, *KRAS*, *MET, PD-L1*, *ERBB2* (HER2), and *ROS1* variants can help to guide treatment for patients with non-small cell lung cancer (NSCLC). In addition, many clinical guidelines based on research recommend testing for patients with this disease. Therefore, this testing may be considered medically necessary for selection of therapy.

There is not enough research to show that for *NTRK, NRG1,* and *RET* gene fusions and *BRAF*, *EGFR*, *ALK*, *KRAS*, *MET, PD-L1*, *ERBB2* (HER2), and *ROS1* variants can improve health outcomes for NSCLC patients when not used for treatment selection. Therefore, this testing is considered investigational when policy criteria are not met.

ONCOMINE™ DX TARGET TEST

The Oncomine™ Dx Target Test is an FDA-approved companion diagnostic test to help identify non-small cell lung cancer (NSCLC) patients that may benefit from certain medications. The test identifies tumors that have variants in the *EGFR*, *ROS1*, and *BRAF* genes, which may respond to targeted treatments. This 23-gene test also includes testing for a number of genes that do not have clear evidence of clinical utility. While genetic test panels are generally considered to be investigational when there is not clinical utility for all genes in the panel, this test is the only FDA-approved companion diagnostic available to NSCLC patients to help with selection of certain targeted medications. Therefore, use of the Oncomine™ Dx Target test may be considered medically necessary to select patients with advanced or metastatic NSCLC for targeted treatment.

There is not enough research to show that the Oncomine™ Dx Target Test can improve health outcomes for NSCLC patients when not used for treatment selection. Therefore, the use of this test is considered investigational for patients that do not meet policy criteria.

CODES

Codes	Number	Description
CPT	0022U	Targeted genomic sequence analysis panel, nonsmall cell lung neoplasia, DNA and RNA analysis, 23 genes, interrogation for sequence variants and rearrangements, reported as presence/or absence of variants and associated therapy(ies) to consider
	0478U	Oncology (non-small cell lung cancer), DNA and RNA, digital PCR analysis of 9 genes (EGFR, KRAS, BRAF, ALK, ROS1, RET, NTRK 1/2/3, ERBB2, and MET) in formalin-fixed paraffin-embedded (FFPE) tissue, interrogation for single-nucleotide variants, insertions/deletions, gene rearrangements, and reported as actionable detected variants for therapy selection
	81191	NTRK1 (neurotrophic receptor tyrosine kinase 1) (eg, solid tumors) translocation analysis
	81192	NTRK2 (neurotrophic receptor tyrosine kinase 2) (eg, solid tumors) translocation analysis
	81193	NTRK3 (neurotrophic receptor tyrosine kinase 3) (eg, solid tumors) translocation analysis
	81194	NTRK (neurotrophic-tropomyosin receptor tyrosine kinase 1, 2, and 3) (eg, solid tumors) translocation analysis
	81210	*BRAF (B-Raf proto-oncogene, serine/threonine kinase) (e.g., colon cancer, melanoma), gene analysis, V600 variant(s)*
	81235	EGFR (epidermal growth factor receptor) (eg, non-small cell lung cancer) gene analysis, common variants (eg, exon 19 LREA deletion, L858R, T790M, G719A, G719S, L861Q)
	81275	KRAS (v-Ki-ras2 Kirsten rat sarcoma viral oncogene) (eg, carcinoma) gene analysis, variants in exon 2 (eg, codons 12 and 13)
	81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
	81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis) – which includes *RET* (ret proto-oncogene) (eg, multiple endocrine neoplasia, type 2B and familial medullary thyroid carcinoma), common variants (eg, M918T, 2647_2648delinsTT, A883F)
	81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis) – which includes *KRAS* (Kirsten rat sarcoma viral oncogene homolog) (eg, Noonan syndrome), full gene sequence; and *RET* (ret proto-oncogene) (eg, multiple endocrine neoplasia, type 2A and familial medullary thyroid carcinoma), targeted sequence analysis (eg, exons 10, 11, 13-16)
	81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons) – which includes *BRAF* (B-Raf proto-oncogene, serine/threonine kinase) (eg, Noonan syndrome), full gene sequence
	81479	Unlisted molecular pathology procedure
	84999	Unlisted chemistry procedure

Medical Policy Manual Genetic Testing, Policy No. 59

Genetic Testing for Myeloid Neoplasms and Leukemia

Effective: June 1, 2024

Next Review: February 2025
Last Review: April 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genetic testing, including testing for BCR/ABL1 (t(9;22)) translocations and for *ABL1, ASXL1, CALR, CEBPA, FLT3, IDH1, IDH2, JAK2*, *KIT, MPL, NPM1*, *RUNX1*, and/or *TP53* variants may inform the diagnostic, prognostic, and treatment selection processes for myelodysplastic-myeloproliferative neoplasms and select myeloid neoplasms.

MEDICAL POLICY CRITERIA

Note: Please refer to the Cross References section below for genetic testing not addressed in this policy, including but not limited to single-gene testing.

I. Genetic testing, including panel testing, for *BCR/ABL1* translocation (Philadelphia chromosome) and/or variants in any of the following genes may be considered **medically necessary** for evaluation, diagnosis, and/or treatment monitoring in myeloid neoplasms and leukemia: *JAK2, CALR, MPL, ASXL1, IDH1, IDH2, TP53, CEBPA*, *FLT3*, *KIT*, *NPM1* and/or *RUNX1*.

II. Targeted genetic panel testing for myeloproliferative neoplasms (MPN), myelodysplastic syndromes (MDS), and myelodysplastic myeloproliferative neoplasms (MPN/MDS), including acute myeloid leukemia (AML), may be considered **medically**

necessary for patients being evaluated for these disorders (see Policy Guidelines and Table 1).

III. Genetic testing for *ABL1* may be considered **medically necessary** to evaluate patients when either of the following are met:

A. In patients with chronic myelogenous (myeloid) leukemia (CML), to monitor response to tyrosine kinase inhibitor therapy; or

B. In patients with Philadelphia chromosome-positive acute lymphoblastic leukemia (Ph+ ALL), to evaluate for tyrosine kinase inhibitor resistance.

IV. Genetic testing for *ABL1* is considered **investigational** when Criterion III. is not met.

V. Non-targeted profiling panels for hematologic disorders are considered **investigational** (see Policy Guidelines).

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

PANEL TESTING

Targeted Panels for Myeloid Neoplasms

Targeted panel testing for myeloid neoplasms, (i.e., MPN, MDS, MPN/MDS, and AML, see Table 1 below) includes panels that are specifically designed to assess variants in patients suspected of having a myeloproliferative neoplasm, a myelodysplastic syndrome, or a disorder with overlapping features. They are generally less than 50 genes and may include the following genes: *ASXL1*, *CALR, CBL, EZH2*, *KIT*, *FLT3, JAK2, MPL*, *NMP1*, *CEBPA*, *IDH1*, *IDH2*, and *TP53*.

Examples of targeted panels for MPN/MDS/AML include, but are not limited to:

- NeoTYPE™ Myeloid Disorders Profile (Neogenomics)
- NGS Myeloid 37 Gene panel (Cellnetix)
- MyeloSeq™ (Washington University School of Medicine)
- NGS_AML Panel (Cellnetix)
- AML Mutation Analysis Panel (Molecular Pathology Laboratory Network)
- Onkosight™ Myeloid Malignancies Panel, MPN Panel, MDS Panel, or AML Panel
- Myeloid MPN/MDS/CMML Comprehensive Panel (Providence)
- Myeloid Gene Panel by NGS (University of Washington)
- TruSight® Myeloid Sequencing Panel

Non-targeted Panels

Some commercially available panels are not targeted toward genes that have clinical significance for a specific type of hematolymphoid disorder. They often include testing for a large number of genes that do not have demonstrated clinical utility, as well as testing for many disorders that could be distinguished based on clinical presentation.

Non-targeted panels for hematologic disorders include, but are not limited to:

- FoundationOne Heme (Foundation Medicine)
- FusionPlex Pan-Heme Panel (Laboratory for Precision Diagnostics, University of Washington)
- GeneTrails® Hematologic Malignancies 220 Gene Panel (Knight Diagnostic Laboratories)
- MyAML® 194 Targeted NGS Gene Panel (Invivoscribe)
- HopeSeq HemeComplete (City of Hope)
- NGS Hematology Molecular Profile (Sonora Quest Laboratories)
- Rapid Heme Panel (Dana-Farber Cancer Institute)
- Hematologic Malignancy Sequencing Panel (Penn Medicine)
- Neo Comprehensive™ - Myeloid Disorders (Neogenomics)

Table 1. Selected Diagnoses from the World Health Organization Classification of Hematolymphoid Disorders[1, 2]

Myeloproliferative neoplasms (MPN)
Chronic myeloid leukemia (CML), *BCR-ABL1*$^{+}$
Chronic neutrophilic leukemia
Chronic eosinophilic leukemia
Polycythemia vera
Essential thrombocythemia
Primary myelofibrosis
Juvenile myelomonocytic leukemia (JMML)
Mastocytosis
Cutaneous mastocytosis
Systemic mastocytosis
Mast cell sarcoma
Myelodysplastic neoplasms (MDS)
MDS with low blasts and 5q deletion
MDS with low blasts and *SF3B1* mutation
Myelodysplastic neoplasm with increased blasts
Refractory cytopenia of childhood
Chronic myelomonocytic leukemia (CMML)
Acute myeloid leukemia (AML) and related neoplasms
AML with defining genetic abnormalities
AML, defined by differentiation
Acute basophilic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Myeloid sarcoma

LIST OF INFORMATION NEEDED FOR REVIEW

REQUIRED DOCUMENTATION:

The information below **must** be submitted for review to determine whether policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested

4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test:
    - History and physical exam including any relevant diagnoses related to the genetic testing
    - Sample collection (e.g., blood draw) date
    - Conventional testing and results

BACKGROUND

DIAGNOSING MYELOID NEOPLASMS AND ACUTE LEUKEMIA

Myeloid neoplasms may be acute or chronic, are a type of hematologic malignancy, and usually derive from bone marrow progenitor cells that normally develop into erythrocytes, granulocytes (neutrophils, basophils, and eosinophils), monocytes, or megakaryocytes. Classification of myeloid neoplasms and acute leukemias has evolved over the past decade, based in part on the advancement of available technologies and results from repeat validation studies.

In recent history, diagnosis of the various forms of myeloid neoplasms has been based on a complex set of clinical, pathological, and biological criteria first introduced by the Polycythemia Vera Study Group (PVSG) in 1996[3, 4] and the World Health Organization (WHO) in 2001.[5] Both of these classifications use a combination of clinical, pathological, and/or biological criteria to arrive at a definitive diagnosis, predominantly reliant on status of Philadelphia chromosome presence. An important component of the diagnostic process is a clinical and laboratory assessment to rule out reactive or secondary causes of disease. Some diagnostic methods (e.g., bone marrow microscopy) are not well standardized and others (e.g., endogenous erythroid colony formation) are neither standardized nor widely available.[6-8] Diagnosis and monitoring of patients with Philadelphia chromosome negative myeloid neoplasms poses a challenge because many of the laboratory and clinical features of these diseases can be mimicked by other conditions such as reactive or secondary erythrocytosis, thrombocytosis or myeloid fibrosis. In addition, these entities can be difficult to distinguish on morphological bone marrow exam and diagnosis can be complicated by changing disease patterns.

The most up-to-date classification and benchmark for diagnosis of hematopoietic and lymphoid tissues is a result of collaboration between the Society for Hematopathology and the European

Association for Haematopathology and is published by the WHO, most recently in 2022.[2] This edition varies from the previous versions with a refinement of diagnostic criteria and emphasis on actionable biomarkers. The current classification of myeloid neoplasm and acute leukemia subgroups are delineated in Table 2.

Table 2. WHO Myeloid Proliferations and Neoplasms Classification, adapted[2]

MYELOID NEOPLASMS, CHRONIC

Myeloproliferative Neoplasms (MPN)

- Chronic myeloid leukemia (CML), *BCR-ABL1*$^{+}$
- Polycythemia vera (PV)
- Essential thrombocythemia (ET)
- Primary myelofibrosis (PMF)
- Chronic neutrophilic leukemia (CNL)
- Chronic eosinophilic leukemia
- Juvenile myelomonocytic leukemia (JMML)
- MPN, not otherwise specified (NOS)

Mastocytosis

- Cutaneous mastocytosis
- Systemic mastocytosis
- Mast cell sarcoma

Myelodysplastic Neoplasms (MDS)

- MDS with low blasts and isolated 5q deletion
- MDS with low blasts and SF3B1 mutation
- MDS with low blasts, NOS
- MDS with increased blasts
- MDS with fibrosis
- MDS, NOS
- MDS with biallelic TP53 alteration (provisional)
- MDS with other defined driver gene alterations

MDS / acute myeloid leukemia (MDS/AML)

- MDS/AML with *NMP1* mutation
- MDS/AML with *MECOM* rearragement
- MDS/AML, NOS

MDS of childhood

- Refractory cytopenia of childhood
- Childhood MDS

MDS with proliferative evolution

- Chronic myelomonocytic leukemia
- MDS with proliferative evolution and neutrophilia
- MDS with proliferative evolution, SF3B1 mutation and thrombocytosis
- MDX with proliferative evolution, NOS

MYELOID NEOPLASMS, ACUTE

AML with defining genetic abnormalities

- Acute promyelocytic leukemia
- AML with *RUNX1::RUNX1T1* fusion
- AML with *CBFB::MYH11* fusion
- AML with *DEK::NUP214* fusion
- AML with *RBM15::MRTFA* fusion
- AML with *BCR::ABL1* fusion
- AML with *NUP98* rearrangement
- AML with *NPM1* mutation
- AML with *NUP98* rearrangement
- AML with other defined driver gene alterations
- AML with myelodysplasia-related cytogenetics

AML, defined by differentiation

- AML with minimal differentiation
- AML with without maturation
- AML with maturation
- Acute basophilic leukemia
- AML with myelomonocytic differentiation
- AML with monocytic differentiation
- AML with plasmacytoid dendritic cell differentiation (provisional)
- Pure erythroid leukemia
- Acute megakaryoblastic leukemia

Myeloid sarcoma

MYELOID NEOPLASMS, SECONDARY

Myeloid neoplasms and proliferations associated with antecedent or predisposing conditions

- Myeloid neoplasm post cytotoxic therapy
- Myeloid neoplasm associated with germline predisposition
- AML following other hematolymphoid malignancy
- Myeloid proliferations associated with Down syndrome
- Myeloid neoplasm associated with malignant germ cell tumor

MYELOID/LYMPHOID NEOPLASMS AND OTHER LEUKAEMIAS OF AMBIGUOUS LINEAGE

Myeloid/Lymphoid neoplasms with eosinophilia and defining gene rearrangement

- Myeloid/lymphoid neoplasm with *PDGFRA* rearrangement
- Myeloid/lymphoid neoplasm with *PDGFRB* rearrangement
- Myeloid/lymphoid neoplasm with *FGFR1* rearrangement
- Myeloid/lymphoid neoplasms with *PMC1-JAK2* fustion

Acute leukemias of ambiguous lineage

Mixed-phenotype acute leukaemia with *BCR-ABL1* fusion

Mixed-phenotype acute leukaemia with *KMT2A* rearrangement

Mixed-phenotype acute leukaemia, B/myeloid

Acute leukaemia of ambiguous lineage, NOS

It is important to note that the presence of any one or more of the gene variants included in this policy may not be sufficient to confirm a diagnosis, rather, testing may help support other

clinical, laboratory, or pathological findings.

TREATMENT MONITORING

CML represents one of the earliest examples of the use of molecular information to revolutionize patient management. A unique chromosomal change (the Philadelphia chromosome) and an accompanying unique gene rearrangement (*BCR-ABL*) resulting in a continuously activated tyrosine kinase enzyme were identified. These led to the development of a targeted tyrosine kinase inhibitor drug therapy (imatinib) that produces long-lasting remissions.

REGULATORY STATUS

More than a dozen commercial laboratories currently offer a wide variety of diagnostic procedures for gene variant testing related to myeloid neoplasms and acute lymphoblastic leukemia. These tests are available as laboratory developed procedures under the U.S. Food and Drug Administration (FDA) enforcement discretion policy for laboratory developed tests (LDTs). Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; LDTs must meet the general regulatory standards of Clinical Laboratory Improvement Act (CLIA) and laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, FDA does not require regulatory review of LDTs.

The FDA Centers for Devices and Radiological Health (CDRH), for Biologics Evaluation and Research (CBER), and for Drug Evaluation and Research (CDER) developed a draft guidance on in vitro companion diagnostic devices, which was released on July 14, 2011,[9] to address the “emergence of new technologies that can distinguish subsets of populations that respond differently to treatment.” As stated, the FDA encourages the development of treatments that depend on the use of companion diagnostic devices “when an appropriate scientific rationale supports such an approach.” In such cases, the FDA intends to review the safety and effectiveness of the companion diagnostic test as used with the therapeutic treatment that depends on its use. The rationale for co-review and approval is the desire to avoid exposing patients to preventable treatment risk.

The LeukoStrat® CDx *FLT3* Mutation Assay offered by Invivoscribe. According to Invivoscribe, the test is indicated at initial diagnosis of AML to determine eligibility for Rydapt® (midostaurin), Xospata® (gilteritinib), and Vanflyta® (quizartinib), and may also be used for risk stratification.[10] The assay includes internal tandem duplication variant testing for *FLT3* as well as variants in the tyrosine kinase domain. The assay is an FDA-approved companion diagnostic test for use with these medications and therefore may be standard of care in screening patients for use with this specific kinase inhibitor.

Abbott Real*Time* IDH2 is an *in vitro* polymerase chain reaction (PCR) assay for the qualitative detection of single nucleotide variants (SNVs) in the human isocitrate dehydrogenase-2 (IDH2) gene. The test aids in identifying acute myeloid leukemia patients for treatment with Idhifa® (enasidenib). Enasidenib is an oral medication used to treat patients with AML when the disease recurs after or does not respond to front-line therapies. The Abbott Real*Time* IDH2 assay received FDA premarket approval in August 2017.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature is used to describe variants found in

DNA and serves as an international standard.[11] It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

1. The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent;
2. The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. The clinical utility of the test, i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

The focus of this review is on evidence related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention, and
- Improve health outcomes as a result of those decisions.

BCR-ABL1 (*ABL1*) KINASE DOMAIN ANALYSIS

Screening for *BCR-ABL1* kinase domain variants in chronic phase CML is recommended for patients with inadequate initial response to TKI treatment, those with evidence of loss of response, and for patients who have progressed to accelerated or blast phase CML.[3] The focus of the following discussion is on kinase domain point variants and treatment outcomes in systematic reviews.

In 2010, the Agency for Healthcare Research and Quality published a systematic review on *BCR-ABL1* pharmacogenetic testing for tyrosine kinase inhibitors in CML.[12] Thirty-one publications of *BCR-ABL1* testing met the eligibility criteria and were included in the review (20 of dasatinib, seven of imatinib, three of nilotinib, and one with various TKIs). The report concluded that the presence of any *BCR-ABL1* variant does not predict differential response to TKI therapy, although the presence of the T315I variant uniformly predicts TKI failure. However, during the public comment period the review was strongly criticized by respected pathology organizations for lack of attention to several issues that were subsequently insufficiently addressed in the final report. Importantly, the review grouped together studies that used kinase domain variant screening methods with those that used targeted methods and combined studies that used variant detection technologies with very different sensitivities. The authors dismissed the issues as related to analytic validity and beyond the scope of the report. However, in this clinical scenario assays with different intent (screening vs. targeted) and assays of very different sensitivities may lead to different clinical conclusions, so an understanding of these points is critical.

Branford (2009) summarized much of the available evidence regarding kinase domain variants detected at imatinib failure, and subsequent treatment success or failure with dasatinib or nilotinib.[13] The T315I variant was most common; although about 100 variants have been

reported, the seven most common (at residues T315, Y253, E255, M351, G250, F359, and H396) accounted for 60-66% of all variants. However, preexisting or emerging variants T315A, F317L/I/V/C, and V299L are associated with decreased clinical efficacy with dasatinib treatment following imatinib failure. Detection of the T315I variant at imatinib failure is associated with lack of subsequent response to high-dose imatinib, or to dasatinib or nilotinib. For these patients, allogeneic stem-cell transplantation remained the only available treatment until the advent of new agents such as ponatinib.[14] However these variants do not correspond to clinical significance, and based on clinical studies, the majority of imatinib-resistant variants remain sensitive to dasatinib and nilotinib.

Preexisting or emerging variants T315A, F317L/I/V/C, and V299L are associated with decreased clinical efficacy with dasatinib treatment following imatinib failure. Similarly, preexisting or emerging variantsY253H, E255K/V, and F359V/C have been reported for decreased clinical efficacy with nilotinib treatment following imatinib failure. In the survey reported by Branford, a total of 42% of patients tested had T315I or one of these dasatinib- or nilotinib-resistant variants. In the absence of any of these actionable variants, various treatment options are available. Note that these data have been obtained from studies in which patients were all initially treated with imatinib; no data are available regarding variants developing during first-line therapy with dasatinib or nilotinib.[15]

Unlike in CML, resistance in ALL to TKIs is less well studied. Resistance does not necessarily arise from dominant tumor clone(s), but possibly in response to TKI-driven selective pressure and/or by competition of other coexisting subclones.[16] In patients with ALL that are receiving a TKI, a rise in the BCR-ABL level while in hematologic complete response or clinical relapse warrants variant analysis.

***ASXL1*, *CALR*, *IDH1, IDH2* AND *TP53* IN MYELOID NEOPLASMS AND LEUKEMIA**

Testing for the *ASXL1*, *CALR*, *IDH1, IDH2* and *TP53* is required to meet WHO diagnostic criteria for patients with all of the most common Philadelphia-chromosome-negative MPNs.. The most recent revisions to the WHO criteria (2022) are heavily based on repeat validation studies.[2] The following evidence highlights the diagnostic and prognostic significance of *ASXL1*, *CALR*, *IDH1, IDH2* and *TP53* as specified by WHO diagnostic criteria and National Comprehensive Cancer Network (NCCN) guidelines.

ASXL1

For chronic myelomonocytic leukemia (CMML), *ASXL1* is amongst the most frequently mutated genes, observed in 40-50% of CMML patients.[17, 18] *ASXL1* is also reported to be associated with chromatin modification in MPNs, including polycythemia vera, as well as pre- and overt primary myelofibrosis.[19, 20]

CALR

Evidence for *CALR* demonstrates that a significant proportion of patients with myeloproliferative neoplasms and normal *JAK2* V617F status have a *CALR* variant.[21-23] Variants in exon 9 of *CALR* are found in 20-35% of all patients with ET and myelofibrosis. Fifty-two base pair deletions (*Type 1*) and five base pair insertions (*Type 2*) are the most common.

It is suggested that ET patients with *CALR* variants have lower polycythemic transformation rates, but not lower myelofibrotic transformation rate, compared with ET patients harboring a *JAK2* variant. Chen (2014) reported a higher platelet count, younger age of diagnosis, lower

leukocyte count, and decreased risk for thrombosis, compared with a *JAK2* positive ET population.[24] Tefferi (2014) reported survival and blast transformation in primary myelofibrosis (PMF) were significantly affected by variant status, though not in ET.[25] The outcome was best in *CALR*-variant patients and worst in *JAK2/CALR/MPL*-negative PMF patients. *CALR*-variant ET has also been associated with better thrombosis-free survival and lower leukocyte counts. However, overall survival has been reported as not different among *CALR*-variant and non-variant ET.[26, 27]

IDH1/2

For PMF and ET, WHO criteria specify *IDH1/2* (as well as others, including *ASXL1*) as having diagnostic significance for those without *JAK2, CALR,* and *MPL* variants. In myeloproliferative neoplasms, *IDH1* and *IDH2* variants are among a growing number of higher-risk molecular markers. Both are associated with shorter overall survival and leukemia-free survival in patients with PMF and polycythemia vera.[20, 28] In a study of the prognostic significance of *ASXL1, EZH2, SRSF2, IDH1* and *IDH2,* Vannucchi (2013) analyzed samples from 897 PMF patients (483 European patients and 396 from the Mayo clinical validation cohort). Median survival was significantly shorter (81 vs. 148 months, $p<0.0001$) in PMF patients with at least one of the genes.

TP53

Like *IDH1/2* described above, for PMF, *TP53* is associated with leukemic transformation, which is a common risk amongst patients with myeloproliferative neoplasms.[29] Furthermore, *TP53* is associated with inferior leukemia-free survival in those with ET. This progression is associated with poor clinical outcomes and resistance to standard AML therapies. Thus, *TP53* variants have also been analyzed to subdivide AML into prognostic subsets (see below). Additionally, *TP53* variants have been identified as one of the most common molecular abnormalities associated with myelodysplastic syndromes and may aid in diagnosis.[30-32]

ACUTE MYELOID LEUKEMIA

AML is a group of diverse hematologic malignancies characterized by the clonal expansion of myeloid blasts in the bone marrow, blood, and/or other tissues. It is the most common type of leukemia in adults and is generally associated with a poor prognosis. It was estimated that in 2014, 18,860 people would be diagnosed with AML and 10,460 would die of the disease. Median age at diagnosis is 66 years, with approximately one in three patients diagnosed at 75 years of age or older.[33]

Conventional cytogenetic analysis (karyotyping) is a key component of the diagnostic evaluation of patients with suspected acute leukemia. The cytogenetic profile of the tumor is currently the most powerful predictor of prognosis in AML and is used to guide risk-adapted treatment strategies. Molecular variants, including those in *CEBPA*, *FLT3*, *KIT*, *NPM1*, *RUNX1*, and *TP53* genes, can be used to subdivide AML into prognostic subsets. (See Table 3.) Patients with better-prognosis disease based on cytogenetics (e.g., core-binding factor AML) who have a *c-KIT* variant in leukemic blast cells do just as poorly with post-remission standard chemotherapy as patients with cytogenetically poor-risk AML.[34] Similarly, individuals with cytogenetically normal AML (intermediate-prognosis disease) can be subcategorized into groups with better or worse prognosis based on the variant status of the *NPM1* and *FLT3* genes. Patients with variants in *NPM1* but without a *FLT3-ITD* fusion have post-remission outcomes with standard chemotherapy that are similar to those with better-prognosis

cytogenetics; in contrast, patients with any other combination of variants in those genes have outcomes similar to those with poor-prognosis cytogenetics.[35] A provisional category of AML with a *RUNX1* variant classifies de novo cases which are not associated with MDS-related cytogenetic abnormalities. This distinct group of AML patients also appears to have a worse prognosis than other AML types.[36-39]

The World Health Organization (WHO) classification of AML was adapted by the NCCN to estimate individual patient prognosis to guide management, as shown in Table 3:[40]

Table 3. Risk Status of AML Based on Cytogenetic and Molecular Factors

Risk Category	Genetic Abnormality
Favorable	t(8;21)(q22;q22.1)/ *RUNX1*::*RUNX1T1* inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB::MYH11* Mutated *NPM1* without *FLT3*-ITD bZIP in-frame mutated *CEBPA*
Intermediate	Mutated *NPM1* with *FLT3*-ITD Wild-type *NPM1* with FLT3-ITD (without adverse-risk genetic lesions) t(9;11)(p21.3;q23.3)/ *MLLT3::KMT2A* Cytogenetic and/or molecular abnormalities not classified as favorable or adverse
Poor/Adverse	t(6;9)(p23;q34.1)/ *DEK*::*NUP214* t(v;11q23.3)/ *KMT2A*-rearranged t(9;22)(q34.1;q11.2)/ *BCR::ABL1* t(8;16)(p11.2;p13.3)/ *KAT6A::CREBBP* inv(3)(q21.3;q26.2) or t(3;3)(q21.3;q26.2)/ *GATA2*, *MECOM*(*EVI1*) -5 or del(5q); -7; -17/abn(17p) Complex karyotype, monosomal karyotype Mutated *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1, and/or ZRSR2* Mutated *TP53*

Genetic Testing for Molecular Subtypes of AML

A number of systematic reviews with meta-analyses have highlighted the evolving classification of AML into distinct molecular subtypes based on *CEBPA*, *FLT3-ITD*, *KIT*, *NPM1*, and *TP53*, particularly in patients with normal karyotype.[41-46] These studies support the WHO and NCCN risk status classifications, and additionally highlight the importance of *KIT* testing in the initial evaluation and for prognosis.

PANEL TESTING FOR MYELOID NEOPLASMS

As indicated in NCCN guidelines and the WHO classification system, testing for variants in multiple genes may be indicated for diagnosis or treatment decisions in patients diagnosed with, or suspected of having, a myeloid neoplasm (see Practice Guideline Summary below). A number of studies have been published that describe the use of genetic panel tests that include these genes for diagnosis and prognosis of AML[47-51] and MDS[52-54].

PRACTICE GUIDELINE SUMMARY

WORLD HEALTH ORGANIZATION

In 2016 the WHO published diagnostic criteria for myeloid neoplasms and acute leukemia, which include testing for a number of genetic variants, as shown in Table 2.[1] The 2022 major criteria for myeloproliferative neoplasms are unchanged.[2]

NATIONAL COMPREHENSIVE CANCER NETWORK

The NCCN has published guidelines for Chronic Myeloid Leukemia (v.2.2024)[55], Acute Lymphoblastic Leukemia (v.4.2023)[56], which include recommendations regarding *BCR-ABL1* testing.

NCCN guidelines for Acute Myeloid Leukemia (v.2.2024)[40], Myelodysplastic Syndromes (v.1.2024)[57], and Myeloproliferative Neoplasms (v.1.2024)[58] include recommendations for testing a number of genes that have clinical significance for these disorders, including *JAK2, CALR, MPL, ASXL1, IDH1, IDH2, TP53, CEBPA*, *FLT3*, *KIT*, *NPM1,* and *RUNX1*.

SUMMARY

BCR/ABL1 (t(9;22)) TRANSLOCATION ANALYSIS, *JAK2, CALR, MPL, ASXL1, IDH1, IDH2, TP53, CEBPA*, *FLT3*, *KIT*, *NPM1* AND/OR *RUNX1*

There is enough research to show that *BCR/ABL1* (t(9;22)) translocation analysis (Philadelphia chromosome) and genetic testing for *JAK2, CALR, MPL, ASXL1, IDH1, IDH2, TP53, CEBPA, FLT3, KIT, NPM1 and/or RUNX1* variants is important to guide diagnosis and treatment of myeloid neoplasms and leukemia. Additionally, these tests are recommended by clinical practice guidelines for various myeloid disorders. Therefore, testing for *BCR/ABL1* (t(9;22)) translocation analysis (Philadelphia chromosome) and genetic testing for *JAK2, CALR, MPL, ASXL1, IDH1, IDH2, TP53, CEBPA, FLT3, KIT, NPM1 and/or RUNX1* variants is considered medically necessary for evaluation, diagnosis, and/or treatment monitoring for myeloid neoplasms and leukemia.

BCR-ABL KINASE DOMAIN (*ABL1*)

In chronic myeloid leukemia, there is enough research to show clinical utility for evaluation of *ABL1* variants for tyrosine kinase inhibitor (TKI) resistance. TKI resistance in acute lymphoblastic leukemia (ALL) has not been studied as well as in CML. However, there is enough research to show *ABL1* genetic testing for evaluation of TKI resistance may lead to an improvement in health outcomes for patients with ALL who are receiving a TKI. Practice guidelines based on research recommend *ABL1* testing for ALL and CML in specific clinical scenarios. Therefore, *ABL1* genetic testing for evaluation of TKI resistance may be considered medically necessary when policy criteria are met. Due to insufficient evidence, evaluation of *ABL1* variants is considered investigational when policy criteria are not met.

TARGETED PANEL TESTING

There is enough research to show that targeted panel testing may be important for diagnosis and guide treatment decisions for patients suspected of having or diagnosed with myeloproliferative neoplasms (MPN), myelodysplastic neoplasms (MDS), and myelodysplastic myeloproliferative neoplasms (MPN/MDS), including acute myeloid leukemia (AML). Clinical practice guidelines recommend panel testing for these disorders.

Therefore, targeted panel testing for MPN, MDS, MPN/MDS or AML may be considered medically necessary.

NON-TARGETED PANEL TESTING

Non-targeted panels include testing for a large number of genes and are not targeted toward genes that have clinical significance for a specific type of hematolymphoid disorder. They often include testing for many genes that are not necessary to guide treatment, as well as testing for disorders that could be distinguished based on clinical presentation. There are no clinical practice guidelines based on research that recommend testing for all of the genes in these panels. Therefore, the use of non-targeted hematologic panel testing is considered investigational.

CODES

NOTE: BCR/ABL1 (t(9;22)) translocation analysis has specific CPT codes: 81206-8, 0016U, and 0040U. This differs from than BCR-ABL kinase domain (*ABL1*) variant analysis.

Codes	Number	Description
CPT	0016U	Oncology (hematolymphoid neoplasia), RNA, BCR/ABL1 major and minor breakpoint fusion transcripts, quantitative PCR amplification, blood or bone marrow, report of fusion not detected or detected with quantitation
	0017U	Oncology (hematolymphoid neoplasia), JAK2 mutation, DNA, PCR amplification of exons 12-14 and sequence analysis, blood or bone marrow, report of JAK2 mutation not detected or detected
	0023U	Oncology (acute myelogenous leukemia), DNA, genotyping of internal tandem duplication, p.D835, p.I836, using mononuclear cells, reported as detection or non-detection of FLT3 mutation and indication for or against the use of midostaurin
	0027U	*JAK2* (Janus kinase 2) (eg, myeloproliferative disorder) gene analysis, targeted sequence analysis exons 12-15
	0040U	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis, major breakpoint, quantitative
	0046U	FLT3 (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia) internal tandem duplication (ITD) variants, quantitative
	0049U	NPM1 (nucleophosmin) (eg, acute myeloid leukemia) gene analysis, quantitative
	0050U	Targeted genomic sequence analysis panel, acute myelogenous leukemia, DNA analysis, 194 genes, interrogation for sequence variants, copy number variants or rearrangements
	81120	IDH1 (isocitrate dehydrogenase 1 [NADP+], soluble) (eg, glioma), common variants (eg, R132H, R132C)
	81121	IDH2 (isocitrate dehydrogenase 2 [NADP+], mitochondrial) (eg, glioma), common variants (eg, R140W, R172M)
	81170	*ABL1* (ABL proto-oncogene 1, non-receptor tyrosine kinase) (eg, acquired imatinib tyrosine kinase inhibitor resistance), gene analysis, variants in the kinase domain
	81175	*ASXL1* (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; full gene sequence
	81176	*ASXL1* (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; targeted sequence analysis (eg, EXON 12)
	81206	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; major breakpoint, qualitative or quantitative
	81207	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; minor breakpoint, qualitative or quantitative
	81208	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; other breakpoint, qualitative or quantitative
	81218	*CEBPA* (CCAAT/enhancer binding protein [C/EBP], alpha) (eg, acute myeloid leukemia), gene analysis, full gene sequence
	81219	*CALR* (calreticulin) (eg, myeloproliferative disorders), gene analysis, common variants in exon 9
	81245	*FLT3* (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia), gene analysis; internal tandem duplication (ITD) variants (ie, exons 14, 15)
	81246	*FLT3* (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia), gene analysis; tyrosine kinase domain (TKD) variants (eg, D835, I836)

Codes	Number	Description
	81270	*JAK2* (Janus kinase 2) (eg, myeloproliferative disorder) gene analysis, p.Val617Phe (V617F) variant
	81272	*KIT* (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, gastrointestinal stromal tumor [GIST], acute myeloid leukemia, melanoma), gene analysis, targeted sequence analysis (eg, exons 8, 11, 13, 17, 18)
	81273	*KIT* (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, mastocytosis), gene analysis, D816 variant(s)
	81279	*JAK2* (Janus kinase 2) (eg, myeloproliferative disorder) targeted sequence analysis (eg, exons 12 and 13)
	81310	*NPM1* (nucleophosmin) (eg, acute myeloid leukemia) gene analysis, exon 12 variants
	81334	*RUNX1* (runt related transcription factor 1) (eg, acute myeloid leukemia, familial platelet disorder with associated myeloid malignancy), gene analysis, targeted sequence analysis (eg, EXONS 3-8)
	81338	MPL (MPL proto-oncogene, thrombopoietin receptor) (eg, myeloproliferative disorder) gene analysis; common variants (eg, W515A, W515K, W515L, W515R)
	81339	MPL (MPL proto-oncogene, thrombopoietin receptor) (eg, myeloproliferative disorder) gene analysis; sequence analysis, exon 10
	81351	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; full gene sequence
	81352	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; targeted sequence analysis (eg, 4 oncology)
	81353	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; known familial variant
	81401	Molecular pathology procedure, Level 2 - which includes *ABL1 (ABL proto oncogene 1, non-receptor tyrosine kinase)* (eg, acquired imatinib resistance), T315I variant
	81402	Molecular pathology procedure, Level 3 (eg, >10 SNPs, 2-10 methylated variants, or 2-10 somatic variants [typically using non-sequencing target variant analysis], immunoglobulin and T-cell receptor gene rearrangements, duplication/deletion variants 1 exon)
	81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
	81450	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
	81451	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; RNA analysis
	81455	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed DNA analysis or combined DNA and RNA analysis
	81456	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and

Codes	Number	Description
		copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; RNA analysis

Genetic Testing for PTEN Hamartoma Tumor Syndrome

Effective: September 1, 2024

Next Review: May 2025
Last Review: July 2024

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

The *PTEN* hamartoma tumor syndrome (PHTS) includes several syndromes with heterogeneous clinical symptoms, which may place individuals at an increased risk of developing certain types of cancer. PHTS can be diagnosed with the identification of a *PTEN* variant.

MEDICAL POLICY CRITERIA

I. Genetic testing for *PTEN*, including in the evaluation of *PTEN* hamartoma tumor syndrome, may be considered **medically necessary** when one or more of the following criteria are met:

   A. In a first-degree relative of a proband with a known *PTEN* disease-associated variant

   B. In a patient with any of the following:

      1. Two or more biopsy-proven trichilemmomas
      2. Autism spectrum disorder and macrocephaly
      3. Adult Lhermitte-Duclos syndrome

   C. In a patient with two or more of the following:

1. Autism spectrum disorder
2. Breast Cancer
3. Colon cancer
4. Endometrial cancer (epithelial)
5. Esophageal glycogenic acanthoses, three or more
6. Gastrointestinal hamartomas (including ganglioneuromas, adenomas, hyperplastic polyps; three or more)
7. Intellectual disability defined as IQ less than or equal to 75
8. Lipomas, three or more
9. Macrocephaly (megalocephaly; defined as greater than or equal to 97th percentile, 58 cm in adult woman, 60 cm in adult men)
10. Macular pigmentation of glans penis
11. Mucocutaneous lesions, three or more with clinical documentation
12. Renal cell carcinoma
13. Testicular lipomatosis
14. Thyroid cancer or thyroid structural lesions (e.g. adenoma, multinodular goiter)
15. Vascular anomalies (including multiple intracranial developmental venous anomalies)

II. Genetic testing for *PTEN* is considered **investigational** when Criterion I. is not met.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

POLICY GUIDELINES

TESTING IN A FIRST-DEGREE RELATIVE

When a *PTEN* pathogenic variant has been identified in the proband, testing of asymptomatic at-risk relatives can identify those family members who have the family-specific variant, for whom an initial evaluation and ongoing surveillance should be performed.

LIST OF INFORMATION NEEDED FOR REVIEW

SUBMISSION OF DOCUMENTATION

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Current Symptomology
- Documentation of first-degree relative when there is known variant

BACKGROUND

The *PTEN* (phosphatase and tensin homologue) hamartoma tumor syndrome is characterized by hamartomatous tumors and *PTEN* germline disease-associated variants. Clinically, PHTS includes Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), *PTEN*-related Proteus syndrome (PS), and Proteus-like syndrome (PLS).

CS is a multiple hamartoma syndrome with a high risk for benign and malignant tumors of the thyroid, breast, and endometrium. Affected individuals usually have macrocephaly, trichilemmomas, and papillomatous papules and present by the late 20s. The lifetime risk of developing breast cancer is 25-50%, with an average age of diagnosis between 38 and 46 years. The lifetime risk for thyroid cancer, which is usually follicular carcinoma, is approximately 10%. The risk for endometrial cancer is not well defined but may approach 5-10%.

BRRS is characterized by macrocephaly, intestinal hamartomatous polyposis, lipomas, and pigmented macules of the glans penis. Additional features include high birth weight, developmental delay and mental deficiency (50% of affected individuals), a myopathic process in proximal muscles (60%), joint hyperextensibility, pectus excavatum, and scoliosis (50%).

PS is a complex, highly variable disorder involving congenital malformations and hamartomatous overgrowth of multiple tissues, as well as connective tissue nevi, epidermal nevi, and hyperostoses.

Proteus-like syndrome is undefined but refers to individuals with significant clinical features of PS who do not meet the diagnostic criteria for PS.

CS is the only PHTS disorder associated with a documented predisposition to cancer; however, it has been suggested that patients with other PHTS diagnoses associated with *PTEN* pathogenic variants should be assumed to have cancer risks similar to those with CS.

CLINICAL DIAGNOSIS

A presumptive diagnosis of PHTS is based on clinical findings; however, because of the phenotypic heterogeneity associated with the hamartoma syndromes, the diagnosis of PHTS is made only when a *PTEN* disease-associated variant is identified.

MANAGEMENT

Treatment

Treatment of the benign and malignant manifestations of PHTS is the same as for their sporadic counterparts.

Surveillance

The most serious consequences of PHTS relate to the increased risk of cancers, including breast, thyroid and endometrial, and to a lesser extent, renal. Therefore, the most important aspect of management of an individual with a *PTEN* disease-associated variant is increased cancer surveillance to detect tumors at the earliest, most treatable stages.

MOLECULAR DIAGNOSIS

PTEN is a tumor suppressor gene on chromosome 10q23 and is dual specificity phosphatase with multiple but incompletely understood roles in cellular regulation.[1] *PTEN* pathogenic variants are inherited in an autosomal dominant manner.

Because CS is likely underdiagnosed, the actual proportion of simplex cases (defined as individuals with no obvious family history) and familial cases (defined as ≥2 related affected individuals) cannot be determined. The majority of CS cases are simplex. It is estimated that 50-90% of cases of CS are de novo and approximately 10-50% of individuals with CS have an affected parent.

Because of the phenotypic heterogeneity associated with the hamartoma syndromes, the diagnosis of PHTS is made only when a *PTEN* disease-associated variant is identified. Up to 85% of patients who meet the clinical criteria for a diagnosis of CS and 65% of patients with a clinical diagnosis of BRRS have a detectable *PTEN* variant. Some data suggest the up to 20% of patients with Proteus syndrome and up to 50% of patients with a Proteus-like syndrome have *PTEN* variants.

Most of these pathogenic variants can be identified by sequence analysis of the coding and flanking intronic regions of genomic DNA. A smaller number of variants are detected by deletion/duplication or promoter region analysis.

Penetrance: More than 90% of individuals with CS have some clinical manifestation of the disorder by the late 20s. By the third decade, 99% of affected individuals develop the mucocutaneous stigmata, primarily trichilemmomas and papillomatous papules, as well as acral and plantar keratoses.

REGULATORY STATUS

Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; laboratory-developed tests (LDTs) must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). Laboratory testing for PTEN variants is available under the auspices of CLIA. Laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, the U.S. Food and Drug Administration has chosen not to require any regulatory review of this test.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[2] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

1. Analytic validity, which refers to the technical accuracy of the test in detecting a pathogenic variant that is present or in excluding a variant that is absent;
2. Clinical validity, which refers to the diagnostic performance of the test (i.e., sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and
3. Clinical utility, which refers to how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

The focus of this review is on evidence from well designed, studies related to the ability of test results to:

- Guide decisions in the clinical setting related to either treatment, management, or prevention; and
- Improve health outcomes as a result of those decisions.

ANALYTIC VALIDITY

According to a large reference laboratory, analytical sensitivity and specificity for bidirectional sequencing of the *PTEN*-related promoter, coding region and intron-exon boundaries is 99%.[3]

CLINICAL VALIDITY

Many reports on the prevalence of the features of Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS) have been based upon data compiled from case reports and studies of small cohorts. Most of these reports were published before adoption of the International Cowden Consortium diagnostic criteria for CS in 1996, and the true frequencies of the clinical features in CS and BRRS are not known.[1]

According to a large reference laboratory, the clinical sensitivity of *PTEN*-related disorders sequencing is 85% for CS, 65% for BRRS, 20% for *PTEN*-related Proteus syndrome (PS) and 50% for Proteus-like syndrome (PSL). For *PTEN*-related deletion/duplication, it is up to 10% for BRRS and/or CS-like syndrome.[3]

Germline *PTEN* variants have been identified in ~80% of patients meeting diagnostic criteria for CS and in 50 to 60% of patients with a diagnosis of BRRS, using PCR-based sequence analysis of the coding and flanking intronic regions of the gene.[4, 5] Marsh (1998) screened DNA from 37 CS families and *PTEN* variants were identified in 30 of 37 CS families (81%), including single nucleotide variants, insertions, and deletions.[4] The *PTEN* variant detection rate is much lower in breast cancer patients without other symptoms.[6, 7]

Whether the remaining patients have undetected *PTEN* variants or variants in other, unidentified genes, is not known.[8]

A study by Pilarski (2011) determined the clinical features that were most predictive of a disease-associated variant in a cohort of patients tested for *PTEN* variants.[1] Molecular and clinical data were reviewed for 802 patients referred for *PTEN* analysis by a single laboratory. All of the patients were classified as to whether they met revised International Cowden Consortium Diagnostic criteria. Two hundred and thirty of the 802 patients met diagnostic criteria for a diagnosis of CS. Of these, 79 had a *PTEN* pathogenic variant, for a detection rate of 34%. The authors commented that this variant frequency was significantly lower than

previously reported, possibly suggesting that the clinical diagnostic criteria for CS are not as robust at identifying patients with germline *PTEN* variants as previously thought. In contrast, in their study, of the patients meeting diagnostic criteria for BRRS, 23 of 42 (55%) had a pathogenic variant, and seven of nine patients (78%) with diagnostic criteria for both CS and BRRS had a variant, consistent with the literature.

Section Summary

Evidence from several small studies indicated that the clinical sensitivity of genetic testing for *PTEN* variants may be highly variable. This may reflect the phenotypic heterogeneity of the syndromes and an inherent referral bias as patients with more clinical features of CS/BRRS are more likely to get tested. The true clinical specificity is uncertain because the syndrome is defined by the variant.

CLINICAL UTILITY

The clinical utility of genetic testing can be considered in the following clinical situations:

1. Individuals with suspected *PTEN* hamartoma tumor syndrome (PHTS)
2. Family members of individuals with PHTS, and
3. Prenatal testing.

Individuals with Suspected PHTS

The clinical utility for these patients depends on the ability of genetic testing to make a definitive diagnosis and for that diagnosis to lead to management changes that improve outcomes. There is no direct evidence for the clinical utility of genetic testing in these patients as no studies were identified that described how a molecular diagnosis of PHTS changed patient management.

However, for patients who are diagnosed with PHTS by identifying a *PTEN* pathogenic variant, the medical management focuses on increased cancer surveillance to detect tumors at the earliest, most treatable stages.

- Family members.

  When a *PTEN* pathogenic variant has been identified in a proband, testing of at-risk relatives can identify those who also have the pathogenic variant and have *PTEN* hamartoma tumor syndrome (PHTS). These individuals need initial evaluation and ongoing surveillance.

- Prenatal screening.

  Prenatal diagnosis is possible for pregnancies at increased risk, by amniocentesis or chorionic villus sampling; the disease-causing allele of an affected family member must be identified before prenatal testing can be performed.

Recent studies reporting on the clinical features of individuals with a *PTEN* pathogenic variant have indicated there is insufficient evidence to support the inclusion of benign breast disease, uterine fibroids, or genitourinary malformations as diagnostic criteria. However, there was sufficient evidence identified to include autism spectrum disorders, colon cancer, esophageal glycogenic acanthosis, penile macules, renal cell carcinoma, testicular lipomatosis and vascular anomalies. These identified clinical features are included in CS testing minor criteria

in National Comprehensive Cancer Network guidelines (see Policy Guidelines section above) and described in a recent systematic review.[9, 10]

Section Summary

Direct evidence for the clinical utility of *PTEN* testing is lacking. However, the clinical utility of genetic testing for *PTEN* variants is that genetic testing can confirm the diagnosis in patients with clinical signs and symptoms of PHTS. Management changes include increased surveillance for the cancers associated with these syndromes.

PRACTICE GUIDELINE SUMMARY

NATIONAL COMPREHENSIVE CANCER NETWORK

The NCCN guidelines on Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic recommend the following for CS/PHTS management (3.2024):[10]

For Women:

- Breast awareness starting at age 18 years.
- Clinical breast exam every 6 to 12 months, starting at age 25 years or 5 to 10 years before the earliest known breast cancer in the family (whichever comes first).
- Breast screening:
    - Annual mammography and breast MRI screening with or without contrast starting at age 30 years or 10 years before the earliest known breast cancer in family (whichever comes first).
    - Age > 75, management should be considered on an individual basis.
    - For individuals with pathogenic/likely pathogenic *PTEN* variant who are treated for breast cancer, and have not had bilateral mastectomy, screening of remaining breast tissue with annual mammography and breast MRI should continue as described above.
- Discuss option of risk-reducing mastectomy in individuals with pathogenic/likely pathogenic variants identified. For those with clinical CS/PTHS syndrome, consideration of risk-reducing surgery should be based on family history.
- Endometrial cancer screening, consider starting by age 35 years:
    - Encourage patient education and prompt response to symptoms (eg abnormal bleeding). Patients are encouraged to keep a calendar in order to identify irregularities in their menstrual cycle.
    - Because endometrial cancer can often be detected early based on symptoms, women should be educated regarding the importance of prompt reporting and evaluation of any abnormal uterine bleeding or postmenopausal bleeding. The evaluation of these symptoms should include endometrial biopsy.
    - Endometrial cancer screening does not have proven benefit in women with CS/PHTS. However, endometrial biopsy is both highly sensitive and highly specific as a diagnostic procedure. Screening via endometrial biopsy every 1 to 2 years can be considered.
    - Transvaginal ultrasound to screen for endometrial cancer in postmenopausal women has not been shown to be sufficiently sensitive or specific as to support a positive recommendation, but may be considered at the clinician's discretion. Transvaginal ultrasound is not recommended as a screening tool in

premenopausal women due to the wide range of endometrial stripe thickness throughout the normal menstrual cycle.

- Discuss option of hysterectomy upon completion of childbearing and counsel regarding degree of protection, extent of cancer risk, and reproductive desires.
- Address psychosocial, social, and quality-of-life aspects of undergoing risk-reducing mastectomy and/or hysterectomy.

For Men and Women:

- Annual comprehensive physical exam starting at age 18 years or 5 years before the youngest age of diagnosis of a component cancer in the family (whichever comes first), with particular attention to thyroid exam.
- Annual thyroid ultrasound, starting at age 7 years. This may also be considered for children at 50% risk of inheriting a known mutation whose parents wish to delay genetic testing until age 18 y.
- Colonoscopy, starting at age 35 years, unless symptomatic or a close relative with colon cancer before age 40 years, then start 5-10 years before earliest known colon cancer in the family. Colonoscopy should be done every 5 years or more frequently if patient is symptomatic or polyps found.
- Consider renal ultrasound starting at age 40 years, then every 1 to 2 years.
- There may be an increased risk of melanoma, and the prevalence of other skin characteristics with CS/PTHS may independently make routine dermatology evaluations of value. Annual dermatology recommendations are recommended.
- Consider psychomotor assessment in children at diagnosis and brain MRI if there are symptoms.
- Education regarding the signs and symptoms of cancer.

For Relatives:

- Advise about possible inherited cancer risk to relatives, options for risk assessment, and management.
- Recommend genetic counseling and consideration of genetic testing for at-risk relatives.

Reproductive options:

- For women of reproductive age, advise about options for prenatal diagnosis and assisted reproduction including preimplantation genetic diagnosis. Discussion should include known risks, limitations, and benefits of these technologies.

U.S MULTI-SOCIETY TASK FORCE ON COLORECTAL CANCER

In 2022, the US Multi-Society Task Force on Colorectal Cancer (USMSTF), a group of colorectal cancer (CRC) content experts appointed by the American College of Gastroenterology, American Gastroenterological Association, and American Society for Gastrointestinal Endoscopy, published recommendations on the diagnosis and management of cancer risk in the gastrointestinal hamartomatous polyposis syndromes, including the following regarding genetic testing:[11]

> We recommend patients with any of the following undergo a genetic evaluation: 2 or more lifetime hamartomatous polyps, a family history of hamartomatous polyps, or a cancer associated with a hamartomatous polyposis syndrome in first- or second-degree

relatives. Genetic testing (if indicated) should be performed using a multigene panel test. (Strong recommendation, low quality of evidence).

We recommend genetic evaluation for any individual with the following: 1) 2 or more histologically confirmed Peutz-Jeghers polyps, 2) any number of Peutz-Jeghers polyps in an individual who has a family history of Peutz-Jeghers syndrome in a first-degree relative, 3) characteristic mucocutaneous pigmentation in a person with a family history of Peutz-Jeghers syndrome, 4) any number of Peutz-Jeghers polyps in a person with the characteristic mucocutaneous pigmentation of Peutz-Jeghers syndrome. (Strong recommendation, low quality of evidence).

We recommend genetic evaluation for any individual with 1) 5 or more juvenile polyps of the colon or rectum; or 2) 2 or more juvenile polyps in other parts of the gastrointestinal tract; or (3) any number of juvenile polyps and 1 or more first-degree relatives with juvenile polyposis syndrome. (Strong recommendation, low quality of evidence).

We recommend individuals with multiple gastrointestinal hamartomas or ganglioneuromas undergo genetic evaluation for Cowden's syndrome and related conditions. (Strong recommendation, low quality of evidence).

SUMMARY

There is enough research to show that *PTEN* genetic testing can help to determine appropriate cancer surveillance, leading to improved health outcomes for patients at high risk for *PTEN* hamartoma tumor syndrome. Clinical guidelines based on research recommend this testing for certain individuals. Therefore, *PTEN* genetic testing may be considered medically necessary when a presumptive diagnosis of a *PTEN* hamartoma tumor syndrome has been made based on clinical signs, and for first-degree relatives of an individual with a known disease-associated *PTEN* variant.

There is not enough research to show that *PTEN* genetic testing improves health outcomes for individuals who do not meet the policy criteria. Therefore, genetic testing for a *PTEN* variant is considered investigational for all other indications.

Medical Policy Manual Genetic Testing, Policy No. 64

Evaluating the Utility of Genetic Panels

Effective: April 1, 2024

Next Review: July 2025
Last Review: March 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genetic panel tests evaluate many genes simultaneously, and have been developed for numerous indications, including hereditary cancer risk assessment, pharmacogenetics, and diagnosis of congenital disorders. Many panel tests include genes that do not have demonstrated clinical utility for their testing.

MEDICAL POLICY CRITERIA

Note: Where applicable, specific policies that have criteria and evidence used to review genetic panel tests are noted (see *Policy Cross-References* in the table below).

When there is not enough research to show that a gene and/or gene variant in a genetic panel test may be used to manage treatment decisions and improve net health outcomes, then the entire genetic panel test is considered **investigational**, including but not limited to the following (with or without any optional add-on genes or components):

Test Name	Laboratory	Policy Cross-Reference
Abnormal Genitalia/ Disorders of Sex Development Panel	Blueprint Genetics	None
Aeon Pain Management PGX Profile	Aeon Clinical Laboratories	GT10

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

LIST OF INFORMATION NEEDED FOR REVIEW

In order to determine the clinical utility of gene test(s), all of the following information must be submitted for review:

1. Name of the genetic test(s) or panel test
2. Name of the performing laboratory and/or genetic testing organization (more than one may be listed)
3. The exact gene(s) and/or variant(s) being tested
4. Relevant billing codes
5. Brief description of how the genetic test results will guide clinical decisions that would not otherwise be made in the absence testing
6. Medical records related to this genetic test, if available:
   - History and physical exam
   - Conventional testing and outcomes
   - Conservative treatment provided

BACKGROUND

New genetic technology, such as next generation sequencing and chromosomal microarray, has led to the ability to examine many genes simultaneously.[1] This in turn has resulted in a proliferation of genetic panels. The intended use for these panels is variable. For example, for the diagnosis of hereditary disorders, a clinical diagnosis may already be established, and genetic testing is performed to determine whether there is a hereditary condition, and/or to determine the specific variant that is present. In other cases, there is a clinical syndrome (phenotype) with a broad number of potential diagnoses and genetic testing is used to make a specific diagnosis. For cancer panels, there are also different intended uses. Some panels may be intended to determine whether a known cancer is part of a hereditary cancer

syndrome. Other panels may include somatic variants in a tumor biopsy specimen that may help identify a cancer type or subtype and/or help select best treatment.

Panels using next generation technology are currently available in the areas of cancer, cardiovascular disease, neurologic disease, psychiatric conditions, and for reproductive testing.[2-4] These panels are intuitively attractive to use in clinical care because they can screen for numerous variants within a single or multiple genes quickly, and may lead to greater efficiency in the work-up of genetic disorders. It is also possible that these "bundled" gene tests can be performed more cost effectively than direct sequencing, although this may not be true in all cases. However, panel testing also provides information on genetic variants that are of unclear clinical significance or which would not lead to changes in patient management.

One potential challenge of genetic panel testing is the availability of a large amount of ancillary genetic information, much of which has uncertain clinical consequences and management strategies. Identification of variants for which the clinical management is uncertain may lead to unnecessary follow-up testing and procedures, all of which have their own inherent risks.

Additionally, the design and composition of genetic panel tests have not been standardized. Composition of the panels is variable, and different commercial products for the same condition may test different sets of genes. The make-up of the panel is determined by the specific lab that has developed the test. In addition, the composition of any individual panel is likely to change over time, as new variants are discovered and added to the existing panels.

GENETIC COUNSELING

Due to the complexity of interpreting genetic test results, patients should receive pre- and post-test genetic counseling from a qualified professional when testing is performed to diagnose or predict susceptibility for inherited diseases. The benefits and risks of genetic testing should be fully disclosed to individuals prior to testing, and counseling concerning the test results should be provided.

REGULATORY STATUS

The majority of genetic panel tests are laboratory derived tests that are not subject to U.S. Food and Drug Administration (FDA) approval. Clinical laboratories may develop and validate tests in-house ("home-brew") and market them as a laboratory service; such tests must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). The laboratory offering the service must be licensed by CLIA for high-complexity testing.

Note: Separate Medical Policies may apply to some specific genetic tests and panels not addressed in the criteria below. See the Genetic Testing Section of the Medical Policy Manual Table of Contents for additional genetic testing policies.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[5] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Genetic cancer susceptibility panels utilizing next generation sequencing are best evaluated in the framework of a diagnostic test, as the test provides diagnostic information that assists in treatment decisions. The clinical utility of genetic panel testing refers to the likelihood that the panel will result in improved health outcomes.
For positive test results, the health benefits are related to interventions that reduce the risk of developing the disease, earlier or more intensive screening to detect and treat early disease symptoms, or interventions to improve quality of life.

- Alternatively, negative test results may prevent unnecessary intensive monitoring, invasive tests or procedures, or ineffective therapies.

For genetic panels that test for a broad number of variants, some components of the panel may be indicated based on the patient's clinical presentation and/or family history, while other components may not be indicated. The impact of test results related to non-indicated variants must be well-defined and take into account the possibility that the information may cause harm by leading to additional unnecessary interventions that would not otherwise be considered based on the patient's clinical presentation and/or family history.

Therefore, the focus of the following review is on evidence from well-designed controlled trials or large cohort studies that demonstrate the clinical utility of each panel test, i.e., the ability of results from the comprehensive genetic panels to:

1. Guide decisions in the clinical setting related to either treatment, management, or prevention; and

2. Improve health outcomes as a result of those decisions.

A limited body of literature exists on the potential clinical utility of available next generation sequencing (NGS) panels.

NONRANDOMIZED STUDIES

Desmond (2015) reported on an observational study assessing whether testing of hereditary cancer gene variants other than BRCA1/2 altered clinical management in a prospectively collected cohort of 1046 patients from three institutions who were negative for BRCA1/2.[6] Patients were tested with the 29-gene Hereditary Cancer Syndromes test (Invitae) or the 25-gene MyRisk test (Myriad Genetics). The investigators evaluated the likelihood of a post-test change in management considering gene-specific consensus management guidelines, gene-associated cancer risks, and personal and family history. Of this cohort, 40 patients (3.8%, 95% CI 2.8% to 5.2%) harbored deleterious variants, most commonly in moderate-risk breast and ovarian cancer genes and Lynch syndrome genes. Among 63 variant-positive patients, 20 were found to harbor variants in high-risk genes associated with detailed NCCN management guidelines which would change the pretest recommendations for screening and/or preventive surgery. However, the most common variants found were those in genes associated with low or moderately increased breast cancer risk (40 of 63 patients), where a change in management would be recommended for these patients in a minority of cases (10 of 40), involving either increased screening or preventive surgery. Since this study only reported anticipated changes in management, these variant-positive patients were not provided with these post-test recommendations. The investigators conceded that the potential clinical effect reported in this cohort is likely to apply only to an appropriately ascertained cohort, thereby limiting the generalizability of the results.

Kurian (2014) evaluated the information from a NGS panel of 42 cancer associated genes in women who had been previously referred for clinical BRCA1/2 testing after clinical evaluation of hereditary breast and ovarian cancer from 2002 to 2012.[7] The authors aimed to assess concordance of the results of the panel with prior clinical sequencing, the prevalence of potentially clinically actionable results, and the downstream effects on cancer screening and risk reduction. Potentially actionable results were defined as pathogenic variants that cause recognized hereditary caner syndromes or have a published association with a two-fold or greater relative risk of breast cancer compared to average risk women. In total, 198 women participated in the study. Of these, 174 had breast cancer and 57 carried 59 germline BRCA variants. Testing with the panel confirmed 57 of 59 of the pathogenic BRCA variants; of the two others, one was detected but reclassified as a VUS and the other was a large insertion that would not be picked up by NGS panel testing. Of the women who tested negative for *BRCA* variants (n=141), 16 had pathogenic variants in other genes (11.4%). The affected genes were *ATM* (n=2), *BLM* (n=1), *CDH1* (n=1), *CDKN2A* (n=1), *MLH1* (n=1), *MUTYH* (n=5), *NBN* (n=2), *PRSS1* (n=1), and *SLX4* (n=2). Eleven of these variants had been previously reported in the literature and five were novel. 80% of the women with pathogenic variants in the non BRCA1/2 genes had a personal history of breast cancer. Overall, a total of 428 VUS were identified in 39 genes, among 175 patients.

Six women with variants in *ATM*, *BLM*, *CDH1*, *NBN* and *SLX4* were advised to consider annual breast MRIs because of an estimated doubling of breast cancer risk, and six with variants in CDH1, MLH1 and MUTYH were advised to consider frequent colonoscopy and/or endoscopic gastroduodenoscopy (once every 1 to 2 years) due to estimated increases in gastrointestinal cancer risk. One patient with a MLH1 variant consistent with Lynch syndrome underwent risk-reducing salpingo-oophorectomy and early colonoscopy which identified a tubular adenoma that was excised (she had previously undergone hysterectomy for endometrial carcinoma).

Mauer (2014) reported a single academic center's genetics program's experience with NGS panels for cancer susceptibility.[8] The authors conducted a retrospective review of the outcomes and clinical indications for the ordering of Ambry's next generation sequencing panels (BreastNext, OvaNext, ColoNext, and CancerNext) for patients seen for cancer genetics counseling from April 2012 to January 2013. Of 1,521 new patients seen for cancer genetics counseling, 1,233 (81.1%) had genetic testing. Sixty of these patients (4.9% of the total) had a next generation sequencing panel ordered, 54 of which were ordered as a second-tier test after single-gene testing was performed. Ten tests were cancelled due to out-of-pocket costs or previously identified variants. Of the 50 tests obtained, five were found to have a deleterious result (10%, compared with 131 [10.6%] of the 1,233 single-gene tests ordered at the same center during the study time frame). The authors report that of the 50 completed tests, 30 (60%) did not affect management decisions, 15 (30%) introduced uncertainty regarding the patients' cancer risks, and five (10%) directly influenced management decisions.

A number of other studies have evaluated the impact of panel testing on clinical management of a variety of conditions, including prostate cancer,[9] breast and/or ovarian cancer,[10-13] and non-specific hereditary cancers,[14] as well as genetic profiling of tumor tissue to guide cancer treatment.[15, 16] While some of these studies noted specific changes in medical management resulting from the testing, none of them evaluated whether these changes led to improvements in patient outcomes.

PRACTICE GUIDELINE SUMMARY

AMERICAN SOCIETY OF CLINICAL ONCOLOGY

A 2015 update of a policy statement on genetic and genomic testing for cancer susceptibility from the American Society of Clinical Oncology (ASCO) addresses the application of next-generation sequencing.[17] According to this statement:

> ASCO recognizes that concurrent multigene testing (i.e., panel testing) may be efficient in circumstances that require evaluation of multiple high-penetrance genes of established clinical utility as possible explanations for a patient's personal or family history of cancer. Depending on the specific genes included on the panel employed, panel testing may also identify mutations in genes associated with moderate or low cancer risks and mutations in high-penetrance genes that would not have been evaluated on the basis of the presenting personal or family history. Multigene panel testing will also identify variants of uncertain significance (VUS) in a substantial proportion of patient cases. ASCO affirms that it is sufficient for cancer risk assessment to evaluate genes of established clinical utility that are suggested by the patient's personal and/or family history. Because of the current uncertainties and knowledge gaps, providers with particular expertise in cancer risk assessment should be involved in the ordering and interpretation of multigene panels that include genes of uncertain clinical utility and genes not suggested by the patient's personal and/or family history.
>
> This type of testing may be particularly useful in situations where there are multiple high-penetrance genes associated with a specific cancer, the prevalence of actionable mutations in one of several genes is high, and it is difficult to predict which gene may be mutated on the basis of phenotype or family history.
>
> So far, there is little consensus as to which genes should be included on panels offered for cancer susceptibility testing- this heterogeneity presents a number of challenges. All panels include high-penetrance genes that are known to cause autosomal-dominant predisposition syndromes, but often include genes that are not necessarily linked to the disease for which the testing is being offered. There is uncertainty regarding the appropriate risk estimates and management strategies for families with unexpected mutations in high-penetrance genes when there is no evidence of the associated syndrome. Clinical utility remains the fundamental issue with respect to testing for mutations in moderate penetrance genes. It is not yet clear whether clinical management should change based on the presence or absence of a mutation. There is insufficient evidence at the present time to conclusively demonstrate the clinical utility of testing for moderate-penetrance mutations, and no guidelines exist to assist oncology providers. Early experience with panel-based testing indicates that a substantial proportion of tests identify a VUS in 1 or more genes, and VUSs are more common in broad-panel testing both because of the number of genes tested and because of the limited understanding of the range of normal variation in some of these genes.

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN) guidelines on genetic/familial high-risk assessment for breast, ovarian, and pancreatic cancer (v.1.2023)[18] state the following regarding multi-gene testing:

- An individual's personal and/or family history may be explained by more than one inherited cancer syndrome; thus, phenotype-directed testing based on personal and family history

through a tailored multi-gene panel test is often more efficient and cost-effective and increases the yield of detecting a P/LP [pathogenic/likely pathogenic] variant in a gene that will impact medical management for the individual or their at-risk family members.

- There may also be a role for multi-gene testing in individuals who have tested negative for a single syndrome, but whose personal or family history remains suggestive of an inherited susceptibility.
- Some individuals may carry P/LP germline variants in more than one cancer susceptibility gene; thus, consideration of a multi-gene panel for individuals already known to carry a single P/LP germline variant from phenotype-directed testing may be considered on a case-by-case basis, based on the degree of suspicion for there being additional variants.
- Multi-gene testing can include “intermediate” penetrant (moderate-risk) genes. For many of these genes, there are limited data on the degree of cancer risk, and there may currently be no clear guidelines on risk management for carriers of P/LP variants. Not all genes included on available multi-gene tests will change risk management compared to that based on other risk factors such as family history.
- It may be possible to refine risks associated with both moderate and high-penetrance genes, taking into account the influence of gene/gene or gene/environment interactions. In addition, certain P/LP variants in a gene may pose higher or lower risk than other P/LP variants in that same gene. This information should be taken into consideration when assigning risks and management recommendations for individuals and their at-risk relatives.
- P/LP variants in many breast, ovarian, pancreatic, and prostate cancer susceptibility genes involved in DNA repair may be associated with rare autosomal recessive conditions, thus posing risks to offspring if the partner is also a carrier.
- As more genes are tested, there is an increased likelihood of finding VUS, mosaicism, and clonal hematopoiesis of indeterminate potential (CHIP).
- There are significant limitations in interpretation of polygenic risk scores (PRSs). PRS should not be used for clinical management at this time and use is recommended in the context of a clinical trial, ideally including more diverse populations.

SUMMARY

Genetic test panels are available for many clinical conditions. Genetic test panels may be focused to a few genes or include a large number of genes. The advantage of genetic test panels is the ability to analyze many genes simultaneously, potentially improving the breadth and efficiency of the genetic workup. A disadvantage of genetic test panels is that the results may provide information on genetic variants that are of unclear clinical significance, or which would not lead to changes in patient management. These results may potentially cause harm by leading to additional unnecessary interventions and anxiety that would not otherwise be considered based on the patient’s clinical presentation and/or family history. There is not enough research to show that the genetic panels listed in the policy criteria can lead to better health outcomes for patients. When there is not enough research to show that all genes and/or gene variants in a genetic test panel may be useful for guiding patient management to improve health outcomes, the entire genetic test panel is considered investigational.

CODES

NOTE: There are few specific codes for molecular pathology testing by panels. If the specific analyte is listed with a CPT code, the specific CPT code should be reported. If the specific analyte is not listed with a specific CPT code, unlisted code 81479 should be reported. The unlisted code would be reported once to represent all of the unlisted analytes in the panel.

Codes	Number	Description
CPT	0008U	Helicobacter pylori detection and antibiotic resistance, DNA, 16S and 23S rRNA, gyrA, pbp1, rdxA and rpoB, next generation sequencing, formalin-fixed paraffin embedded or fresh tissue or fecal sample, predictive, reported as positive or negative for resistance to clarithromycin, fluoroquinolones, metronidazole, amoxicillin, tetracycline and rifabutin
	0010U	Infectious disease (bacterial), strain typing by whole genome sequencing, phylogenetic-based report of strain relatedness, per submitted isolate
	0029U	Drug metabolism (adverse drug reactions and drug response), targeted sequence analysis (ie, CYP1A2, CYP2C19, CYP2C9, CYP2D6, CYP3A4, CYP3A5, CYP4F2, SLCO1B1, VKORC1 and rs12777823)
	0030U	Drug metabolism (warfarin drug response), targeted sequence analysis (ie, CYP2C9, CYP4F2, VKORC1, rs12777823)
	0033U	HTR2A (5-hydroxytryptamine receptor 2A), HTR2C (5-hydroxytryptamine receptor 2C) (eg, citalopram metabolism) gene analysis, common variants (ie, HTR2A rs7997012 [c.614-2211T>C], HTR2C rs3813929 [c.-759C>T] and rs1414334 [c.551-3008C>G])
	0050U	Targeted genomic sequence analysis panel, acute myelogenous leukemia, DNA analysis, 194 genes, interrogation for sequence variants, copy number variants or rearrangements
	0101U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated [15 genes (sequencing and deletion/duplication), EPCAM and GREM1 (deletion/duplication only)]
	0102U	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated [17 genes (sequencing and deletion/duplication)]
	0103U	Hereditary ovarian cancer (eg, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated [24 genes (sequencing and deletion/duplication); EPCAM (deletion/duplication only)]
	0129U	Hereditary breast cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), genomic sequence

Codes	Number	Description
		analysis and deletion/duplication analysis panel (ATM, BRCA1, BRCA2, CDH1, CHEK2, PALB2, PTEN, and TP53)
	0130U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis), targeted mRNA sequence analysis panel (APC, CDH1, CHEK2, MLH1, MSH2, MSH6, MUTYH, PMS2, PTEN, and TP53) (List separately in addition to code for primary procedure) (Use 0130U in conjunction with 81435, 0101U)
	0131U	Hereditary breast cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), targeted mRNA sequence analysis panel (13 genes) (List separately in addition to code for primary procedure) (Use 0131U in conjunction with 81162, 81432, 0102U)
	0132U	Hereditary ovarian cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), targeted mRNA sequence analysis panel (17 genes) (List separately in addition to code for primary procedure) (Use 0132U in conjunction with 81162, 81432, 0103U)
	0133U	Hereditary prostate cancer–related disorders, targeted mRNA sequence analysis panel (11 genes) (List separately in addition to code for primary procedure) (Use 0133U in conjunction with 81162)
	0134U	Hereditary pan cancer (eg, hereditary breast and ovarian cancer, hereditary endometrial cancer, hereditary colorectal cancer), targeted mRNA sequence analysis panel (18 genes) (List separately in addition to code for primary procedure) (Use 0134U in conjunction with 81162, 81432, 81435)
	0135U	Hereditary gynecological cancer (eg, hereditary breast and ovarian cancer, hereditary endometrial cancer, hereditary colorectal cancer), targeted mRNA sequence analysis panel (12 genes) (List separately in addition to code for primary procedure) (Use 0135U in conjunction with 81162)
	0171U	Targeted genomic sequence analysis panel, acute myeloid leukemia, myelodysplastic syndrome, and myeloproliferative neoplasms, DNA analysis, 23 genes, interrogation for sequence variants, rearrangements and minimal residual disease, reported as presence/absence
	0173U	Psychiatry (ie, depression, anxiety), genomic analysis panel, includes variant analysis of 14 genes
	0175U	
	0216U	Neurology (inherited ataxias), genomic DNA sequence analysis of 12 common genes including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variant
	0217U	Neurology (inherited ataxias), genomic DNA sequence analysis of 51 genes including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants
	0269U	Hematology (autosomal dominant congenital thrombocytopenia), genomic sequence analysis of 22 genes, blood, buccal swab, or amniotic fluid
	0270U	Hematology (congenital coagulation disorders), genomic sequence analysis of 20 genes, blood, buccal swab, or amniotic fluid
	0272U	Hematology (genetic bleeding disorders), genomic sequence analysis of 60 genes and duplication/deletion of PLAU, blood, buccal swab, or amniotic fluid, comprehensive
	0273U	Hematology (genetic hyperfibrinolysis, delayed bleeding), analysis of 9 genes (F13A1, F13B, FGA, FGB, FGG, SERPINA1, SERPINE1, SERPINF2, by next

Codes	Number	Description
		generation sequencing and PLAU by array comparative genomic hybridization), blood, buccal swab, or amniotic fluid
	0274U	Hematology (genetic platelet disorders), genomic sequence analysis of 62 genes and duplication/deletion of PLAU, blood, buccal swab, or amniotic fluid
		Hematology (inherited thrombocytopenia), genomic sequence analysis of 42 genes, blood, buccal swab, or amniotic fluid
	0277U	Hematology (genetic platelet function disorder), genomic sequence analysis of 40 genes and duplication/deletion of PLAU, blood, buccal swab, or amniotic fluid
	0278U	Hematology (genetic thrombosis), genomic sequence analysis of 14 genes, blood, buccal swab, or amniotic fluid
	0347U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 16 gene report, with variant analysis and reported phenotypes
	0348U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 25 gene report, with variant analysis and reported phenotypes
	0349U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis, including reported phenotypes and impacted gene-drug interactions
	0350U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis and reported phenotypes
	0460U	Oncology, whole blood or buccal, DNA single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, with variant analysis and reported phenotypes
	0461U	Oncology, pharmacogenomic analysis of single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, whole blood or buccal swab, with variant analysis, including impacted gene-drug interactions and reported phenotypes
	0474U	Hereditary pan-cancer (eg, hereditary sarcomas, hereditary endocrine tumors, hereditary neuroendocrine tumors, hereditary cutaneous melanoma), genomic sequence analysis panel of 88 genes with 20 duplications/deletions using next generation sequencing (NGS), Sanger sequencing, blood or saliva, reported as positive or negative for germline variants, each gene
	0475U	Hereditary prostate cancer related disorders, genomic sequence analysis panel using next-generation sequencing (NGS), Sanger sequencing, multiplex ligation-dependent probe amplification (MLPA), and array comparative genomic hybridization (CGH), evaluation of 23 genes and duplications/deletions when indicated, pathologic mutations reported with a genetic risk score for prostate cancer
	0476U	Drug metabolism, psychiatry (eg, major depressive disorder, general anxiety disorder, attention deficit hyperactivity disorder [ADHD], schizophrenia), whole blood, buccal swab, and pharmacogenomic genotyping of 14 genes and CYP2D6 copy number variant analysis and reported phenotypes
	0477U	Drug metabolism, psychiatry (eg, major depressive disorder, general anxiety disorder, attention deficit hyperactivity disorder [ADHD], schizophrenia), whole blood, buccal swab, and pharmacogenomic genotyping of 14 genes and CYP2D6 copy number variant analysis, including impacted gene-drug interactions and reported phenotypes

Codes	Number	Description
	0516U	Drug metabolism, whole blood, pharmacogenomic genotyping of 40 genes and CYP2D6 copy number variant analysis, reported as metabolizer status
	0533U	Drug metabolism (adverse drug reactions and drug response), genotyping of 16 genes (ie, ABCG2, CYP2B6, CYP2C9, CYP2C19, CYP2C, CYP2D6, CYP3A5, CYP4F2, DPYD, G6PD, GGCX, NUDT15, SLCO1B1, TPMT, UGT1A1, VKORC1), reported as metabolizer status and transporter function
	81105	Human platelet antigen 1 genotyping (HPA-1), ITGB3 (integrin, BETA 3 [platelet glycoprotein iiia], antigen CD61 [gpiiia]) (eg, neonatal alloimmune thrombocytopenia [nait], post-transfusion purpura), gene analysis, common variant, HPA-1a/b (L33P)
	81106	Human platelet antigen 2 genotyping (hpa-2), GP1BA (glycoprotein ib [platelet], alpha polypeptide [GPIBA]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, hpa-2a/b (T145M)
	81107	Human platelet antigen 3 genotyping (HPA-3), ITGA2B (integrin, ALPHA 2b [platelet glycoprotein iib of iib/iiia complex], antigen CD41 [GPIIB]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-3a/b (I843S)
	81108	Human platelet antigen 4 genotyping (HPA-4), ITGB3 (integrin, BETA 3 [platelet glycoprotein IIIA], antigen CD61 [GPIIIA]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-4a/b (R143Q)
	81109	Human platelet antigen 5 genotyping (HPA-5), ITGA2 (integrin, ALPHA 2 [CD49B, ALPHA 2 subunit of VLA-2 receptor] [GPIA]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant (eg, HPA-5a/b (K505E))
	81110	Human platelet antigen 6 genotyping (HPA-6W), ITGB3 (integrin, BETA 3 [platelet glycoprotein IIIA, antigen CD61] [GPIIIA]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-6a/b (R489Q)
	81111	Human platelet antigen 9 genotyping (HPA-9W), ITGA2B (integrin, ALPHA 2B [platelet glycoprotein IIB of IIB/IIIA complex, antigen CD41] [GPIIB]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-9a/b (V837M)
	81112	Human platelet antigen 15 genotyping (HPA-15), CD109 (CD109 molecule) (eg, neonatal alloimmune thrombocytopenia [Nait], post-transfusion purpura), gene analysis, common variant, HPA-15a/b (S682Y)
	81170	ABL1 (ABL proto-oncogene 1, non-receptor tyrosine kinase) (eg, acquired imatinib tyrosine kinase inhibitor resistance), gene analysis, variants in the kinase domain
	81175	ASXL1 (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; full gene sequence
	81176	;targeted sequence analysis (eg, EXON 12)
	81200	ASPA (aspartoacylase) (eg, Canavan disease) gene analysis, common variants
	81201	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; full gene sequence
	81202	;known familial variants
	81203	;duplication/deletion variants
	81205	BCKDHB (branched-chain keto acid dehydrogenase E1, beta polypeptide) (eg, Maple syrup urine disease) gene analysis, common variants (eg, R183P, G278S, E422X)

Codes	Number	Description
	81206	*BCR/ABL1 (t(9;22))* (eg, chronic myelogenous leukemia) translocation analysis; major breakpoint, qualitative or quantitative
	81207	;minor breakpoint, qualitative or quantitative
	81208	;other breakpoint, qualitative or quantitative
	81209	*BLM (Bloom syndrome, RecQ helicase-like)* (eg, Bloom syndrome) gene analysis, 2281del6ins7 variant
	81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
	81218	CEBPA (CCAAT/enhancer binding protein [C/EBP], alpha) (eg, acute myeloid leukemia), gene analysis, full gene sequence
	81219	CALR (calreticulin) (eg, myeloproliferative disorders), gene analysis, common variants in exon 9
	81220	*CFTR (cystic fibrosis transmembrane conductance regulator)* (eg, cystic fibrosis) gene analysis; common variants (eg, ACMG/ACOG guidelines)
	81221	;known familial variant
	81222	;duplication/deletion variants
	81223	;full gene sequence
	81224	;intron 8 poly-T analysis (eg, male infertility)
	81225	CYP2C19 (cytochrome P450, family 2, subfamily C, polypeptide 19) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *8, *17)
	81226	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *5, *6, *9, *10, *17, *19, *29, *35, *41, *1XN, *2XN, *4XN)
	81227	CYP2C9 (cytochrome P450, family 2, subfamily C, polypeptide 9) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *5, *6)
	81228	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number variants, comparative genomic hybridization [CGH] microarray analysis
	81229	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number and single nucleotide polymorphism (SNP) variants, comparative genomic hybridization (CGH) microarray analysis
	81235	EGFR (epidermal growth factor receptor) (eg, non-small cell lung cancer) gene analysis, common variants (eg, exon 19 LREA deletion, L858R, T790M, G719A, G719S, L861Q)
	81240	*F2 (prothrombin, coagulation factor II)* (eg, hereditary hypercoagulability) gene analysis, 20210G>A variant
	81241	*F5 (coagulation factor V)* (eg, hereditary hypercoagulability) gene analysis, Leiden variant
	81242	*FANCC (Fanconi anemia, complementation group C)* (eg, Fanconi anemia, type C) gene analysis, common variant (eg, IVS4+4A>T)
	81243	*FMR1 (Fragile X messenger ribonucleoprotein 1)* (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
	81244	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; characterization of alleles (eg, expanded size and promoter methylation status)
	81245	*FLT3 (fms-related tyrosine kinase 3)* (eg, acute myeloid leukemia), gene analysis; internal tandem duplication (ITD) variants (ie, exons 14, 15)
	81246	;tyrosine kinase domain (TKD) variants (eg, D835, I836)
	81247	G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; common variant(s) (eg, a, a-)

Codes	Number	Description
	81248	;known familial variant(s)
	81249	;full gene sequence
	81250	G6PC (glucose-6-phosphatase, catalytic subunit) (eg, Glycogen storage disease, Type 1a, von Gierke disease) gene analysis, common variants (eg, R83C, Q347X)
	81251	GBA (glucosidase, beta, acid) (eg, Gaucher disease) gene analysis, common variants (eg, N370S, 84GG, L444P, IVS2+1G>A)
	81252	*GJB2 (gap junction protein, beta 2, 26kDa, connexin 26)* (eg, nonsyndromic hearing loss) gene analysis; full gene sequence
	81253	;known familial variant
	81254	*GJB6 (gap junction protein, beta 6, 30kDa, connexin 30)* (eg, nonsyndromic hearing loss) gene analysis, common variants (eg, 309kb [del(GJB6-D13S1830)] and 232kb [del(GJB6-D13S1854)])
	81255	HEXA (hexosaminidase A [alpha polypeptide]) (eg, Tay-Sachs disease) gene analysis, common variants (eg, 1278insTATC, 1421+1G>C, G269S)
	81256	*HFE (hemochromatosis)* (eg, hereditary hemochromatosis) gene analysis, common variants (eg, C282Y, H63D)
	81257	*HBA1/HBA2 (alpha globin 1 and alpha globin 2)* (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis, for common deletions or variant (eg, Southeast Asian, Thai, Filipino, Mediterranean, alpha3.7, alpha4.2, alpha20.5, and Constant Spring)
	81260	IKBKAP (inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein) (eg, familial dysautonomia) gene analysis, common variants (eg, 2507+6T>C, R696P)
	81261	*IGH@ (Immunoglobulin heavy chain locus)* (eg, leukemias and lymphomas, B-cell), gene rearrangement analysis to detect abnormal clonal population(s); amplified methodology (eg, polymerase chain reaction)
	81262	;direct probe methodology (eg, Southern blot)
	81263	*IGH@ (Immunoglobulin heavy chain locus)* (eg, leukemia and lymphoma, B-cell), variable region somatic mutation analysis
	81264	*IGK@ (Immunoglobulin kappa light chain locus)* (eg, leukemia and lymphoma, B-cell), gene rearrangement analysis, evaluation to detect abnormal clonal population(s)
	81270	*JAK2 (Janus kinase 2)* (eg, myeloproliferative disorder) gene analysis, p.Val617Phe (V617F) variant
	81272	*KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, gastrointestinal stromal tumor [GIST], acute myeloid leukemia, melanoma), gene analysis, targeted sequence analysis (eg, exons 8, 11, 13, 17, 18)*
	81273	*KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, mastocytosis), gene analysis, D816 variant(s)*
	81275	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; variants in exon 2 (eg, codons 12 and 13)
	81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
	81287	*MGMT (O-6-methylguanine-DNA methyltransferase)* (eg, glioblastoma multiforme), promoter methylation analysis
	81288	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; promoter methylation analysis
	81290	MCOLN1 (mucolipin 1) (eg, Mucolipidosis, type IV) gene analysis, common variants (eg, IVS3-2A>G, del6.4kb)

Codes	Number	Description
	81291	*MTHFR (5,10-methylenetetrahydrofolate reductase)* (eg, hereditary hypercoagulability) gene analysis, common variants (eg, 677T, 1298C)
	81292	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81293	;known familial variants
	81294	;duplication/deletion variants
	81295	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81296	;known familial variants
	81297	;duplication/deletion variants
	81298	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81299	;known familial variants
	81300	;duplication/deletion variants
	81302	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome) gene analysis; full sequence analysis
	81303	;known familial variants
	81304	;duplication/deletion variants
	81310	*NPM1 (nucleophosmin)* (eg, acute myeloid leukemia) gene analysis, exon 12 variants
	81311	*NRAS (neuroblastoma RAS viral [v-ras] oncogene homolog) (eg, colorectal carcinoma), gene analysis, variants in exon 2 (eg, codons 12 and 13) and exon 3 (eg, codon 61)*
	81314	*PDGFRA (platelet-derived growth factor receptor, alpha polypeptide) (eg, gastrointestinal stromal tumor [GIST]), gene analysis, targeted sequence analysis (eg, exons 12, 18)*
	81315	*PML/RARalpha, (t(15;17))*, *(promyelocytic leukemia/retinoic acid receptor alpha)* (eg, promyelocytic leukemia) translocation analysis; common breakpoints (eg, intron 3 and intron 6), qualitative or quantitative
	81316	;single breakpoint (eg, intron 3, intron 6 or exon 6), qualitative or quantitative
	81317	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
	81318	;known familial variants
	81319	;duplication/deletion variants
	81321	*PTEN (phosphatase and tensin homolog)* (eg, Cowden syndrome, *PTEN* hamartoma tumor syndrome) gene analysis; full sequence analysis
	81322	;known familial variants
	81323	;duplication/deletion variants
	81324	*PMP22 (peripheral myelin protein 22)* (eg, Charcot-Marie-Tooth, hereditary neuropathy with liability to pressure palsies) gene analysis; duplication/deletion analysis
	81325	;full sequence analysis
	81326	;known familial variants
	81330	SMPD1(sphingomyelin phosphodiesterase 1, acid lysosomal) (eg, Niemann-Pick disease, Type A) gene analysis, common variants (eg, R496L, L302P, fsP330)

Codes	Number	Description
	81331	*SNRPN/UBE3A (small nuclear ribonucleoprotein polypeptide N and ubiquitin protein ligase E3A)* (eg, Prader-Willi syndrome and/or Angelman syndrome),
	81332	*SERPINA1 (serpin peptidase inhibitor, clade A, alpha-1 antiproteinase, antitrypsin, member 1)* (eg, alpha-1-antitrypsin deficiency), gene analysis, common variants (eg, *S and *Z)
		TRB@ (T cell antigen receptor, beta) (eg, leukemia and lymphoma), gene rearrangement analysis to detect abnormal clonal population(s); using
	81342	*TRG@ (T cell antigen receptor, gamma)* (eg, leukemia and lymphoma), gene rearrangement analysis, evaluation to detect abnormal clonal population(s)
		Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities
	81350	*UGT1A1 (UDP glucuronosyltransferase 1 family, polypeptide A1)* (eg, drug metabolism, hereditary unconjugated hyperbilirubinemia [Gilbert syndrome]) gene analysis, common variants (eg, *28, *36, *37)
	81355	*VKORC1 (vitamin K epoxide reductase complex, subunit 1)* (eg, warfarin metabolism), gene analysis, common variant(s) (eg, -1639G>A, c.173+1000C>T)
	81400	Molecular pathology procedure, Level 1
	81401	Molecular pathology procedure, Level 2
	81402	Molecular pathology procedure, Level 3
	81403	Molecular pathology procedure, Level 4
	81404	Molecular pathology procedure, Level 5
	81405	Molecular pathology procedure, Level 6
	81406	Molecular pathology procedure, Level 7
	81407	Molecular pathology procedure, Level 8
	81408	Molecular pathology procedure, Level 9
	81412	Ashkenazi Jewish associated disorders (eg, Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gaucher disease, Tay-Sachs disease), genomic sequence analysis panel, must include sequencing of at least 9 genes, including ASPA, BLM, CFTR, FANCC, GBA, HEXA, IKBKAP, MCOLN1, and SMPD1
	81413	Cardiac ion channelopathies (eg, Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia); genomic sequence analysis panel, must include sequencing of at least 10 genes, including ANK2, CASQ2, CAV3, KCNE1, KCNE2, KCNH2, KCNJ2, KCNQ1, RYR2, and SCN5A
	81432	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel, must include sequencing of at least 10 genes, always including BRCA1, BRCA2, CDH1, MLH1, MSH2, MSH6, PALB2, PTEN, STK11, and TP53
	~~81433~~	~~Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); duplication/deletion analysis panel, must include analyses for BRCA1, BRCA2, MLH1, MSH2, and STK11~~ (Deleted 01/01/2025)
	81434	Hereditary retinal disorders (eg, retinitis pigmentosa, Leber congenital amaurosis, cone-rod dystrophy), genomic sequence analysis panel, must include sequencing of at least 15 genes, including ABCA4, CNGA1, CRB1, EYS, PDE6A, PDE6B, PRPF31, PRPH2, RDH12, RHO, RP1, RP2, RPE65, RPGR, and USH2A

Codes	Number	Description
	81437	Hereditary neuroendocrine tumor-related disorders (eg, medullary thyroid carcinoma, parathyroid carcinoma, malignant pheochromocytoma or paraganglioma), genomic sequence analysis panel, 5 or more genes, interrogation for sequence variants and copy number variants; genomic sequence analysis panel, must include sequencing of at least 6 genes, including MAX, SDHB, SDHC, SDHD, TMEM127, and VHL
	~~81438~~	~~Hereditary neuroendocrine tumor disorders (eg, medullary thyroid carcinoma, parathyroid carcinoma, malignant pheochromocytoma or paraganglioma); duplication/deletion analysis panel, must include analyses for SDHB, SDHC, SDHD, and VHL~~ (Deleted 01/01/2025)
	81440	Nuclear encoded mitochondrial genes (eg, neurologic or myopathic phenotypes), genomic sequence panel, must include analysis of at least 100 genes, including BCS1L, C10orf2, COQ2, COX10, DGUOK, MPV17, OPA1, PDSS2, POLG, POLG2, RRM2B, SCO1, SCO2, SLC25A4, SUCLA2, SUCLG1, TAZ, TK2, and TYMP
	81441	Inherited bone marrow failure syndromes (IBMFS) (eg, Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan anemia, Shwachman-Diamond syndrome, GATA2 deficiency syndrome, congenital amegakaryocytic thrombocytopenia) sequence analysis panel, must include sequencing of at least 30 genes, including BRCA2, BRIP1, DKC1, FANCA, FANCB, FANCC, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCL, GATA1, GATA2, MPL, NHP2, NOP10, PALB2, RAD51C, RPL11, RPL35A, RPL5, RPS10, RPS19, RPS24, RPS26, RPS7, SBDS, TERT, and TINF2
	81443	Genetic testing for severe inherited conditions (eg, cystic fibrosis, Ashkenazi Jewish-associated disorders [eg, Bloom syndrome, Canavan disease, Fanconi anemia type C, mucolipidosis type VI, Gaucher disease, Tay-Sachs disease], beta hemoglobinopathies, phenylketonuria, galactosemia), genomic sequence analysis panel, must include sequencing of at least 15 genes (eg, ACADM, ARSA, ASPA, ATP7B, BCKDHA, BCKDHB, BLM, CFTR, DHCR7, FANCC, G6PC, GAA, GALT, GBA, GBE1, HBB, HEXA, IKBKAP, MCOLN1, PAH)
	81450	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
	81451	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; RNA analysis
	81455	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
	81456	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; RNA analysis
	81460	Whole mitochondrial genome (eg, Leigh syndrome, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes [MELAS], myoclonic epilepsy with ragged-red fibers [MERFF], neuropathy, ataxia, and retinitis pigmentosa [NARP], Leber hereditary optic neuropathy [LHON]), genomic sequence, must include sequence analysis of entire mitochondrial genome with heteroplasmy detection

Codes	Number	Description
	81465	Whole mitochondrial genome large deletion analysis panel (eg, Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia), including heteroplasmy detection, if performed
	81470	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromic XLID); genomic sequence analysis panel, must include sequencing of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3, and SLC16A2
	81471	;duplication/deletion gene analysis, must include analysis of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3, and SLC16A2
	81479	Unlisted molecular pathology procedure
	81599	Unlisted multianalyte assay with algorithmic analysis
HCPCS	None

Genetic Testing for Methionine Metabolism Enzymes, including MTHFR

Effective: March 1, 2025

Next Review: November 2025
Last Review: January 2025

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

Genes involved in methionine metabolism, particularly *MTHFR*, have been associated with a variety of conditions, including depression, epilepsy, thrombophilia, and gastrointestinal conditions.

MEDICAL POLICY CRITERIA

Genetic testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, or *MMADHC* genes is considered **investigational** for all indications.

NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

Methylenetetrahydrofolate reductase (*MTHFR*), methionine synthase (*MTR*), methionine synthase reductase (*MTRR*), cobalamin reductase (*MMADHC),* and cystathione β-synthase (*CBS)* are genes that provide instructions to make the respective enzymes MTHFR, MTR, MTRR, MMADHC, and CBS, which play a role in converting the amino acid homocysteine (Hcy) to methionine. When abnormal copies of the genes are present, they may result in reduced function of the enzyme, leading to elevated homocysteine levels. Abnormally high levels of Hcy in the blood have been associated with several chronic illnesses, such as attention-deficit/hyperactivity disorder (ADHD), cardiovascular disease, epilepsy, headache, gastrointestinal symptoms and conditions, psychiatric disorders, osteoporosis, and Parkinson's disease.

Genetic testing for abnormalities in the *MTHFR*, *MTR*, *MTRR*, *MMADHC* and *CBS* genes has been proposed for several purposes:

- Diagnose or assess disease risk in symptomatic individuals;
- Screen for disease risk in asymptomatic individuals (i.e., general health screening);
- Direct treatment decisions (e.g., nutritional supplementation).

REGULATORY STATUS

Four genotyping tests for variations in the *MTHFR* gene cleared by the U.S. Food and Drug Administration (FDA) were identified as the Verigene MTHFR Nucleic Acid Test (Nanosphere, Inc.), eSensor MTHFR Genotyping Test (Osmetech Molecular Diagnostics), Invader MTHFR 677 (Hologic, Inc.), and Invader MTHFR 1298 (Hologic, Inc.).[1] Genotyping for other components may be offered as a laboratory-developed test. Clinical laboratories may develop and validate tests in-house ("home-brew") and market them as a laboratory service; such tests must meet the general regulatory standards of the Clinical Laboratory Improvement Act (CLIA). The laboratory offering the service must be licensed by CLIA for high-complexity testing.

EVIDENCE SUMMARY

Human Genome Variation Society (HGVS) nomenclature[2] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term "variant" is used to describe a change in a DNA or protein sequence, replacing previously used terms, such as "mutation." Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

Validation of the clinical use of any genetic test focuses on three main principles:

1. The analytic validity of the test, which refers to the technical accuracy of the test in detecting a variant or variation that is present or in excluding a variant or variation that is absent;
2. The clinical validity of the test, which refers to the diagnostic performance of the test (sensitivity, specificity, positive and negative predictive values) in detecting clinical disease; and

3. The clinical utility of the test, i.e., how the results of the diagnostic test will be used to change management of the patient and whether these changes in management lead to clinically important improvements in health outcomes.

For some indications, the published literature regarding genetic testing for homocysteine-related variants in the *CBS*, *MTHFR*, *MTR*, *MTRR*, or *MMADHC* genes is limited to association studies. Studies of genetic associations aim to test whether single-locus alleles or genotype frequencies differ between two groups of individuals (usually diseased subjects and healthy controls). For many indications, evidence has accumulated which supports an association between a homocysteine-related variant and the condition or symptom. However, there is limited evidence to establish a causal relationship or to demonstrate how treatment based on gene testing leads to improved health outcomes related to any condition.

Current guidelines for establishing causality require direct evidence which demonstrates that testing-based treatment is greater than the combined influence of all confounding factors for the given condition.[3] This direct evidence could come from well-designed, randomized controlled trials. Evidence from non-randomized trials may also be considered when testing-based treatment results in an improvement of symptoms which is so sizable that it rules out the combined effect of all other possible causes of the condition. Currently, no published studies have been identified that demonstrate the clinical utility of homocysteine-related variant testing for any associated disease or condition. In order to isolate the independent contribution of homocysteine-related variant testing on health outcomes, studies which control for confounding factors are essential. Large, well-designed, randomized controlled trials (RCTs) with adequate follow-up are needed.

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Examples of studies that investigated the association between the *MTHFR* gene variants and attention-deficit hyperactivity disorder (ADHD) are described below.

Association Studies

Table 1. Evidence for Genes Associated with ADHD

Gene(s)	Condition(s)	Evidence	Conclusions
MTHFR	ADHD	Ergul (2012), case-control[4] Gokcen (2011), case-control [5]	No association between the *MTHFR* 677T allele, *MTHFR* 1298C allele, and ADHD was found. There were no statistically significant differences in genotype distributions of the C677T alleles between the ADHD and the control groups.
MTHFR	ADHD after acute lymphoblastic leukemia	Krull (2008), cohort[6]	The A1298C genotype lead to a 7.4-fold increase in diagnosis, compared with a 1.3-fold increase for the C677T genotype.
MTHFR	ADHD Myelomeningocele	Spellicy (2012), cohort[7]	A positive association was identified between the SNV rs4846049 in the 3'-untranslated region of the *MTHFR* gene and the attention-deficit hyperactivity disorder phenotype in myelomeningocele participants

SNV: Single nucleotide variant

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with ADHD.

CARDIOVASCULAR DISEASE

Randomized Controlled Trials

An RCT by Qin (2020) evaluated the interaction between *MTHFR* genotypes and serum folate and vitamin B_{12} on risk of first ischemic stroke in patients randomized to receive enalapril with or without folic acid in the China Stroke Primary Prevention Trial (CSPPT).[8] CSPPT was a double-blind, RCT conducted from May 19, 2008, to August 24, 2013 in multiple communities in China. The study and included men and women (n=20,499) between 45 and 75 years of age with hypertension, defined as resting systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg or use of antihypertensive medication. Participants were randomized to receive tablets containing either 10 mg enalapril alone (n=10,256) or 10 mg enalapril plus 0.8 mg folic acid (n=10,243) to be taken daily, for a median duration of 4.5 years. There was no overall association found between baseline serum folate and B_{12} levels and risk of stroke in the enalapril-only group. Folic acid supplementation was associated with a reduction in total Hcy (tHcy) levels and stroke risk in patients with baseline low folate and B_{12} levels. Overall, there was no difference in stroke reduction between the MTHFR 677 CC and TT genotypes. However, subgroup analysis showed that the reduction in risk was greater for those with low baseline low folate and B_{12} levels for those with a CC genotype, while for those with a TT genotype, risk reduction was the greatest for those with the highest baseline folate and B_{12} levels.

Association Studies

Examples of studies that address the association of the *CBS* and *MTHFR* genes with cardiovascular disease are described below.

Table 2. Evidence for Genes Associated with Cardiovascular Disease

Gene(s)	Condition(s)	Evidence	Conclusions
MTHFR and *CBS*	Venous thrombosis	Amaral (2017), cohort study[9]	Patients with *MTHFR* 1298CC and *CBS* haplotype 844ins68/T833C homozygotes were at increased risk for venous thrombosis. Significant interactions were identified among the *MTHFR* C677T, *MTHFR* A1298C and *CBS* haplotype 844ins68/T833C variants and Hcy levels.
MTHFR	Congenital heart disease	Yuan (2017), meta-analysis[10] Horita (2017), case-control[11] Zhao (2012), case-control [12]	In the meta-analysis, five studies were considered low-quality and 16 were considered high-quality. The analysis showed a significant association between *MTHFR* C677T and congenital heart disease (CHD). No association was found between variants and coronary heart disease or coronary atherosclerosis. Individuals carrying the heterozygous CG and homozygous GG genotypes had a 15%

Gene(s)	Condition(s)	Evidence	Conclusions
			reduced risk to develop CHD than the CC genotype carriers. Additional stratified analyses demonstrated that *CBS* -4673C>G is significantly related to septation defects and conotruncal defects
MTHFR	Congenital heart defects	Noori (2017), case-control[13] Khatami (2017), case-control[14]	SNVs in the *MTHFD1, eNOS, CBS*, and *ACE* genes were significantly higher in the patients than in controls. The presence of the TT genotype of C677Twas associated with the highest risk of congenital heart defects and ventricular septal defect Significantly higher occurrences of the AG and GG A66G variant, but not the TT C677T variant, occurred in patients as compared to controls. Heterozygous (AG) and homozygous (GG) A66G variants were significantly associated with congenital heart defects and tetralogy of Fallot.
MTHFR	Stroke	Dong (2021), meta-analysis[15] Hou (2018), case-control[16] Zhao (2017), randomized controlled trial[17] Xu (2017), cohort[18] He (2017), case-control[19] Wald (2002), meta-analysis[20]	*MTHFR* A1298C alleles were significantly associated with stroke under the C allelic genetic model (OR 1.19, 95% CI 1.07 to1.32, p=0.001), as well as dominant and recessive models. Subgroup analysis showed this association only in Asian populations. The frequency of T allele of *MTHFR* C677T (rs1801133) was significantly higher in ischemic stroke patients than in controls and the presence of the MTHFR T allele was an independent risk factor for ischemic stroke even after adjusting for conventional risk factors. Folic acid intervention significantly reduced stroke risk in participants with CC/CT genotypes and high homocysteine levels. *MTHFR* genotype alone had did not significantly associate with mortality, but the tHcy-mortality association was significantly stronger in the CC/CT genotype than in the TT genotype. When compared to the homozygous TT genotype, *MTHFR* rs868014 TC and CC genotypes were significantly associated with increased risk of ischemic stroke. The seven *MTHFR* studies of stroke (1217 cases, mean age at event 63 years) yielded

Gene(s)	Condition(s)	Evidence	Conclusions
			relatively few data, so the confidence interval for the summary result was wide.
CBS	Stroke	Hendrix (2017), case-control [21] Ding (2012), meta-analysis [22]	Significant associations between *CBS* T833C genetic variant and risk of stroke were observed in most genetic models. In the subgroup analysis based on ethnicity, significant associations were observed in most genetic models in Chinese but not in Caucasian. The insertion allele of the 844ins68 insertion variant was significantly associated with aneurysmal subarachnoid hemorrhage. The GG genotype of the CBS G/A single nucleotide variant (rs234706) was independently associated with poor functional outcome at discharge and last follow-up. No association was found with clinical vasospasm or delayed cerebral ischemia (DCI).
BHMT1, BHMT2, *CBS*, *CTH*, *MTHFR*, *MTR*, *MTRR*, *TCN1*, and *TCN2*	Stroke	Hsu (2011), cohort [23]	Only *TCN2* SNV rs731991 was associated with recurrent stroke risk
MTRR	Acyanotic congenital heart disease in children	Hassan (2017), case-control[24]	Statistically significant differences in genotype frequencies were found for both variants, with more TT and GG genotypes of the C524T and A66G variants, respectively in the patient populations as compared to controls
MTHFR	Rheumatoid arthritis and atherosclerosis	Adb El-Aziz (2017), cohort[25]	The T variant had significantly greater chances of developing rheumatoid arthritis and atherosclerosis. The *MTHFR* TT genotype was an independent risk factor for thick carotid intima-media and was associated with higher Hcy levels.
MTHFR	Coronary artery disease	Conkbayir (2017), cohort[26] Bickel (2016) [27] van Meurs (2013), meta-analysis [28]	Statistically significant associations were found between the *MTHFR* C677 wild-type allele and a decreased rate of high LDL cholesterol ($p<0.05$) and between the *HPA-1* a/b variant and an increased rate of high total cholesterol levels ($p<0.05$) While Hcy levels were associated with cardiovascular events and *MTHFR* SNVs were associated with Hcy levels ($p<0.001$), the SNVs

Gene(s)	Condition(s)	Evidence	Conclusions
			had no impact on coronary artery disease prognosis Individuals within the highest 10% of the genotype risk score (GRS) had 3-µmol/L higher mean tHcy concentrations than did those within the lowest 10% of the GRS ($p=1\times10^{-36}$). The GRS was not associated with risk of CAD
MTHFR	Hypertension	Liu (2017), cohort[29] Tang (2016), case-control[30] Ghogomu (2016), case-control[31] Armani-Midoun (2016), case-control [32]	In patients with mild-to-moderate essential hypertension the TT *MTHFR* 677 genotype carriers had higher risk of hypercholesterolemia and abnormal low-density lipoprotein cholesterol than those with the CC and CT genotypes. No significant gene-disease association was found in an Algerian population A higher frequency of the *MTHFR* 677T allele was found in patients with H-type hypertension compared to those with common hypertension. A significant association between the *MTHFR* variant and hypertension was found in Camaroonian patients.
MTHFR	Cardiovascular disease	Grarup (2013), cohort[33] Raina (2016), case-control [34] Chen, case-control[35] Wald (2002)	Authors did not find consistent association of the variants with cardiovascular diseases C677T and *MTR* A2756G were linked to cardiovascular disease an association between *MTHFR* C677T and coronary heart disease
MTHFR	Heart failure	Strauss (2017), case-control [36]	Hyperhomocysteinemia and the *MTHFR* 677TT/1298AA, 677CC/1298CC genotypes were associated heart failure, regardless of etiology.
MTHFR	abdominal aortic aneurysm	Liu (2016), meta-analysis[37]	An analysis of 12 case-control studies with a total of 3,555 cases and 6,568 controls found no significant association between the *MTHFR* C677T variant and AAA risk in the overall population and within Caucasian or Asian subpopulations. Significant associations were found in other subgroups, including cases with a mean age < 70 years.
MTHFR	Cervico-cerebral artery dissection	Ruiz-Franco (2016), case-control[38]	A higher prevalence of the TT genotype was seen among cases verses controls.

Gene(s)	Condition(s)	Evidence	Conclusions
MTHFR	atherosclerosis	Lin (2016), case-control[39] Heidari (2016), case-control[40]	There was a higher prevalence of the TT genotype in cases LINE-1 methylation levels were lower in cases than controls, and that this methylation was also lower in carriers of the *MTHFR* 677T allele An association between *MTHFR* genotype and atherosclerosis was found in Iranian patients.
MTHFR	myocardial infarction	Hmimech (2016), case-control[41]	No significant gene-disease association was found for *MTHFR* C677T.
MTHFR	peripheral artery disease	Liu (2021), meta-analysis[42]	An association between *MTHFR* C677T homozygosity and peripheral arterial disease were found, but there was no significant association between the T allele carrier and peripheral arterial disease.

SNV: single nucleotide variant; tHcy: total homocysteine

Clinical Utility

Additional meta-analysis, systematic reviews and cohort studies were identified which evaluated the associated of *MTHFR* and *CBS* variants and cardiovascular disease[43-50]; however, no studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with cardiovascular disease.

DIABETES

Studies describing the association between *MTHFR* variants and diabetes and diabetes-associated conditions are described.

Association Studies

Table 3. Evidence for Genes Associated with Diabetes

Gene(s)	Condition(s)	Evidence	Conclusions
MTHFR	Diabetic nephropathy	Ramanathan (2017), case-control [51]	C677T and A1298C *MTHFR* variants were associated with diabetic C677T was significantly associated with advanced stage chronic kidney disease
MTHFR	Diabetic neuropathy	Kakavand Hamidi (2017), case-control [52] Jiménez-Ramírez (2017), case-control[53]	677C>T variant was significantly less frequent in patients with neuropathy in two studies Results regarding the association of the 1298A>C variant and neuropathy were mixed
ACE, *FABP2*, *MTHFR*, and *FTO*	Dyslipidemia	Raza (2017), case-control[54]	*ACE* and *MTHFR* variants were significantly associated with type 2 diabetes regardless of dyslipidemia status *FABP2* and *FTO* variants were significantly associated with type 2 diabetes without dyslipidemia

ENZYME DEFICIENCY

Studies that address the clinical utility of gene testing for enzyme deficiency (enzymes made by the *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* genes) and gene testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* were not identified.

EPILEPSY

Examples of studies describing the association between *MTHFR* variants and epilepsy are described below.

Association Studies

Ullah (2018) assessed the association between *MTHFR* variants and seizure control in epileptic patients treated with carbamazepine.[55] Patients included were from the Pakhtun population of Khyber Pakhtunkhwa. Poor seizure control was significantly more likely in patients with heterozygous variants (677CT and 1298AC) of *MTHFR* at both three and six months following the initiation of therapy. However, no statistically significant association was identified in dose and plasma level of carbamazepine between different *MTHFR* genotypes or between responder and non-responder patients.

Scher (2011) studied whether the *MTHFR* C677T or A1298C variants are associated with risk of epilepsy including post-traumatic epilepsy (PTE) in a representative military cohort.[56] Authors randomly selected 800 epilepsy patients and 800 matched controls based on ICD-9-CM diagnostic codes. The odds of epilepsy were increased in subjects with the TT versus CC genotype (crude odds ratio [OR] 1.52, 95% confidence interval [CI] 1.04 to 2.22, p=0.031; adjusted OR 1.57, 95% CI 1.07 to 2.32, p=0.023). In the sensitivity analysis, risk was most evident for patients with repeated rather than single medical encounters for epilepsy (crude OR 1.85, 95% CI 1.14 to 2.97, p=0.011, adjusted OR 1.95 95% CI 1.19 to 3.19, p=0.008), and particularly for PTE (crude OR 3.14, 95% CI 1.41 to 6.99, p=0.005; adjusted OR 2.55. 95% CI 1.12 to 5.80, p=0.026). Authors conclude a potential role for the common *MTHFR* C677T variant as predisposing factors for epilepsy including PTE.

Semmler (2013) aimed to determine whether there was a pharmacogenetic interaction between folate, vitamin B12 and genetic variants and Hcy plasma level in antiepileptic drug (AED)-treated patients.[57] In this single center study, authors measured Hcy, folate and vitamin B12 plasma levels in a population of 498 AED-treated adult patients with epilepsy. In addition, authors analyzed the genotypes of seven common genetic variants of Hcy metabolism: *MTHFR* C677CT and A1298C, *MTR* c.2756A>G, dihydrofolate reductase (*DHFR*) c.594+59del19bp, *CBS* c.844_855ins68, transcobalamin 2 (*TCN2*) C776G and *MTRR* G66A. Authors concluded, in AED-treated patients, folate and vitamin B12 play important roles in the development of hyperhomocysteinemia, whereas genetic variants of Hcy metabolism do not and thus do not contribute to the risk of developing hyperhomocysteinemia during AED treatment.

Coppola (2012) assessed the role of AEDs and *MTHFR* C677T on tHcy in pediatric patients with epilepsy treated for at least six months with various treatment regimens protocols including the newer AEDs.[58] The study group was composed of 78 patients (35 males, 43 females), aged between 3 and 15 years (mean 8.9 years). Thirty-five patients were taking AED monotherapy, 43 polytherapy. Sixty-three healthy sex- and age-matched children and adolescents served as controls. The mean tHcy value in the patient group was higher than the

mean value in the control group (12.11 ± 7.68 µmol/L vs. 7.4±4.01 µmol/L, p<0.01). DNA analysis for the *MTHFR* C677T variant showed the CT genotype in 46%, CC in 35% and TT in 17.8% of cases. Decreased folic acid serum levels significantly correlated with increased tHcy levels (p<0.003). The authors concluded that their study confirmed the association between hyperhomocysteinemia and epilepsy. The elevation of tHcy is essentially related to low folate levels. Correction of poor folate status, through supplementation, remains the most effective approach to normalize tHcy levels in patients on AED mono- or polytherapy.

Additional association studies[59-61] were identified which evaluated the association of *MTHFR* variants and epilepsy.

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with epilepsy.

HEADACHE

Association studies were limited to the *MTHFR*, *MTR*, and *MTRR* gene variants and headache.

Systematic Reviews

Schürks (2010) conducted a systematic review and meta-analysis on the association of *MTHFR* C677T and ACE D/I variants and migraine including aura status.[62] Thirteen studies investigated the association between the *MTHFR* C677T variant and migraine. The TT genotype was associated with an increased risk for any migraine, which only appeared for migraine with aura (pooled OR 1.48, 95% CI 1.02 to 2.13), but not for migraine without aura. Nine studies investigated the association of the ACE D/I variant with migraine. The II genotype was associated with a reduced risk for migraine with aura (pooled OR 0.71, 95% CI 0.55 to 0.93) and migraine without aura (pooled OR 0.84, 95% CI 0.70 to 0.99). Extractable data did not allow investigation of gene-gene interactions. Authors concluded that the *MTHFR* 677TT genotype is associated with an increased risk for migraine with aura among non-Caucasian populations.

Samaan (2011) investigated the effect of *MTHFR* C677T on propensity for migraine and to perform a systematic review and meta-analysis of studies of *MTHFR* and migraine to date.[63] Individuals with migraine (n=447) were selected from the Depression Case Control (DeCC) study to investigate the association between migraine and *MTHFR* C677T single nucleotide variant (SNV) rs1801133 using an additive model compared to non-migraineurs adjusting for depression status. A meta-analysis was performed and included 15 studies of *MTHFR* and migraine. *MTHFR* C677T variant was associated with migraine with aura (MA) (OR 1.31, 95% CI 1.01 to 1.70, p=0.039) that remained significant after adjusting for age, sex and depression status. A meta-analysis of 15 case-control studies showed that T allele homozygosity is significantly associated with MA (OR 1.42, 95% CI 1.10 to 1.82) and total migraine (OR 1.37, 95% CI 1.07 to 1.76), but not migraine without aura (OR 1.16, 95% CI 0.36 to 3.76). In studies of non-Caucasian population, the TT genotype was associated with total migraine (OR 3.46, 95% CI 1.22 to 9.82), whereas in studies of Caucasians this variant was associated with MA only (OR 1.28, 95% CI 1.002 to 1.63). Authors concluded that *MTHFR* C677T is associated with MA in individuals selected for depression study.

Association Studies

The following association studies were published following the search dates of the above systematic reviews.

Menon (2012) examined the genotypic effects of *MTHFR* and *MTRR* gene variants on the occurrence of migraine in response to vitamin supplementation.[64] Authors used a six-month randomized, double-blinded placebo-controlled trial of daily vitamin B supplementation (B6, B9 and B12) on reduction of Hcy and of the occurrence of migraine in 206 female patients diagnosed with migraine with aura. Vitamin supplementation significantly reduced Hcy levels ($p<0.001$), severity of headache in migraine ($p=0.017$) and high migraine disability ($p=0.022$) in migraineurs compared with the placebo effect ($p>0.1$). When the vitamin-treated group was stratified by genotype, the C allele carriers of the *MTHFR* C677T variant showed a higher reduction in Hcy levels ($p<0.001$), severity of pain in migraine ($p=0.01$) and percentage of high migraine disability ($p=0.009$) compared with those with the TT genotypes. Similarly, the A allele carriers of the *MTRR* A66G variants showed a higher level of reduction in Hcy levels ($p<0.001$), severity of pain in migraine ($p=0.002$) and percentage of high migraine disability ($p=0.006$) compared with those with the GG genotypes. Genotypic analysis for both genes combined indicated that the treatment effect modification of the *MTRR* variant was independent of the *MTHFR* variant. Authors concluded that vitamin supplementation is effective in reducing migraine.

Roecklein (2013) performed a haplotype analysis of migraine risk and *MTHFR*, *MTR*, and *MTRR*.[65] Study participants are from a random sub-sample participating in the population-based AGES-Reykjavik Study, including subjects with non-migraine headache (n=367), migraine without aura (n=85), migraine with aura (n=167), and no headache (n=1,347). Authors concluded that haplotype analysis suggested an association between *MTRR* haplotypes and reduced risk of migraine with aura.

Essmeister (2016) performed a study to confirm reports that *MTHFR* C677T and an ACE variant increased susceptibility to migraines.[66] There were 420 migraine patients and 258 controls included in the study, which ultimately found no significant associations between the variants and any type of migraine.

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with headache.

COLORECTAL CANCER

Association studies on gastrointestinal symptoms and conditions were limited to the *MTHFR*, *MTR*, *MTRR*, and the *CBS* genes.

Systematic Reviews

Wu (2015) performed a meta-analysis to determine the association between *MTRR* A66G variant and colorectal cancer (CRC) susceptibility, including a total of 6,020 cases and 8,317 controls in 15 studies.[67] Increased risk of CRC was observed, when using the allele model (G vs A: $p=0.01$, OR 1.07, 95% CI 1.02 to 1.12), the genotype model (GG vs AA: $p=0.006$, OR 1.15, 95% CI 1.04 to 1.28). When using the genotype model, increased risk of CRC was observed when using the dominant model (GG+GA vs AA: OR 1.11, 95% CI 1.01 to 1.22, $p=0.04$) and the recessive model (GG vs GA+AA: OR 1.08, 95% CI 1.00 to 1.17, $p=0.04$).

Ethnicity-specific analysis determined that these associations are significant among Caucasians, but not East Asians.

Figueiredo (2013) note that over 60 observational studies primarily in non-Hispanic White populations have been conducted on selected genetic variants in specific genes, *MTHFR*, *MTR*, *MTRR*, *CBS*, *TCNII, RFC, GCPII, SHMT, TYMS*, and *MTHFD1*. These include five meta-analyses on *MTHFR* C677T (rs1801133) and *MTHFR* C1298T (rs1801131); two meta-analyses on *MTR* A2756C (rs1805087); and one for *MTRR* A66G (rs1801394).[68] In this meta-analysis authors observed some evidence for *SHMT* C1420T (rs1979277) (OR 0.85, 95% CI 0.73 to 1.00 for TT v. CC) and *TYMS* 5' 28 bp repeat (rs34743033) and CRC risk (OR 0.84, 95% CI 0.75 to 0.94 for 2R/3R v. 3R/3R and OR 0.82, 95% CI 0.69 to 0.98 for 2R/2R v. 3R/3R). Authors conclude in order to gain further insight into the role of folate variants in colorectal neoplasia, incorporating measures of the metabolites, including B-vitamin cofactors, Hcy and S-adenosylmethionine, and innovative statistical methods to better approximate the folate one-carbon metabolism pathway are necessary.

Teng (2013) investigated the association between the *MTHFR* C677T variant and the risk of colorectal cancer in a meta-analysis[69]. Overall, 71 publications including 31,572 cases and 44,066 controls were identified. The *MTHFR* C677T variant genotypes are significantly associated with increased risk of colorectal cancer. In the stratified analysis by ethnicity, significantly increased risks were also found among Caucasians for CC vs TT (OR 1.076, 95% CI 1.008 to 1.150, I^2=52.3%), CT vs TT (OR 1.102, 95%CI 1.032 to 1.177, I^2=51.4%) and dominant model (OR 1.086, 95%CI 1.021 to 1.156, I^2=53.6%). Asians for CC vs TT (OR1.226, 95% CI1.116 to 1.346, I^2=55.3%), CT vs TT (OR 1.180, 95% CI 1.079 to 1.291, I^2 =36.2%), recessive (OR 1.069, 95% CI 1.003 to 1.140, I^2=30.9%) and dominant model (OR 1.198, 95% CI 1.101 to 1.303, I^2=52.4%), and mixed populations for CT vs TT (OR 1.142, 95% CI 1.005 to 1.296, I^2=0.0%). However, no associations were found in Africans for all genetic models. Authors concluded that this meta-analysis suggests that the *MTHFR* C677T variant increases the risk for developing colorectal cancer, however no causality is noted.

Theodoratou (2012) reported on the first comprehensive field synopsis and creation of a parallel publicly available and regularly updated database (CRCgene) that cataloged all genetic association studies on colorectal cancer (http://www.chs.med.ed.ac.uk/CRCgene/).[70] Authors extracted data from 635 publications reporting on 445 variants in 110 different genes. Authors identified 16 independent variants at 13 loci (*MUTYH*, *MTHFR*, *SMAD7*, and common variants tagging the loci 8q24, 8q23.3, 11q23.1, 14q22.2, 1q41, 20p12.3, 20q13.33, 3q26.2, 16q22.1, and 19q13.1) to have the most highly credible associations with colorectal cancer, with all variants except those in *MUTYH* and 19q13.1 reaching genome-wide statistical significance in at least one meta-analysis model. Authors identified less-credible (higher heterogeneity, lower statistical power, BFDP>0.2) associations with 23 more variants at 22 loci. The meta-analyses of a further 20 variants for which associations have previously been reported found no evidence to support these as true associations.

Taioli (2009) performed both a meta-analysis (29 studies: 11,936 cases, 18,714 controls) and a pooled analysis (14 studies: 5,068 cases, 7,876 controls) of the C677T *MTHFR* variant and CRC, with stratification by racial/ethnic population and behavioral risk factors.[71] There were few studies on different racial/ethnic populations. The overall meta-analysis odds ratio for CRC for persons with the TT genotype was 0.83 (95% CI 0.77 to 0.90). An inverse association was observed in whites (OR 0.83, 95% CI 0.74 to 0.94) and Asians (OR 0.80, 95% CI 0.67 to 0.96) but not in Latinos or blacks. Similar results were observed for Asians, Latinos, and blacks in

the pooled analysis. The inverse association between the *MTHFR* 677TT genotype and CRC was not significantly modified by smoking status or body mass index; however, it was present in regular alcohol users only. Authors concluded that the *MTHFR* 677TT genotype seems to be associated with a reduced risk of CRC, but this may not hold true for all populations.

Association Studies

The following association studies were published following the search dates of the above systematic reviews.

Morishita (2018) assessed the association between variants in *MTR, MTRR, MTHFR,* and *SHMT* and risk of weight loss in patients with gastrointestinal cancers.[72] Clinical data from 59 patients with gastrointestinal cancers who visited the outpatient clinic for chemotherapy were analyzed. Weight loss of more than 5% or more than 10% over the first six months after the initiation of chemotherapy was assessed and no significantly association with the examined variants was identified.

Ding (2013), addressing the issue that studies on the association between *MTR* A2756G variant and CRC and colorectal adenoma (CRA) remain conflicting, conducted a meta-analysis of 27 studies, including 13,465 cases and 20,430 controls for CRC, and 4,844 cases and 11,743 controls for CRA.[73] . Potential sources of heterogeneity and publication bias were also systematically explored. Overall, the summary odds ratio of G variant for CRC was 1.03 (95% CI 0.96 to 1.09) and 1.05 (95% CI 0.99 to 1.12) for CRA. No significant results were observed in heterozygous and homozygous when compared with wild genotype for these variants. In the stratified analyses according to ethnicity, source of controls, sample size, sex, and tumor site, no evidence of any gene-disease association was obtained. Results from the meta-analysis of four studies on *MTR* stratified according to smoking and alcohol drinking status showed an increased CRC risk in heavy smokers (OR 2.06, 95% CI 1.32 to 3.20) and heavy drinkers (OR 2.00, 95% CI 1.28 to 3.09) for G allele carriers. This meta-analysis suggested that the *MTR* A2756G variant is not associated with CRC/CRA susceptibility, and that gene-environment interaction may exist.

Cheng (2015) investigated the association between SNVs in thirty folate-mediated one-carbon metabolism genes and CRC in 821 CRC case-control matched pairs in the Women's Health Initiative Observational Study cohort.[74] A statistically significant association was observed between CRC risk and a functionally defined candidate SNV (rs16879334, p.P450R) in *MTRR* (OR 0.61, 95% CI 0.4 to 0.93, p=0.02).

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients diagnosed with or suspected of having colorectal cancer or adenoma.

GENERAL HEALTH SCREENING

Studies that address the clinical utility for general health screening for gene testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* were not identified.

MANAGEMENT OF HOMOCYSTEINE LEVELS

Studies that address the clinical utility of gene testing for the management of Hcy levels and gene testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* were not identified.

MANAGEMENT OF VITAMIN B DEFICIENCIES (FOLATE, B_6, AND B_{12})

Studies that address the clinical utility of gene testing for the management of vitamin deficiencies and gene testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* were not identified.

OSTEOPOROSIS

There was a single report on *CBS* gene association with osteoporosis.

Authors determined the molecular basis of *CBS* deficiency in 36 Australian patients from 28 unrelated families, using direct sequencing of the entire coding region of the *CBS* gene.[75] The G307S and I278T variants were the most common. They were present in 19% and 18% of independent alleles, respectively.

PARKINSON'S DISEASE

Studies that address the association between *MTHFR* gene variants and Parkinson's disease (PD) are described below.

Association Studies

The objective of a small trial was to compare B6, B12, folic acid and tHcy levels in plasma of 83 levodopa treated PD patients and 44 controls.[76] Authors reported PD patients with the CT or TT genotype had significant higher tHcy levels than controls or PD patients with the CC allele. The concentrations of B6 or B12 did not differ, but folic acid was significant higher in PD patients with the CT variant. Based on results, authors recommended *MTHFR* genotyping, tHcy monitoring and early vitamin supplementation in PD patients.

Yasui (2000) measured plasma Hcy and cysteine levels in 90 patients with PD with the *MTHFR* C677T (T/T) genotype.[77] The authors found that the levels of Hcy-a possible risk factor for vascular disease-were elevated by 60% in levodopa-treated patients with PD, with the most marked elevation occurring in patients with the T/T genotype. Cysteine levels in subjects with PD did not differ from levels in control subjects. In the T/T genotype patients, Hcy and folate levels were inversely correlated. Authors concluded that increased Hcy might be related to levodopa, *MTHFR* genotype, and folate in PD.

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with Parkinson's disease.

PSYCHIATRIC DISORDERS

Mixed Psychiatric Disorders

Studies regarding the association between *MTHFR* and *MTR* variants and multiple psychiatric disorders are described below.

Systematic Reviews

Hu (2015) evaluated the association between *MTHFR* variants and risk of bipolar disorder or schizophrenia.[78] In a meta-analysis of 38 studies, the authors found a significant association between the *MTHFR* C677T variant and schizophrenia (comparison, TT vs CT or CC; OR 1.34, 95% CI 1.18 to 1.53). For bipolar disorder, there was a marginal association between the C677T variant and disease risk (comparison, TT vs CT or CC, OR 1.26, 95% CI 1.00 to 1.59). The clinical utility of *MTHFR* genotyping was not addressed in this analysis.

Peerbooms (2011) conducted a meta-analysis of all published case-control studies investigating associations between two common *MTHFR* single nucleotide variants, *MTHFR* C677T (sample size 29,502) and A1298C (sample size 7,934), and the major psychiatric disorders (i) schizophrenia (SZ), (ii) bipolar disorder (BPD), and (iii) unipolar depressive disorder (UDD).[79] In order to examine possible shared genetic vulnerability, authors also tested for associations between *MTHFR* and all of these major psychiatric disorders (SZ, BPD and UDD) combined. *MTHFR* C677T was significantly associated with all of the combined psychiatric disorders (SZ, BPD, and UDD); random effects OR 1.26 for TT versus CC genotype carriers, 95% CI 1.09 to 1.46); meta-regression did not suggest moderating effects of psychiatric diagnosis, sex, ethnic group or year of publication. Although *MTHFR* A1298C was not significantly associated with the combination of major psychiatric disorders, nor with SZ, there was evidence for diagnostic moderation indicating a significant association with BPD (random effects OR 2.03 for AA versus CC genotype carriers, 95% CI 1.07 to 3.86). The meta-analysis on UDD was not possible due to the small number of studies available.

Gilbody (2007) performed a meta-analysis of studies examining the association between variants in the *MTHFR* gene, including *MTHFR* C677T and A1298C, and common psychiatric disorders, including unipolar depression, anxiety disorders, bipolar disorder, and schizophrenia.**[80]** The primary comparison was between homozygote variants and the wild type for *MTHFR* C677T and A1298C. Authors conclude this meta-analysis did not identify an association between the *MTHFR* C677T variant and anxiety. The clinical utility of *MTHFR* was not addressed in this study.

Association Studies

Additional studies were identified which evaluated the association of *MTHFR* variants and psychiatric disorders.[81]

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with anxiety or other psychiatric disorders.

Bipolar Disorder

Association studies addressing *MTHFR* and bipolar disorders are described below.

Systematic Reviews

In the study described above, Peerbooms conducted a meta-analysis of all published case-control studies investigating associations between two common *MTHFR* SNVs, *MTHFR* C677T (sample size 29,502) and A1298C (sample size 7,934), and the major psychiatric disorders (i) SZ, (ii) BPD, and (iii) UDD.[79] Authors concluded this study provides evidence for shared genetic vulnerability for mood disorders, BPD and UDD, mediated by *MTHFR* 677TT

genotype, which is in line with epigenetic involvement in the pathophysiology of these psychiatric disorders.

Association Studies

No studies published after the search date of the above systematic review were identified that addressed MTHFR and bipolar disorders.

Clinical Utility

No studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with bipolar disorders.

Depression

Studies regarding the association between *MTHFR* and *MTR* variants and depression are described below.

Systematic Reviews

Wu (2013) conducted a meta-analysis to investigate a more reliable estimate of the association between the *MTHFR* C677T variant and depression.[82] The meta-analysis included 26 studies, including 4,992 depression cases and 17,082 controls. The authors concluded the *MTHFR* C677T variant was associated with an increased risk of depression, especially in Asian populations. However, there was no evidence indicating a correlation in the elderly.

Association Studies

Additional association studies[83-91] were identified which evaluated the association of *MTHFR* variants and depression. These studies reported mixed results.

Clinical Utility

Only one study has been identified, to date, that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with depression.

Bousman (2010) conducted a prospective cohort study to evaluate the association between *MTHFR* genetic variants and prognosis of major depressive disorder.[92] The study included 147 primary care attendees with major depression who underwent genotyping for two functional *MTHFR* variants (C677T [rs1801133] and A1298C [rs1801131]) and seven haplotype-tagging SNVs and serial measures of depression. The C677T variant was significantly associated with symptom severity trajectory measured by the Primary Care Evaluation of Mental Disorders Patient Health Questionnaire–9 (p=0.038). The A1298C variant and the haplotype-tagging SNVs were not associated with disease prognosis. This study had several limitations, including small sample size, which leads to inadequate statistical power to detect differences in prognosis. Additionally, none of reported results were statistically significant after correction for multiple comparisons.

Schizophrenia

Studies that address the association between the *CBS* and *MTHFR* gene variants and schizophrenia are described below.

Association Studies

In a study by Kim (2014), the association of the two functional variants of *MTHFR*, C677T and A1298C, with the risk for schizophrenia was investigated.[93] The authors additionally conducted an updated meta-analysis on these associations. The authors also investigated the relationship between the variants and minor physical anomaly, which may represent neurodevelopmental aberrations in 201 schizophrenia patients and 350 normal control subjects. There was no significant association between either of the two variants and the risk of schizophrenia (X^2=0.001, p=0.971 for C677T; X^2=1.319, p=0.251 for A1298C). However, in meta-analysis, the C677T variant showed a significant association in the combined and Asian populations (OR 1.13, p=0.005, OR 1.21, p=0.011, respectively) but not in the Korean and Caucasian populations alone. The authors concluded, the present findings suggest that in the Korean population, the MTHFR variants are unlikely to be associated with the risk for schizophrenia and neurodevelopmental abnormalities related to schizophrenia.

In the study described above, Peerbooms conducted a meta-analysis of all published case-control studies investigating associations between two common *MTHFR* SNVs, *MTHFR* C677T (sample size 29,502) and A1298C (sample size 7,934), and the major psychiatric disorders (i) SZ, (ii) BPD, and (iii) UDD.[79] Authors concluded this study provides evidence for shared genetic vulnerability for SZ, BPD and UDD mediated by *MTHFR* 677TT genotype, which is in line with epigenetic involvement in the pathophysiology of these psychiatric disorders.

In the study described above, Gilbody performed a meta-analysis of studies examining the association between variants in the *MTHFR* gene, including *MTHFR* C677T and A1298C, and common psychiatric disorders, including schizophrenia.[80] The primary comparison was between homozygote variants and the wild type for *MTHFR* C677T and A1298C. For schizophrenia and *MTHFR* C677T, the fixed-effects odds ratio for TT versus CC was 1.44 (95% CI 1.21 to 1.70), with low heterogeneity (I^2=42%) based on 2,762 cases and 3,363 controls. Authors concluded this meta-analysis demonstrated an association between the *MTHFR* C677T variant and schizophrenia, though clinical utility was not addressed.

Golimbet (2009) investigated the association between the 844ins68 variant of the *CBS* gene and schizophrenia in a large Russian sample using case-control and family-based designs.[94] The sample comprised 1,135 patients, 626 controls and 172 families. There was a trend for association between the 844ins68 variant and schizophrenia in the case-control study, with higher frequency of the insertion in the control group. The FBAT revealed a statistically significant difference in transmission of alleles from parents to the affected proband, with preferential transmission of the variant without insertion. When the sample of patients was stratified by sex and forms of schizophrenia, the significantly lower frequency of insertion was observed in the group of female patients with chronic schizophrenia (n=180) as compared to psychiatrically well women. Authors concluded their study revealed a possible relation of the *CBS* 844ins68 variant to schizophrenia.

Van Winkel (2010) studied naturalistic cohort of 518 patients with a schizophrenia spectrum disorder screened for metabolic disturbances.[95] *MTHFR* A1298C, but not C677T, was associated with the metabolic syndrome, C/C genotypes having a 2.4 times higher risk compared to A/A genotypes (95% CI 1.25 to 4.76, p=0.009). Haplotype analysis revealed similar findings, showing greater risk for metabolic syndrome associated with the 677C/1298C haplotype compared to the reference 677C/1298A haplotype (OR 1.72, 95% CI 1.24 to 2.39,

p=0.001). These associations were not explained by circulating folate levels. Differences between A1298C genotype groups were considerably greater in the subsample treated with clozapine or olanzapine (OR C/C versus A/A 3.87, 95% CI 1.51 to 9.96) than in subsample treated with any of the other antipsychotics (OR C/C versus A/A 1.30, 95% CI 0.47 to 3.74), although this did not formally reach statistical significance in the current cross-sectional study (gene-by-group interaction X^2=3.0, df=1, p=0.08). Authors suggest that prospective studies evaluating the course of metabolic outcomes after initiation of antipsychotic medication are needed to evaluate possible gene-by-treatment interaction more specifically.

Clinical Utility

Additional studies[96] were identified which evaluated the association of methionine metabolism gene variants and schizophrenia; however, no studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with schizophrenia.

METHOTREXATE EFFICIENCY AND TOXICITY

Studies that address the association between the *MTHFR* gene variants and methotrexate efficiency and toxicity are described below.

Song (2021) published a systematic review on gene variants and high-dose methotrexate response and toxicity, which included nine polymorphisms in seven genes: *MTHFR*, *RFC1*, *ABCB1*, *SLCO1B1*, *TYMS*, *FPGS*, and *ATIC*.[97] The *MTHFR* C677T variant was associated with hepatic and renal toxicity and mucositis, while the A1298C polymorphism was associated with a reduced risk of renal toxicity.

In a systematic review, Fan (2017) examined evidence regarding an association between the *MTHFR* A1298C variant and outcome of methotrexate treatment in rheumatoid arthritis patients. Relevant literature through May 2016 was assessed.[98] Ten studies of methotrexate efficacy and 18 studies of methotrexate toxicity met inclusion criteria. Studies were not assessed for quality. Meta-analysis results did not show a significant association between *MTHFR* A1298C variants and methotrexate toxicity or efficiency. Subgroup analyses identified significant associations between *MTHFR* A128C variants and decreased methotrexate efficacy in the South Asian population and in the partial folate supplementation group. However, there were few studies in these subgroup analyses.

Another systematic review by Qiu (2017) assessed the association of variants in 28 genes with methotrexate toxicity in rheumatoid arthritis patients.[99] A literature search in February 2016 identified 16 studies that met inclusion criteria addressing *MTHFR* variants. No significant association between *MTHFR* variants and methotrexate toxicity was identified.

Clinical Utility

Additional studies published after the search dates of the above systematic reviews were identified which evaluated the association of methionine metabolism gene variants and toxicity and efficacy of methotrexate treatment.[100-106] However, no studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients being treated with methotrexate.

VENOUS THROMBOEMBOLISM

Variants in the *MTHFR* gene, particularly C667T, are associated with hyper-homocysteinemia, which is in turn considered a weak risk factor for venous thromboembolism (VTE). However, the clinical utility of testing for homocysteine levels has not been established. There is a large literature base on the association of homocysteine levels with coronary artery disease (CAD), and clinical trials on the impact of lowering homocysteine levels. This body of evidence indicates that testing or treating for homocysteinemia is not associated with improved outcomes.

For the association of *MTHFR* with VTE, the evidence is not definitive. Some studies have shown an association, but others have not. In one of the larger studies, the MEGA study, there was no association of the *MTHFR* variant with recurrent VTE.[107] Similarly, a systematic review by Wu (2006) reported that *MTHFR* was not associated with increased risk of postoperative VTE following orthopedic surgery.[108] A randomized controlled trial published in abstract form reported that there was no reduction in VTE associated with treatment of hyperhomocysteinemia.[109]

OTHER CONDITIONS

Additional studies were identified which evaluated the association of methionine metabolism gene variants and other conditions such as glaucoma,[110] psoriasis,[111-113] inflammatory bowel disease,[114-116] retinoblastoma,[117] leukemia,[118] rheumatoid arthritis,[119] Graves' ophthalmopathy,[120] autism,[121-124] myelodysplastic syndromes,[125] breast cancer,[19, 126-130] cancer susceptibility and prognosis,[131-138] fluoropyrimidine toxicity,[139] sudden sensorineural hearing loss,[140] male infertility,[141] amyotrophic lateral sclerosis,[142] and in vitro fertilization pregnancy outcome and pregnancy loss[143-151]; however, no studies were identified that addressed the clinical utility of *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene testing in patients with these conditions.

PRACTICE GUIDELINE SUMMARY

Currently no published clinical practice guidelines recommend gene testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, or *MMADHC*.

AMERICAN COLLEGE OF MEDICAL GENETICS AND GENOMICS (ACMG)

ACMG published a 2013 guidelines that states, "*MTHFR* variant is only one of many factors contributing to the overall clinical picture, the utility of this testing is currently ambiguous."[152]

ACMG recommends *MTHFR* variant genotyping should **not** be ordered as part of the clinical evaluation for thrombophilia or recurrent pregnancy loss. Further, *MTHFR* variant genotyping should not be ordered for at risk family members. *MTHFR* status does not change the recommendation that women of childbearing age should take the standard dose of folic acid supplementation to reduce the risk of neural tube defects as per the general population guidelines.

Genetic testing for *CBS*, *MTR*, *MTRR*, and *MMADHC* is not addressed in ACMG guidelines.

SOCIETY FOR MATERNAL-FETAL MEDICINE

Originally released in 2019, and updated in 2022, the Society for Maternal-Fetal Medicine published the following recommendation for the Choosing Wisely initiative:[153]

"Don't test women for MTHFR mutations.

MTHFR is responsible for the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate. Genetic variant C677T and A1286C have been associated with a mild decrease in enzymatic activity, which in the setting of reduced folate levels has been found to be a risk factor for hyperhomocysteinemia. Although hyperhomocysteinemia is a risk factor for cardiovascular disease and venous thrombosis, its cause is multifactorial and independent of the MTHFR genotype, even in homozygotic individuals. Despite earlier (mostly case control) studies that found an association between the MTHFR genotype and adverse outcomes, recent studies of more robust design have not replicated these findings. Due to the lack of evidence associating genotype independently with thrombosis, recurrent pregnancy loss, or other adverse pregnancy outcomes, MTHFR genotyping should not be ordered as part of a workup for thrombophilia."

SUMMARY

There is not enough research to show that testing for variants in the *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* genes can improve health outcomes for people with any conditions. While many studies have found associations between MTHFR variants and a number of conditions, there is a lack of evidence that treating patients based on genetic testing can improve these conditions. In addition, clinical practice guidelines specifically recommend against *MTHFR* genetic testing, and there are no clinical guidelines based on research that recommend testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* gene variants. Therefore, genetic testing for *CBS*, *MTHFR*, *MTR*, *MTRR*, and *MMADHC* is considered investigational for all indications.
